This book is dedicated to my alma mater –
Medical College and Hospital, Thiruvananthapuram –
where I started learning the first principles of medicine and
thereafter; had the honour to serve as its staff and
continue my close association with the college
even several years after my retirement

Contributors

Ananda Kumar MD, DM

Professor, Department of Neurology
Amrita Institute of Medical Sciences, Kochi
Chapters 194,195,197,199, 200

Asha Kishore MD, DM

Preface to the Fifth Edition

This volume has evolved through four editions, the fourth one was published in 2002. The first edition was introduced as 'A Short Textbook of Medicine', now it has increased in the volume of contents and improved in its quality, commensurate with the quantitative and qualitative advancements in medical information.

Six years is too long a gap for a textbook to be up-to-date and useful, but the demand among students and teachers were the guidelines to continue with the fourth edition until 2008.

As mentioned earlier, the book has been given a new direction, both in its get up and format, so as to include the latest information and present it in a student-friendly manner. This book has been designed to include the up-to-date information obtainable from print material and electronic data and has been presented in a simple language in form of direct statements, so as to make the matter more vivid and comprehensible to the medical students and doctors in India and the neighbouring countries coming from different social and language backgrounds. In areas where more detailed information is desirable for the practitioners and the postgraduate students, authentic reviews and original works are referred to.

Several new figures, many of them taken personally by the contributors from their own clinical practice and flow charts and tables have been added.

Along with several chapters a short summary is given to serve as a ready-reckoner for the students preparing for the examination or the busy practitioners who have only limited time at their disposal.

This volume is intended for the use of undergraduate and postgraduate students of medicine, dental sciences and other allied subjects, students preparing for entrance examinations and practitioners working in India and the neighbouring countries.

All the sections have been thoroughly revised. The number of contributors has also increased including teachers in specialities who have made their mark in their respective specialisation.

The first edition of the "Short Textbook" was produced in 1986 to fulfil a long-felt and widespread need among the undergraduate and postgraduate students, majority of whom relied on class notes or handbooks written on the various subjects by several authors. Many had no access to textbooks and the big volumes available were beyond their understanding. Comprehensive textbooks catering to the needs of the undergraduate medical students written by Indian authors were only a handful. Books published in other countries are quite freely available to our students, but naturally their emphasis is on the conditions prevailing in those countries.

The medical problems of India are unique as the peculiar disease-spectrum here is a blend of what is seen in the affluent countries with what is seen in most developing countries. This Textbook of Medicine has been written with this picture in mind. The section on tropical diseases, which usually gets a separate deal in most of the western textbooks, has been dovetailed into the other sections such as infections, physical agents, nutrition and others to improve the understanding of these subjects. Almost the whole of India is in tropical belt and therefore diseases rampant in tropical countries with a few exceptions like trypanosomiasis, onchocerciasis and others are present in all parts of the country.

This book has its companion volume "Clinical Medicine" third edition edited by me and published by the same publishers in 2005. It gives in detail the clinical aspects of medical practice and investigations. The reader is referred to "Clinical Medicine" for further details on physical examination, clinical symptoms, signs and investigation procedures.

Obsession with the printed matter is the habit of the mediocre; the wise go beyond it and use their common-sense, experience and creativity to form their own decisions.

My contributors have strived hard to collect the material and present it the way it has been done. All of them are veteran teachers and their presentations will be helpful to the entire readership. This book is the collective effort of the whole team, laying emphasis on several aspects of Internal Medicine with special emphasis on conditions prevailing in India and the neighbouring countries.

Human efforts by themselves are lifeless "*karma tat jadam*" (Ramana Maharshi in his Upadesa Sara). They get life and effect only when blessed by the Almighty to achieve the desired effect. This is especially so in medicine, in that both the patient and his physician have to be lucky to get the best results of investigation and treatment. I wish and pray to Almighty, the first physician in the universe to bless all and alleviate suffering. Yajurveda proclaims "*prathamam daivam bhishak*" meaning the "first physician is God". I would consider the work of my teammates and myself fulfilled, if the young entrants into the medical profession in India and the neighbouring countries find this book useful in his studies and career.

K.V. Krishna Das

Preface to the First Edition

This book is written to fulfil a long-felt and widespread need among the undergraduate students. A questionnaire sent to several hundreds of clinical students revealed that majority of them rely on class notes, and handbooks written in the subject by several authors. Many had no access to textbooks in the subject and the big volumes available were beyond their understanding. Comprehensive textbooks catering to the need of undergraduates written by Indian authors are only a few. Books published in other countries are quite freely available to our students, but naturally their emphasis is on conditions prevailing in their lands.

The medical problems of India are unique in that the disease-spectrum is a blend of what is seen in the affluent countries with what is seen in developing countries. This book has been written with this picture in mind. The section on “tropical diseases” which usually gets a separate deal in most of the textbooks has been dovetailed into the other sections such as infections, physical agents, nutrition, etc. It is my feeling that with modern jet travel and the rapidly changing life-styles of Indian subjects, all diseases—the most modern and the most ancient are likely to be encountered by the clinical student in this country. Moreover, the so-called tropical diseases which used to be confined to the tropical belt, are now seen widely all over the world as a result of free and fast migration of population.

I consider my purpose fulfilled if the undergraduates in this country find this book useful.

K.V. Krishna Das

Acknowledgements

I acknowledge with thanks the help, support and patience of my wife Smt L.N.Kamalam who encouraged me in my task and endured all the inconvenience and disruption of domestic routine due to my prolonged and generally untimely work schedule, I had to pursue in completing the task.

I had to depend heavily on doctors S. Aswini Kumar, K. Sreekanthan, Mathew Thomas and P.K. Sasidharan who helped me to review the chapters and offered suggestions for improvement and also reviewed the proofs critically.

I express my indebtedness to Shri J.P. Vij, Chairman and Managing Director of M/s Jaypee Brothers Medical Publishers (P) Ltd and his teammates especially Mr Tarun Duneja, Director (Publishing) who gave constant support in the form of timely suggestions, prompt execution of the work and appropriate technical help. I thank M/s. Krishnakumar and Associates for the typographical work and preparation of the matter in print and CD.

To all human efforts the divine influence has to be in constant attendance. I thank the Almighty to have allowed me to complete this task of editing the fifth revised and enlarged edition along with my team of section editors and contributors.

- The Final Diagnosis 4
- Concept of Millennium Development Goals (MDGs) 4
- The Concept of Global Burden of Disease 5
- Recording of Medical Data 5
- Evidence Based Medicine 5
- Computer in Medicine 6

History of Medicine

The practice of medicine existed even in the earliest periods of recorded human history.

Medical knowledge always existed in folklore, local health traditions, verbal testimony and other sources. It is their periodic systematization and improvement that led to medical progress.

The fifth century BC was the golden age of Greek medicine and it was during this period that *Asclepid Hippocrates* (born around 460 BC), introduced scientific system of administering medicine which till then was dominated by religious and mystic practices.

Hippocrates embodied the ideal virtues of a physician such as knowledge, readiness to help, purity of life, compassion, skill and patriotism. Hippocratic medicine was based on practice as well as theory with little emphasis on anatomy.

The history of Indian medicine dates back to 3000 BC and excavations of *Mohanjodaro* and *Harappa* throw light on medical practices that flourished at that age, which consisted mainly of religious, magical and empirical procedures.

Ayurveda (the science of life) arose as an offshoot of Atharva Veda which is the fourth Veda. Atharva veda is dated to belong to 1500 BC. It consists of 6000 verses and 1000 prose lines. There are several pieces of evidence and statements that it is very closely associated with

Atharva veda. In any case the science of life (*Ayurveda* means knowledge of life sciences) originated in India along with the vedas. It laid emphasis not only on healing, but also on the prolongation of life, preservation and promotion of health and prevention of illness. The ancient sages recognized health as the very basis of virtue, wealth, enjoyment and salvation. From very early times Ayurveda had developed independent of religious precepts. *Agnivesa* has been credited with the authorship of Ayurveda. Agnivesa composed *Agnivesa tantra* a few centuries before Charaka. The latter produced *Charaka Samhita* between the 2nd century BC and 1st century AD (post Buddhist period) during the reign of the Kusanas. *Charaka samhita* is a creative revision of *Agnivesa tantra* *Charaka samhita* is still in vogue as a basic text used by practitioners of Ayurveda. *Charaka* edited his encyclopedic text, *Charaka Samhita*. *Susruta*, who was a medical teacher of Varanasi during the Buddhist period, practised surgery. *Vagbhata*, another Buddhist physician living in the Indus region (second century AD) wrote two classics in Ayurveda—*Astanga Sangraha* and *Astanga Hridaya*. *Vagbhata* emphasized the principles of medicine, *Susruta* dealt mainly with surgery and anatomy, while *Charaka* emphasized therapeutics. The Yoga concept of physical and mental culture to preserve the health of body and the mind developed in India. Even when the Aryan influx into India brought in Ayurveda, other systems of medicine such as *Siddha* and *Chintamani* existed in this subcontinent, especially in the South from pre-Aryan times. The *Buddha* (sixth century BC) and his disciples practised medicine and consequently healing of the sick was given great importance.

Arabic and middle eastern countries share the tradition of Arabic folk medicine and the *Unani* or adopted *Greek medicine*. It was essentially taken from Galenic teachings during the early Islamic period. Several names stand out prominently among those who developed this system; *Ibn Sina* of Andolasia in Spain, *Al Mansur* of Baghdad, *Avicenna*, *Razi*, *Rhazes* and others. The backbone of the theoretical instruction was the *Alexandrian canons* which summarized a few books compiled by Galen. The

major works in *Unani* were *Al qnanun-Fi-Tibh* by Ibn Sina, *Continend* by Rhazes, *Kitab-Al-Shifa* by Avicenna *Al-Tarsiff* by Abu-Quasim-Az-Zuhra-Wi and several others. Hospitals were established from the tenth century AD in several towns. Surgery and ophthalmology were practised during this period and the works of Unani surgeons paved the way for development of surgery in Europe. In India the Muslim rulers popularized the *Unani* system side by side with *Ayurveda*.

The golden age of Unani Medicine was possibly the twelfth century AD. The Chinese system of medicine had great sway over the far East from very ancient times. Several of its tenets and the herbal pharmacopia have percolated into other systems of medicine far and wide. Though all these systems of medicine flourished during various periods in their countries of origin and the neighbouring regions, many of them suffered from want of continuing research. The homeopathic system of Medicine which was founded by Dr SCF Hahnemann in 1796 in Philadelphia grew into a very popular therapeutic system which continues to grow and attract large sections of people all over the world.

In modern times it is common to include all these traditional systems of medicine as the “alternate systems”. These flourish along with the system of allopathic medicine in almost all the countries and they provide health care services to large sections of the population. The government of India has accepted many of these systems as part of the health care delivery agencies. There are also several institutions imparting teaching in these various systems.

The growth and development of the allopathic system (modern medicine) have been much more rapid and prolific compared to the other systems. Whereas the alternate systems are most accepted in their countries of origin, the allopathic system has gained global acceptance. The term allopathy literally means “treatment of disease by measures which contrast the effect of the disease, in contrast to homeopathy which literally means “treatment of disease by drugs that produce symptoms like those of the disease”. In homeopathy the doses of drugs are minute.

The sixteenth and seventeenth centuries witnessed the growth of modern physical sciences and its scientific methods of study and analysis. Andreas Vesalius, born in 1514, in Brussels made extensive dissections of the human body and produced his classic in anatomy “*De Humani Corporis Fabrica Libri*” on September 1, 1543. William Harvey, a British physician, published his monumental work on circulation of blood, *De mortu cordis* in 1628. It was Harvey who established the scientific basis of medicine. Harvey is often credited with the invention of medical research, (ie) the search for factual evidence about bodily functions and structure.

Starting in the late eighteenth century and developing with a great rapidity in the nineteenth century, the modern medical theory and practice made great progress. Discovery of the microscope by *Leewenhoek* three hundred years ago led to the identification of the cell as the basis of biological existence. Koch’s postulates laid firm basis for establishing the etiology of microbial diseases. *Gregor Mendel* published his observations in 1865 and laid the foundations of modern genetics. Molecular diseases also were identified in the early part of the nineteenth century. From the middle of this century the development of knowledge has been explosive. The discovery of the structure of DNA and the advances in the study of chromosomes and the study of genetic loci which confer susceptibility to disease were of great help in understanding the nature of molecular diseases. Studies of genes, availability of techniques such as polymerase chain reaction (PCR) which helps to identify the presence of nucleic acids (DNA and RNA) enabled great advances in genetic medicine. Completion of the human genome mapping project made available the blueprint of the human genome. Further genomic studies which aim at identification of the effect of different genes in causing and preventing diseases have helped to understand the genetic basis of several diseases including prediction of diseases such as cancer.

Availability of monoclonal antibodies have enabled specific diagnosis of heterogenous diseases such as lymphomas and breast cancers. They are also used in targeted therapy of malignancies, immune mediated diseases and several others for which treatment used to be unsatisfactory.

Though earlier medicine was practised as an art, at present it is a harmonious blend of scientific practices generously tempered with human warmth, kindness and above all, sound commonsense. What is spoken of as a clinical picture is not just the photograph of a man sick in bed, it is the sum total of the patient’s condition, his home, his work, his relations, friends, joys, sorrows, hopes and fears. A good physician honours his patient and his time; sympathy and understanding are lavishly dispensed, and the reward is to be found in that joy of personal bond which forms the source of the greatest satisfaction in the practice of medicine.

Medicine as a Profession

The word ‘doctor’ is derived from the Latin word “docere” which means to teach, since the doctor has the function of instructing the patient and his relatives regarding treatment. Medicine moreover is a technique (an art or a craft of a special kind) with a broad philosophy. The medical profession is supported by a plethora of scientific knowledge which is continuously growing. It is also

guided by the norm of conduct termed “ethics”. Ethics deal with the principles of morality, of right and wrong. Over the centuries the *Hippocratic oath* has been handed down from one to the next generation of practitioners of medical science. Though generally, the code of ethics has been attributed to Hippocrates, it is quite likely that in its present form it came into existence much later. The ethics were laid down to be followed by the students and practitioners so as to command veneration from the public and to prevent misuse of the medical knowledge and exploitation of the society. In modern times of high cost of patient care, availability of invasive investigations and treatment, organ transplantation, prenatal diagnosis of the gender of the fetus and the several others have contributed to unethical use of medical knowledge. This has led to the creation of *ethical committees* in all institutions for controlling research on humans and animals, and ensuring proper treatment to all types of patients.

The progress and achievements in the field of medical sciences have been phenomenal. But in comparison to several other fields such as engineering or technology the safety margin and success rate in techniques requiring precision and skill are considerably less. For example, a failure rate of 1-2% in a major surgical procedure is still acceptable whereas in modern industrial process this would not be so. The relatively higher margin of failure rates are accepted due to the fact that the physician has to deal with subjects whose internal environment and biological processes are not fully available to him before he starts treatment. This leads to unexpected problems such as adverse drug reactions, surgical failures, immunological complications, secondary infections and several others.

The position of the doctor in society was an exalted one from the early stages of human civilization. It continues to be so even in modern times, since his role in relieving human suffering has been accepted in all cultures, especially in India. To perform his task ideally, the physician should combine knowledge, skills, empathy and a readiness to serve his fellow men at all times.

In India, the medical profession has come under the Consumer Protection Act which made the doctor accountable to the public for his actions. This law empowers them to exert their right to receive proper care and consideration from the physician. The patients and their relatives can implicate the doctor for malpractice and negligence. The law requires of the doctor to use the appropriate skills and care in discharging his duties to the public.

The Final Diagnosis

The physician approaches the patient with the total picture of the patient in mind, and with the determination and skill of a detective to unravel the disease and its cause.

While ascertaining the history and conducting the physical examination, an experienced observer forms an impression about the probable diagnosis and the immediate differential diagnosis. The clinical diagnosis should always be supported by investigations. The purpose of investigations may be summarized as: (1) confirmation of the clinical diagnosis, e.g. sputum for acid fast bacilli in tuberculosis or blood culture in typhoid fever, (2) assessment of the severity of affection or damage to organs, e.g. liver function, renal function, etc., (3) assessment of prognosis, e.g. biopsy in malignancy, (4) differentiation of the condition from the closely resembling diseases, e.g. liver biopsy in hepatomegaly or rheumatoid factor in subacute arthritis, (5) planning the therapeutic modality; e.g. determination of acetylase status to decide on the dose of INH therapy, and (6) follow-up of the treatment and to detect early recurrence.

While appropriate investigations are essential to establish the diagnosis and to institute therapy and follow-up, the availability of different types of investigative procedures and the over-dependence on them have led to unnecessary, and sometimes even invasive investigations which may jeopardize the patient's health and life.

In general, invasive procedures include biopsies of vital organs, catheterization of vital structures, angiography, contrast radiography and endoscopies. These may cause temporary or permanent morbidity and even mortality in a small number. Hence the decision to employ them should be taken after evaluating non-invasive methods and only if the risks involved are justifiable. Over-investigation should be avoided and this is possible only if the interrogation and physical examination are properly done. Moreover, results of the investigations should be interpreted in the light of the clinical findings, otherwise they may be misleading and may result in administering inappropriate therapy.

Concept of Millennium Development Goals (MDGs)

In 2000 AD, The United Nations (UN) adopted the *millennium development goals* and made the UN'S *millennium declaration* signed by 189 countries which aimed at achieving the MDGs by the year 2015. Three of the MDGs aims are related to health. These include:

1. Reduction of child mortality by two-thirds compared to 1990
2. Reduction of maternal mortality by 75% compared to 1990 and
3. Prevention of spread of HIV/AIDS, malaria, tuberculosis and other diseases.

The burden of *chronic diseases* comprise mainly of cardiovascular diseases including strokes, cancer, chronic respiratory disease and diabetes. The predicted global deaths from the major diseases projected for 2005 AD are given in Table 1.1.

TABLE 1.1

The projected number of deaths in 2005 AD

Diseases	Approximate figures (millions)
Cardiovascular diseases	17.53
Cancer	7.57
Chronic respiratory diseases	4.1
HIV/AIDS	2.8
Tuberculosis	1.6
Diabetes	1.13
Malaria	0.8

TABLE 1.2

Global distribution of total deaths in an year

Cardiovascular causes	30%
Communicable diseases, maternal and perinatal diseases, and malnutrition	30%
Cancer	13%
Other chronic diseases	9%
Injuries	9%
Chronic respiratory diseases	7%
Diabetes mellitus	2%

Chronic diseases burden affects both developing and developed countries. In India 35% of all cardiovascular disease deaths occurred in persons aged 35-64 years. The trend is for these diseases to affect a greater proportion of younger persons in developing countries compared to those in developed nations.

The global distribution of total deaths (58 million) by major causes in 2005 is given in Table 1.2.

The Concept of Global Burden of Disease

Prevalence of selected major risk factors in different regions of the world has been studied by international agencies such as the World Health Organization (WHO) and others, both governmental and non-governmental. This information has been utilized to estimate the global prevalence of disease and Disability Adjusted Life Years (DALY). Maternal and childhood underweight, tobacco smoking, alcoholism, unsafe sex practices and hypertension account for the majority of the leading causes of global burden of disease. In the poor regions of the world maternal and childhood underweight, unsafe sex practices, unsafe drinking water, poor sanitation and hygiene, indoor air pollution by smoke from burning solid bio-fuels and various micronutrient deficiencies were the main contributory factors.

In both the developed and poor countries alcohol, tobacco, hypertension and high cholesterol levels were equally prevalent.

Recording of Medical Data

Recording of data is important and the method of recording has been considerably improved in recent years. The *problem-oriented medical record (POMR)* is a generally accepted form which greatly helps data retrieval and also helps the physician to make decisions on the spot.

Flow charts giving the design of management have been constructed for many of the common ailments. These help the physician to plan investigations and institute sequential therapy. Customized computer softwares designed for use in doctors' clinics and hospitals are available commercially. The doctor of the future will have to use them in order to keep up with modern progress and to guide him in his day to day work.

Many professional associations have produced consensus statements for the diagnosis, management, and prognosis of several common diseases. These have to be strictly complied with by the doctors of the future, since such consensus statements are based on evidence based information. Though the doctor has freedom to decide on management strategies in individual cases under special circumstances, in general consensus statements come up as ready and reliable data sources. This also will help as safeguards against litigations which may come up.

Evidence Based Medicine

This branch of medicine has developed during the past three decades. Several modern investigative and therapeutic modalities are very expensive, invasive and are liable to legal scrutiny. The ethical responsibility of the doctor in recommending such procedures is also great.

Evidence based medicine gives the status report on

- 1. The efficiency of the modality
- 2. Risks involved regarding mortality and morbidity
- 3. Cost-benefit analysis and
- 4. The improvement in the quality of life

Collection and regular updating of objective evidence of the efficacy and safety of invasive investigations, therapeutic modalities such as drugs, surgery, invasive interventions, implanted equipment like coronary stents, organ transplantations and several others are systematically done by the process of meta-analysis of published data, multi-centre and international prospective studies, reviews, seminars, international consensus conferences and other communications through the Internet. There are several accepted bodies such as the Medline, Pubmed, Cochrane library, Embase and others which collect, analyse and store data for reference by scientists. This data is available in the Internet. Decisions taken by the doctor have to be supported by such evidence based consensus.

Availability of the evidence based consensus is a firm basis for doctors to take decisions in complex and difficult situations and to defend themselves in legal matters. All

modern medical men have to follow the guidelines based on evidence and justify their action if it is at variance from evidence based norms.

Computers in Medicine

Computers are integral equipment for the physician’s profession. Patient’s data, investigations, prescriptions, consultations, referrals, can all be stored by the computer and readily retrieved. Modern information available through the internet, textbooks, prescription guides, and abstracts from journals can be stored in the computer and readily accessed. There are different software designed for assisting the doctor in his clinic and office, including

financial matters, drug information, drug interactions and incompatibilities, safety information on drugs and several other facilities. Many libraries have computerized their procedures and knowledge of computer methods is absolutely essential to retrieve information from libraries and other data sources.

Transplant associations, matching of donor and recipient for transplantation, cancer registries, blood banking data, population data, epidemiological studies, genetic information of population and multicentric and multinational clinical studies have all to depend on computing methodology for performing their tasks. It will not be an exaggeration to state that computer incompetence is even more serious a handicap than total illiteracy.

Glossary of Terms Used in Genetics 14

General Considerations

6 Many diseases develop as a result of the interaction between the genetic and environmental factors. Some

diseases are predominantly genetic, e.g. achondroplasia and Turner’s syndrome, other cases are predominantly environmental, e.g. typhoid fever and tuberculosis, while in many others genetic and environmental factors play similar roles, e.g. diabetes and hypertension.

The observations in genetics in modern biological sciences are credited to Gregor Mendel, an Augustinian monk and a naturalist at the monastery at Bronn, Bohemia. He observed the results of breeding experiments on peas planted in his garden, for over eight years and published his paper in 1865, on inheritance patterns. He also postulated mathematical laws of inheritance, generally known as Mendel’s laws. Cytogenetics is the genetic analysis of cells using chromosome banding techniques, designed to demonstrate the number and structural integrity of the chromosomes. Several genes are contained in each chromosome and some of them have been mapped. The adult human cell nucleus contains 23 autosomes and one pair of sex chromosomes. The latter contains either two X-chromosomes (female) or X- and Y-chromosomes (male) respectively. Chromosomes can be studied by karyotyping rapidly dividing tissues like the bone marrow or by growing the cells in culture media and examining them during mitosis.

Gene is that length of deoxyribonucleic acid (DNA) which acts as a functional unit. It is also termed as cistron. One gene produces one polypeptide, which may combine with other polypeptides produced by other genes to form biologically active proteins like hormones or enzymes.

The size of fragments of double-stranded DNA is indicated by their length in base pairs (bp) or nucleotides. Each chromosome carries several thousand genes. The DNA from all the human chromosomes exceed 3 billion nucleotide base pairs.

Genetic disorders may be classified as:

1. Single gene disorders
2. Polygenic disorders
3. Chromosomal disorders

Single gene disorders are those involving a mutation or change in a single gene, e.g. achondroplasia, thalassemia, sickle cell disease, hemophilia and others. In these the genetic change is sub-microscopic and hence these have to be demonstrated by other methods. Polygenic disorders are those which arise from the combined influence of multiple small genetic defects. Chromosomal disorders are those in which a change or alteration of the chromosomal number or pattern can be demonstrated, e.g. Down's syndrome, Klinefelter's syndrome or Turner's syndrome. In these the genetic alteration involves large portions of the chromosomal structures so as to become demonstrable microscopically.

Genetic information is contained in deoxyribonucleic acid (DNA). It has a double stranded structure, twisted in the form of a helix, and distributed along the chromosomes. The strand consists of deoxyribose residues linked by phosphate (covalent phosphate diester) bonds. Each strand is connected with one of the four bases—adenine, thymine, cytosine or guanine. The bases on the opposite sides in the two strands are aligned together as base pairs by hydrogen bonds. Adenine always pairs with thymine and cytosine with guanine.

The role of the DNA is to contain and transmit genetic information. That information is encoded by the sequence of bases. DNA transmits this genetic information by unraveling its two strands and exposing previously paired bases, thus forming a template for assembly of a new strand of nucleic acid. If the information is to be propagated to daughter cells, the new strand of nucleic acid synthesized is more DNA. This process of propagation is called *replication*. If the information is to be used by the cell, the new strand is ribonucleic acid (RNA). This process is called *transcription*.

RNA differs from DNA in having ribose as its sugar, and the base uracil instead of thymine. Uracil, like thymine forms base pair with adenine.

The "transcribed" RNA acts as a *messenger* RNA (mRNA), which travels from the chromosome on which it is synthesized to the cytoplasmic ribosomes, where it directs the assembly of amino acids into proteins. This

process is called *translation*. The amino acids are carried to the ribosomes by small RNA molecules called transfer RNAs (tRNAs). Each of the 20 amino acids has one or more specific tRNAs.

Common Terms used in Genetic Studies

Diploid cells: These are somatic cells having two sets of chromosomes, each set derived from either parent, totalling 23 pairs in each cell.

Haploid cells: These are cells containing only half the number of chromosomes that are seen in somatic or body cells. These are germ cells of the ova and sperms.

Autosomes: These are the chromosomes other than sex chromosomes. X and Y are the sex chromosomes; the female pattern being X-X and male pattern being X-Y.

Alleles: These are one of two or more different genes containing specific inheritable characteristics, that occupy corresponding portions (loci) on paired chromosomes. If the alleles are identical, either dominant or recessive, such an individual is termed homozygous for that particular gene. If one of the alleles is abnormal and the other is normal, such an individual is heterozygous for that particular characteristic.

Aneuploidy: This is the condition in which the chromosomal number is abnormal for the particular species.

If one of the pair of genes is altered in such a fashion that it manifests itself in a clinical disorder even when present in a single dose, it is called a dominant gene. If the mutant gene has to be present in double dose to express itself as a disorder it is termed as recessive gene. Thus, both the genes of that pair are abnormal, one derived from each parent.

In general, it is seen that single gene disorders occur with a frequency of 10 per 1000 births. Of these, six are autosomal dominant, three autosomal recessive and one is X-linked recessive. Autosomal dominant disorders are mild and variable in manifestation due to the presence of the other gene (allele) which may be normal. On the other hand autosomal recessive disorders are more severe and uniform in pattern since both the genes are abnormal. The X-linked recessive disorders are intermediate in severity.

Human Genome Project

A highly ambitious project to map the genes present in the human cell nucleus undertaken by the National Institute of Health (NIH), Bethesda (USA) with active participation from many other laboratories internationally, was completed ahead of schedule.

The human genome contains about 80000 genes with about 3 billion base pairs. About 35000 were identified till the end of 2004. Further studies are progressing. About 50% of these genes code for unknown proteins, which

are being studied continuously and fresh information is being added on. Unrelated persons have 99.9% of their DNA in common.

Genomics is the study of molecular abnormalities involving the genes, gene-gene interactions, gene-environment interactions and their phenotypic expression. These involve the study of the proteins they produce. Genomic research has improved our understanding of molecular pathology and pathogenesis of complex diseases.

98% of the genome does not code for any protein. Genes which code for proteins control metabolic functions. Several genes may code for the same protein or the same protein may be controlled by different genes. Study of the effects of the protein products is called **proteomics** and this branch is wider than genomics. While the genes are responsible for determining the inherited characteristics, the environment is equally important in determining their expression.

Identification of genetic variations will help clinicians to subclassify diseases and tailor therapy to fit in with the genetic pattern. On an average one boy in every 100 and one girl in every 150 has a major congenital abnormality, some of which are genetically related. The prevalence of lesser causes of disadvantage caused by congenital abnormalities is at least ten times higher.

Note: The mapping of the genes has been completed ahead of schedule and the information is available from several sources including web sites.

The next step is to correlate diseases patterns with the genetic abnormalities and workout the practical application of the new information.

Types of Inheritance

1. Autosomal recessive
2. Autosomal dominant
3. X-linked recessive
4. X-linked dominant

The pattern of inheritance is determined by taking a family history to cover three generations in full and constructing a pedigree.

Autosomal Recessive Inheritance (Fig. 2.1)

1. The affected individuals are in one generation. This is, therefore, called the horizontal transmission.
2. Males and females are equally affected.
3. There is a 25% chance of recurrence in siblings. In other words, on an average, one-fourth of the children are affected.
4. Both parents are carriers of the disease. In the affected offspring one mutant gene comes from one parent, the other mutant gene in the pair is from the other parent.
5. There is often consanguinity in the parents. The more rare the disorder in question, the more likely it is that

Fig. 2.1: Pedigree of a disorder with autosomal recessive inheritance (horizontal transmission). Roman numerals I-III indicate generations. The nos. 1-4 indicate siblings. Blacked out symbol means an affected individual. Those with one-half blackened indicate carriers

the parents are consanguineous. Each individual is the carrier of 6-8 harmful autosomal recessive genes. In a consanguineous marriage, there is a greater likelihood that the offspring would inherit the same mutant gene from the parents, as a proportion of the genes are common in consanguineous parents, e.g. Friedrich's ataxia, phenylketonuria, Fanconi's syndrome.

Autosomal Dominant Inheritance (Fig. 2.2)

1. The affected individuals are in more than one generation and if, in the pedigree one draws a line through the affected individuals, it will be a vertical line. Hence, it is also called 'vertical transmission'.
2. Males and females are equally affected.
3. There is a 50% chance of recurrence in siblings, irrespective of sex. In other words, on an average, one-half of the children are affected.
4. A male-to-male transmission provides evidence that the disease is not X-linked but is autosomal dominant.
5. Occasionally, both parents of an affected child are normal. In such cases, it is presumed that the offspring has acquired the disease by a new mutation in the gametes of one of the parents. The more an autosomal disorder limits reproduction, the higher is the rate of

Fig. 2.2: Pedigree of a disorder with autosomal dominant inheritance (vertical transmission). Normal persons do not pass on the trait to their offspring

new mutation for that disorder. Where the disorder arises by a new mutation, the risk of recurrence in future siblings is negligible.

6. Occasionally, an offspring affected by an autosomal dominant disorder is born to normal parents, while one of the grandparents is affected. In such cases it is presumed that the parent on the side of the affected grandparent has the gene but is not manifesting the disease. Such genes are considered *nonpenetrant*.
7. The clinical manifestations in an autosomal dominant disorder vary considerably in the same family. This is partly explained by the fact that only one of the genes of a particular pair is abnormal, while the other gene is normal. The degree to which the presence of a gene is expressed clinically is termed as the *expressivity*. If the expressivity is reduced to an extreme extent so that there is no clinical manifestation, such a gene is called *nonpenetrant*, e.g. achondroplasia, Huntington's chorea, Marfan's syndrome.

Sex Chromosome Related Disorders

In all females one of the 'X' chromosome derived from either parent undergoes inactivation at the early period of gestation, in a random manner governed by the laws of probability Lyon's hypothesis (1961). Females, therefore contain a mosaic of tissue cells containing either the maternal or the paternal X-chromosome. Inactivation of the X-chromosome is effected by the action of a gene called the X-inactivation specific transcript which is located in the long arm of the X-chromosomes. Since 50% of the X-chromosomes in carrier females are normal, they do not manifest signs of the disease, but male offsprings suffer from the disease.

X-linked Recessive Inheritance (Fig. 2.3)

1. There is 'oblique' transmission, i.e., in the pedigree a line drawn through the affected persons is oblique.
2. Only males are affected, females are only carriers.

Fig. 2.3: Pedigree of a disorder with X-linked recessive inheritance (oblique transmission). Circles with dots in the centre represent carrier females

3. For the offsprings of a carrier female there is a 50% chance of sons being affected and a 50% chance of daughters being carriers.
4. Among offsprings of an affected male, none of the sons will carry the trait, while all the daughters will be carriers.

A female may manifest an X-linked trait if the normal X-chromosome is inactivated during early fetal life or if she is the offspring of a carrier female and affected male, or if the unaffected X-chromosome is structurally abnormal, as in Turner's syndrome, e.g., hemophilia, Christmas disease, pseudohypertrophic muscular dystrophy.

X-linked Dominant Inheritance (Fig. 2.4)

1. The number of females affected is double the number of affected males.
2. The affected male passes Y-chromosome to his sons (and not the X-chromosome). Therefore, all sons of an affected male are normal, whereas all daughters of an affected male are abnormal.
3. The affected female passes the mutant X-chromosome to half her daughters and to half her sons and, therefore, half the daughters and half the sons are affected.

The disease is usually milder in the female, because of the normal gene on the other X-chromosome, e.g. hypophosphatemic type of vitamin D resistant rickets.

Polygenic Disorders

Polygenic disorders (or disorders due to multifactorial inheritance) are caused by the additive effect of several minor abnormal genes and environmental factors. These are some of the commonest disorders encountered in clinical practice, e.g. anencephaly, spina bifida, talipes equinovarus, congenital dislocation of the hip, diabetes mellitus, essential hypertension, coronary artery disease, and asthma, etc.

In such disorders the environmental factors also play a major part in the development of clinical abnormality.

Fig. 2.4: Pedigree of a disorder with X-linked dominant inheritance. Double the number of females than males are affected

Chromosomal Disorders

These are disorders in which abnormalities in the number or pattern of chromosomes are demonstrable. The abnormality may involve the autosomes or sex chromosomes. Characteristics of autosomal disorders are:

1. Mental retardation,
2. Retardation of physical growth,
3. Congenital malformations, and
4. Dysmorphic features.

Sex chromosome disorders are characterized by:

1. Abnormalities of body configuration,
2. Gonadal abnormalities,
3. Abnormalities of the genitalia and secondary sexual characters, and
4. Disturbances of sexual and reproductive function.

Several of the chromosomal disorders are associated with higher incidence of other congenital abnormalities or neoplasms, e.g. congenital heart disease in Turner's syndrome, acute leukemia in mongolism.

Autosomal Disorders

DOWN'S SYNDROME

Syn: Trisomy 21: This occurs with a frequency of 1 per 1000 live births. Chromosome No. 21 is present in triplicate, making the total number of chromosomes to 47. The clinical features include (i) marked hypotonia, easily appreciated by lifting the infant up in one's arms, (ii) poor Moro's reflex, (iii) flat facies, (iv) upward slant of eyes, (v) small circular and dysplastic ears, (vi) loose folds of skin near the neck, (vii) clinodactyly of little finger (short and incurved), (viii) dysplastic middle phalanx of little finger, and (ix) dysplastic pelvis.

Radiologically the iliac bones appear wide and flat with absence of projection of the posterior superior iliac spine.

Diagnosis in the older child is fairly easy. The flat facies, the upward slant of the eyes, the flat occiput, the rough and dry skin, mental and physical retardation, clinodactyly, short and broad hands with simian crease (transverse creases), and wide gap between the big toe and other toes are some of the common features. About 40% have associated congenital heart disease, most commonly ventricular septal defect, endocardial cushion defects or Fallot's tetralogy, and these may prove fatal in the third or fourth decades.

Maternal serum markers are available for diagnosis of pregnancy with a Down's syndrome fetus. The alpha-fetoprotein level at 9-12 weeks of gestation is lower than normal. Other markers include maternal human chorionic gonadotropin, free beta subunit of human chorionic gonadotropin and pregnancy-associated protein A.

The incidence of Down's syndrome increases with increasing maternal age, being 1-2% in the age group of 38-45 years and 5% above this age. There is a twenty-fold increase in the incidence of acute leukemia (both ALL and ANLL) in Down's syndrome.

Other common trisomy syndromes involve chromosomes 18, 13 and 8 and show characteristic morphological abnormalities. Deletion syndromes are those in which a part of a chromosome is lost. Common deletion syndromes involve chromosomes 4, 5 and 13.

Sex Chromosomal Disorders

These constitute 50% of the chromosomal disorders seen at birth. Acquisition of extra X-chromosomes in the male leads to Klinefelter's syndrome. Deletion of one of the X-chromosomes gives rise to Turner's syndrome. The latter commonly affects females, but males also may be affected.

KLINEFELTER'S SYNDROME: It accounts for 1-3% of infertile males. It is characterized by tall stature and small atrophic testes (less than 2 cm in length or 6 ml in volume), scanty facial, pubic and axillary hair, X-chromatin positive buccal smear and XXY chromosomal constitution. The span (the distance between finger tips of outstretched hands) is greater than the height, and lower segment greater than upper segment (lower segment is the distance from heels to the upper end of pubic bone and upper segment from top of the skull to the upper end of pubic bone). The testosterone level in the blood is low or low normal and FSH and LH levels are increased. Almost half the patients have gynecomastia. The testes show atrophic and hyalinized seminiferous tubules and hypertrophic Leydig cells on biopsy.

In some cases the number of extra X-chromosomes may be more than one, i.e. more than two X-chromosomes. Increase in the number of X-chromosomes increases the chance of mental retardation, as well as skeletal and somatic defects.

Treatment consists of administration of long acting testosterone to induce male secondary sexual characteristics during puberty. The dose has to be varied from 25 to 250 mg given IM once in three weeks. Azoospermia does not improve, though the physical features of the patient may change, if treatment is given early.

TURNER'S SYNDROME: This condition was first described in 1938. It occurs with a frequency of 1/2500 to 1/1500 live born female infants. One of the X-chromosome is deleted. The remaining X-chromosome is of maternal origin in 2/3 and paternal origin in 1/3 cases. In Turner's syndrome the sex chromosome pattern is XO. In normal females, the epithelial cells obtained by buccal smear show sex chromatin consisting of inactivated X-

chromosomes. These are called Barr bodies. These are present in all cells. A proportion of neutrophils in peripheral blood shows the X-chromosomes as a knob like projection. In Turner's syndrome these sex chromatin bodies are absent.

Mosaic patterns such as XO/XX and others are sometimes seen. Structural abnormalities such as deletion of parts of the X-chromosome may occur.

Turner's syndrome is characterized by short stature (height below 141 cm), short neck with webbing, undeveloped breasts, scanty pubic hair, hypoplastic uterus and the presence of fibrous streaks instead of ovaries. Often there is edema of the dorsum of the hands and feet at birth due to hypoplasia of lymphatic vessels. The face is triangular with depressed nose, large mouth, small chin and loose folds of skin below the eyelids. Epicanthic folds and high arched palate may be seen. The chest is shield shaped with widely separated nipples and pectus excavatum. Large pigmented naevi, hyperconvex or hypoplastic nails, cubitus valgus, clinodactyly, short metacarpals and increased dermatoglyphic ridges on fingers may occur. 17-40% of patients with Turner's syndrome have congenital heart defects. Coarctation of the aorta, bicuspid aortic valves and left sided cardiac defects occur in the order of frequency. Hypertension, mitral valve prolapse and conduction defects are also more common. Echocardiography is mandatory in the initial work-up of cases of Turner's syndrome, so as to identify the cardiac abnormalities. Other concomitant abnormalities include hypothyroidism (15-30%), strabismus, cataracts, nystagmus, sensorineural deafness and recurrent otitis media.

Other stigmata include renal anomalies such as horse-shoe kidney. There is no mental retardation. Verbal IQ is lower than the performance IQ. The carrying angle of the elbow is increased.

Most patients are amenorrheic though some may show scanty periods. Replacement therapy with estrogens and progesterone after the age of 15 helps to maintain secondary sexual characters, though the height does not improve.

Therapy with human growth hormone initiated at about 5 years of age when growth retardation becomes manifest helps to restore the height partially. Supplementation of estrogens helps to retard osteoporosis. Assistance for pregnancy may be needed.

Patients with Turner's syndrome have a higher prevalence of diabetes mellitus.

XXX SYNDROME: Presence of an extra Y-chromosome confers mental subnormality and a violent or criminal behaviour. The majority have the karyotype XXX. They are generally taller, but are otherwise not distinguishable from normal individuals. Radioulnar synostosis and cubitus varus may be seen in some.

Methods Employed in Studying Genetic Disorders

Genetic studies are undertaken in all cases of morphological and biochemical abnormalities which may be prenatal, perinatal, postnatal or undetermined. Several techniques are employed in genetic analysis.

1. Karyotyping: Humans have 22 pairs of autosomes and one pair of sex chromosomes. Each chromosome has a constriction along its length, called the centromere which divides the chromosomes into two arms of equal or unequal length. The short arm is called 'p' and the long arm is called 'q' for descriptive purposes. During gametogenesis the chromosome number is halved, and therefore, gametes are said to be haploid, whereas the somatic cells are called diploid. In the laboratory, chromosomal pattern is studied by arresting mitosis in a dividing cell, separating the chromosomes by suitable methods, arranging them in order, and photographing them. Study of this pattern (karyotype) helps to identify deletion, addition, translocation, etc (Fig. 2.5).

Chromosomes are present in pairs. One chromosome of each pair comes from the mother and one from the father. As genes are located on chromosomes, it follows, therefore, that genes are also present in pairs.

2. Banding techniques: By special staining techniques subtle abnormalities in individual chromosomes can be detected. The stained preparations take the form of alternate dark and light bands and the patterns are highly diagnostic. Fluorescent quinacrine (Q banding) Giemsa (G banding) or (R banding) are generally used.

3. Gene mapping: For gene mapping, hybrids between human and mouse cells are created *in vitro*. These hybrids progressively lose human chromosomes, until at last only one human chromosome persists. The genes on this chromosome can be identified by studying the protein synthesis pattern of such a cell.

4. Fluorescence *in situ* hybridization (FISH) is employed to analyse chromosomes.

5. Microarray analysis is a means to probe the expression of thousands of genes simultaneously. This method was introduced into clinical practice in the mid 1990s and it has gained wide popularity for the analysis of several genetic problems.

Newer Developments in Genetics

Human genes were first cloned and sequenced about the end of the seventies. From then, newer knowledge and techniques have developed explosively. The human genome has been almost completely mapped and it is likely that the blueprint of the human genome may soon

Figs 2.5A and B: (A) Normal karyotype of human chromosomes—male G banding
(B) An idiogram showing the G banding pattern

become available. Prenatal diagnosis of genetic diseases is available for many diseases. Normal genes can be introduced into the cells of patients with genetic disorders in an attempt to correct the metabolic abnormality.

Diseases such as severe combined immunodeficiency, phenylketonuria, galactosemia, hemophilia, and diabetes mellitus, may lend themselves to such therapy.

Diagnostic techniques have reached an advanced stage of development at present. Some common terms used in genetic methodology are given below:

Restriction endonuclease: Several enzymes are used for cutting the double stranded DNA at specific nucleotide sequences. These enzymes are highly specific and give rise to predictable and uniform end products. Such enzymes are called restriction endonucleases. They are commonly used to identify the presence of the particular nucleotide sequence and to produce DNA fragments for the polymerase chain reaction (PCR).

DNA polymorphism: This is the inherited condition in which one or two different but normal nucleotide sequences can exist at a particular site in the DNA. Identification of DNA polymorphism can be made use of to identify the inheritance of abnormal genes that produce the disease.

Restriction site polymorphism: This is a specific type of DNA polymorphism in which the sequence of one form of polymorphism contains a recognition site for a

particular endonuclease while the sequence in the other form is devoid of such a site.

Study of DNA polymorphisms is particularly useful to identify the genetic cause for metabolic defects which do not show chromosomal abnormalities. Particular DNA sequences can be identified using DNA probes. DNA probes are fragments of DNA that contain nucleotide sequences specific for the gene or chromosomal region near the region of interest.

The process by which specific DNA probes are made to bind to complementary DNA sequences is called hybridization. Isolation and identification of DNA and RNA are done by blotting studies. If the material being isolated and identified is DNA, the method is called Southern blotting, in honour of EM Southern who developed the method. If the material being identified is RNA, the method is called Northern blotting. Correspondingly the method used for isolation and identification of proteins is called Western blotting, e.g. HIV proteins.

Polymerase chain reaction: A common procedure employed in genetic analysis is the polymerase chain reaction (PCR) by which portions of DNA that carry a particular gene are made to replicate and provide large quantities of the particular gene which is then identified by using biochemical methods. By this technique a particular portion of the genetic material can be multiplied several million folds within a short-time and this can be further submitted for analysis. This method is widely used in genetic studies to analyse genes.

Other non-genetic uses of PCR are in the diagnosis of microbial infection. The nuclear material (DNA or RNA) of the microbe can be detected and quantified. In addition to perfect specificity, PCR studies can detect the infective organism early in the disease even before antibodies develop, thereby helping in early diagnosis.

Prenatal Diagnosis

Many genetic and other disorders can be diagnosed *in utero*. Biochemical tests in pregnant women provide evidence for abnormal pregnancy, e.g., rise in serum alpha-fetoprotein in spina bifida and anencephaly, reduction in urinary estriol in fetal malformations. Direct evidence of fetal abnormality can be provided by imaging techniques such as ultrasonography or genetic analysis of fetal tissues. Materials for prenatal genetic diagnosis include fetal blood cells obtained by amniocentesis and fetoscopy done at 15-16 weeks of pregnancy under ultrasonographic control, and chorionic villus biopsy done towards the end of first trimester by the cervical route. Such procedures are widely undertaken in many parts of the world including a few centres in India. Establishment of major genetic disorder gives the chance for parents to accept abortion. With the availability of assisted reproduction techniques like *in vitro* embryo transfer, pre-implantation genetic investigations are done in order to eliminate genetically defective embryos.

Mitochondria and Mitochondrial Genetics

Mitochondria (MC) are the only organelles in the cell besides the nucleus, that contain their own DNA called mt DNA and their own machinery for synthesizing RNA and proteins. There are hundreds or thousands of mitochondria per cell and each contains approximately five mitochondrial genomes. The total number of genes in the mitochondria is 37. Most of the approximately 900 gene products in the organelles are encoded by nuclear DNA (n DNA) and are imported from the cytoplasm. Structurally MC have four compartments—the outer membrane, the inner membrane, the inter membrane space and the matrix (the region inside the inner membrane). MC perform numerous tasks such as pyruvate oxidation, Krebs's cycle and metabolism of amino acids, fatty acids and steroids. The most crucial function is the production of energy as ATP by means of electron transport chain and the oxidative phosphorylation system the respiratory chain.

The MC is a 16569-base pair double stranded circular molecule containing 37 genes. 24 genes are needed for mt DNA translation and 13 genes code subunits of the respiratory chain.

In MC diseases, some MC may have pathogenic mutations of mt DNA, others may be normal. This situation is known as heteroplasmy. The random distribution of organelles at the time of cell division can change the proportions of mutant mt DNA obtained by daughter cells and when the pathogenic threshold in a previously unaffected tissue is surpassed, the phenotype may also change.

Mitochondrial DNA Related Respiratory Chain Diseases

These share 2 features:

1. Lactic acidosis and 2. massive MC proliferation in muscle giving rise to ragged-red fibre in muscles, MC being present in all cells, many of the MC disorders produce widespread multisystem effects. Several distinct syndromes have been described depending upon the genetic alterations.

Clinical features include symptoms pertaining to all systems.

Nervous system: seizures, ataxia, myoclonus, psychomotor retardation, hemiparesis, cortical blindness, headache, dystonias, peripheral neuropathy and muscle weakness.

Eyes: ptosis, retinopathy, optic atrophy

Blood: sideroblastic anemia

Endocrinology: diabetes mellitus short stature, hypoparathyroidism

Heart: conduction defects, cardiomyopathy

Gastrointestinal system: exocrine pancreatic dysfunction

Kidney: Fanconi's syndrome

Ear: sensorineural deafness.

Genetic Counselling

Genetic counselling is the process of communication which deals with the human problems associated with the birth of an abnormal child or possibility of similar incident, to the concerned parents.

The steps involved are:

1. Making a precise diagnosis and administering appropriate treatment.
2. Reducing anxiety and guilt in the patient or parents and helping them to cope realistically with the affliction.
3. Explaining the relevant genetic facts, informing them about diagnostic facilities, and risk of recurrence in subsequent children, and
4. Helping the couple to make rational decisions regarding further children.

Conclusions: From the days of Charles Darwin 140 years ago, genetics has made great progress so as to become a

major subspeciality in medicine. It is likely to play a major role in the prediction, prevention, diagnosis, and treatment of several major diseases:

1. Study of common diseases help to understand their mechanisms better and provide better care.	Alzheimer's disease, asthma, breast cancer, heart disease, migraine, etc.
2. Re-defining disease mechanism	This helps to identify the geno-type in addition to the pheno-type which will ultimately help to classify more objectively and manage more effectively.
3. Targeting treatment	Genetic studies help to reveal genetic make up predisposing to disease, drug metabolism, effectiveness of drugs, etc. This helps to plan treatment more effectively.
4. Discovering newer targets and effective treatment	Present day treatment, in many cases is the management of the final effect of the disease, e.g. diabetes, asthma, cardiac failure. Understanding the genetic pattern will help to target therapy to the basic abnormality and tackle the cause more effectively.
5. Providing effective preventive care	

Gene Therapy

The first successful attempt at transferring the normal gene for adenosine deaminase to a girl suffering from deficiency of this enzyme was performed on 14th September, 1990. Subsequently several persons have been given normal genes in order to replace defective genes with a view to cure the metabolic defect. The procedure involves isolation of the healthy gene along with the sequences controlling its expression, incorporation of the gene on a carrier or vector as an expression cassette and finally the delivery of the same to the target cells. Gene therapy may be positive or negative. The former is the introduction of a gene whose protein product is necessary for the curative effect. Negative gene therapy implies the inhibition of the 'sick' or over expressed gene function. Gene therapy is likely to become more popular in the near future. Though gene therapy is largely beneficial, insertion of a defective gene may lead to adverse effects in future, e.g. lymphatic leukemia in children treated with single gene therapy for severe combined immunodeficiency.

The other modality of treatment which has been successful in some of the genetically determined diseases is bone marrow transplantation, e.g. thalassemia, hemoglobinopathies.

GENETIC EPIDEMIOLOGY

Genetic epidemiology which is a developing discipline is closely related to traditional epidemiology. It particularly focusses on the familial and in particular, the genetic determinants of diseases and the joint effects of genetic and non-genetic determinants.

The fusion of epidemiology and genetics provides the foundation for genetic epidemiology. Genetic epidemiology can contribute to establishing the causative role of environmentally modifiable risk factors and help in planning preventive measures in future. Pharmacogenomics is that branch of genetic study in which the appropriate dosing with maximum cost effectiveness can be selected, based on genetic information.

Glossary of Terms Used in Genetics

- Allele**—An alternative form of a gene.
- Alternative splicing**—A regulatory mechanism by which variations in the incorporation of a gene's exons or coding regions, into messenger RNA lead to the production of more than one related protein, or isoform.
- Autosomes**—All of the chromosomes except for the sex chromosomes and the mitochondrial chromosome.
- Centromere**—The constricted region near the centre of a chromosome that has a critical role in cell division.
- Codon**—A three-base sequence of DNA or RNA that specifies a single amino acid.
- Conservative mutation**—A change in a DNA or RNA sequence that leads to the replacement of one amino acid with a biochemically similar one.
- Epigenetic**—A term describing non-mutational phenomena, such as methylation and histone modification, that modify the expression of a gene.
- Exon**—A region of a gene that codes for a protein.
- Frame-shift mutation**—The addition or deletion of a number of DNA bases that is not a multiple of three, thus causing a shift in the reading frame of the gene. This shift leads to a change in the reading frame of all parts of the gene that are downstream from the mutation, often leading to a premature stop codon and ultimately, to a truncated protein.
- Gain-of-function mutation**—A mutation that produces a protein that takes on a new or enhanced function.
- Genomics**—The study of the functions and interactions of all the genes in the genome, including their interactions with environmental factors.

Genotype—A person's genetic makeup, as reflected by his or her DNA sequence.

Haplotype—A group of nearby alleles that are inherited together.

Heterozygous—Having two different alleles at a specific autosomal (or X-chromosome in a female) gene locus.

Homozygous—Having two identical alleles at a specific autosomal (or X-chromosome in a female) gene locus.

Intron—A region of a gene that does not code for a protein.

Linkage disequilibrium—The nonrandom association in a population of alleles at nearby loci.

Loss-of-function mutation—A mutation that decreases the production or function of a protein (or does both).

Missense mutation—Substitution of a single DNA base that results in a codon that specifies an alternative amino acid.

Monogenic—Caused by a mutation in a single gene.

Motif—A DNA sequence pattern within a gene that, because of its similarity to sequences in other known genes, suggests a possible function of the gene, its protein product, or both.

Multifactorial—Caused by the interaction of multiple genetic and environmental factors.

Nonconservative mutation—A change in the DNA or RNA sequence that leads to the replacement of one amino acid with a very dissimilar one.

Nonsense mutation—Substitution of a single DNA base that results in a stop codon, thus leading to the truncation of a protein.

Penetrance—The likelihood that a person carrying a particular mutant gene will have an altered phenotype.

Phenotype—The clinical presentation or expression of a specific gene or genes, which may be influenced by environmental factors, or both.

Point mutation—The substitution of a single DNA base in the normal DNA sequence.

Regulatory mutation—A mutation in a region of the genome that does not encode a protein but affects the expression of a gene.

Repeat sequence—A stretch of DNA bases that occurs in the genome in multiple identical or closely related copies.

Silent mutation—Substitution of a single DNA base that produces no change in the amino acid sequence of the encoded protein.

Single-nucleotide polymorphism (SNP)—A common variant in the genome sequence; the human genome contains about 10 million SNPs.

Stop codon—A codon that leads to the termination of a protein rather than to the addition of an amino acid. The three stop codons are TGA, TAA, and TAG.

Translation—This is the production of protein via mRNA
Most genes contain alternating regions called exons and introns.

Defence Mechanisms of the Host and Clinical Immunology

K.V. Krishna Das, Aswini Kumar

Chapter Summary

Nonspecific Defence Mechanisms 16
Specific Mechanisms 16
Diagnostic Procedures 22

Serum Sickness 23
Immunodeficiency States 24
Immunization 25
HLA System in Humans 25
Modulation of Cellular Behaviour 28

Immunology has developed and reached a high level of achievement in the past few decades. Immunological principles have helped in understanding the mechanisms of several disease processes and their management. Man has several defence mechanisms to protect him against microbial invasion. These may be nonspecific and specific.

Nonspecific Defence Mechanisms

1. The skin and mucous membranes form protective barriers against bacteria. The stratum corneum which is a desiccated layer of the epidermis is impermeable to microbes. If microbes enter through wounds, the organisms are killed by neutrophils and macrophages through the mechanism of oxygen intermediates. Antimicrobial substances such as defensins and cathepsidins act against bacteria, viruses and fungi. In atopic dermatitis these antimicrobial peptides may be deficient and this predisposes to bacterial infections, especially *S. aureus*.
2. Lactic acid in the sweat and fatty acids in the sebaceous secretions inhibit growth of pathogenic flora. Fungal infections are common in parts devoid of sebaceous glands, e.g., interspaces between toes, the soles and the sides of the feet.
3. Ciliary movement helps to carry away bacteria through mucous secretions in the respiratory tract. Organisms such as *Pseudomonas aeruginosa* colonize in the lungs, especially in cystic fibrosis. They form biofilms in the respiratory tract and thrive within the biofilm in a free-living planktonic state (a free-living drifting state) which resists all defense forces of the host.

In the normal state, inhaled pathogens are cleared by mucociliary action and natural defenses. If the bacterial population exceeds a threshold number they produce sensors which monitor the defenses forces of the host and in turn, develop virulence genes which protect them against phagocytosis.
4. Mucus of respiratory and urogenital tracts possesses bactericidal properties due to the enzyme lysozyme which lyses the cell wall of the invading bacteria. Moreover, the neuraminic acid content of the mucus competitively inhibits the myxoviruses.
5. Normal commensals of the skin and gastrointestinal tract inhibit the proliferation of pathogenic bacteria.
6. Phagocytosis is the most important nonspecific mechanism by which body tries to eliminate invading organisms. Cells with phagocytic properties are:
 - a. Neutrophil leukocytes,
 - b. Eosinophils,
 - c. Monocytes,
 - d. Histiocytes in tissues,
 - e. Sinus lining cells in the liver (Kupffer's cells), spleen and bone marrow,

- f. Reticulum cells in lymph nodes, and
- g. Microglia in the central nervous system.

Foreign materials are ingested by the phagocytes and later digested intracellularly. The myeloperoxidase present inside the phagocytes also destroys viable bacteria. When the phagocytic function is reduced, generalized infections like septicemia develop leading to high mortality. Several processes aid in phagocytosis. These are:

- i. Chemotaxis by complement breakdown products,
- ii. Opsonization by specific antibodies which neutralise the negative surface charges of bacteria, and
- iii. Cytokines such as macrophage activating factors and macrophage migration inhibition factors released by the T-lymphocytes which lead to local accumulation of active macrophages (Table 3.1).

Colloidal substances, high molecular weight substances and dyes may saturate phagocytic capacity and increase the susceptibility to infection, e.g., carbon particles in heavy smokers, silica particles in mine workers, etc. Some organisms (e.g., *M. leprae*) are not destroyed by the macrophages. On the other hand they multiply in the protected environment of the cell.

Specific Mechanisms

The Immune Response

Any substance which evokes an immunological reaction is an *antigen*. Certain components of the cell membranes act as *specific antigens*. They differ from person to person in their chemical composition and three dimensional structure. The immunocompetent cells can recognize the self from the non-self. Moreover, the body can recognize one antigen from another leading to specificity of immunological reaction. Some substances are strongly antigenic, e.g., dinitrochlorobenzene, while others are weakly antigenic, e.g., bacterial capsular antigen. *Antibody response* is usually selective against certain important regions of the antigen which are termed the antigenic determinant sites. A *hapten* is a small molecule which by itself cannot elicit antibody production, but when combined with a carrier molecule, can do so. The antibodies can combine with the hapten directly, without the help of the carrier. The presence of haptens in tissue proteins is one of the reasons for the development of autoimmunity.

The main cells involved in immune reactions are the lymphocytes. They originate from the totipotent cells of the bone marrow. Some of them pass through the thymus from where they develop to become T-lymphocytes with their specific antigens and functional capacities. They are then specialized for cell mediated immune reactions and are recognizable by thymus specific antigens on their surface. These T-lymphocytes are found mainly in the

TABLE 3.1

Cytokines of importance				
Cytokine	Primary source	Other	Target	Effects
Interleukins Tumour necrosis factor (TNF)	Macrophages Lymphocytes		Macrophages Granulocytes Tissue cells	Activation of cytotoxic cell activity, cachexia, adherence of leukocytes to endothelium
Interferons	Leukocytes T-lymphocytes NK cells	Fibroblast Epithelium	Tissue cells Leukocytes	Antiviral, macrophage activation
Macrophage (M) Colony stimulating factor (CSF)	Monocytes	Endothelium Fibroblast	Stem cells	Stimulation to divide and differentiate
Granulocyte (G) CSF	Macrophages	Fibroblast	Stem cells	-Do-
Migration inhibition factors (MIF)	T-lymphocytes	—	Macrophages	Migration inhibition
Chemotactic factors	Lymphocytes Macrophages Granulocytes	Tissue cells and their components	Leukocytes	Attract to site of infection or tissue damage

paracortical areas of lymph nodes and periarteriolar sheaths in the spleen. On the other hand, the stem cells passing through gut and lung associated lymph nodes (bursa equivalent) are transformed into B-lymphocytes. They eventually occupy germinal centres of lymph nodes and spleen. Upon antigenic stimulation, they transform into plasma cells which synthesize the immunoglobulins and form mediators of humoral immunity. In peripheral blood, 80% of lymphocytes are T-cells, 15% are B-cells and 5% are K-cells (killer).

T-lymphocytes form spontaneous rosettes with sheep erythrocytes (*E. rosette*) at 4°C. These receptors are identified as the CD2 molecules on T-cells. They are also recognised by the presence of specific antigens on their cell surfaces, identified by monoclonal antibodies. CD3 marker is present on T-cells. T-cells include many subsets, most important ones are TH (T helper or CD4 +ve) cells carrying CD4 antigen and TS (T suppressor or CD8 +ve) cells carrying CD8 antigen. (CD stands for cluster determinant).

All T-cells have the T-cell antigen receptor (TCR) on their surface. TCR-2 contains alpha and beta chains; TCR-1 consists of gamma and delta polypeptides. Both are further associated with a set of 5 polypeptides, to form the CD3 complex or TCR complex. In human peripheral blood 90% T cells are TCR-2 and the remaining are TCR-1. TCR-2 cells are further divided into two groups, depending on the presence of CD4 or CD8 markers on their cell surface. The subset, which carries the CD4 marker, helps the B cells to divide, differentiate and make antibody response; these are therefore called T helper (TH) cells. CD4 T cells recognise their specific antigens in association with MHC class II molecules. CD4 positive T helper cells also carry CD 29 antigen.

The CD4 positive cells are further subdivided into two subsets, depending on their capacity to produce cytokines. The TH-1 subset secretes interleukin-2 (IL-2) and interferon-gamma; induces cytotoxic T-cells; enhances delayed hypersensitivity; and activates macrophages. On the other hand TH-2 subset produces IL-4, IL-5 and IL-6; stimulates B-cells; enhances humoral immunity, and activates eosinophils. A small number of CD4 cells belong to a third group, they are the memory cells (TH-M).

The second TCR-2 subset, which carries the CD8 marker, is responsible for suppressing antibody response and so they are termed as T suppressor (TS) cells. CD8 T-cells recognise antigens in association with MHC class I molecules.

The CD8 positive cells are also subdivided into 2 subclasses. The subset that expresses CD28 molecule secretes IL-2 and is mainly suppressor in function. The other subset that carries CD18 antigen does not produce IL-2, but responds to IL-2, and is mainly cytotoxic. This group is responsible for the destruction of host cells that are infected by viruses or intracellular pathogens; they are therefore also called as T cytotoxic (TC) cells.

B-lymphocytes are identified either by the rosette formation with sheep erythrocytes coated with antibodies and complement (*EAC rosette*) or by demonstration of surface immunoglobulins by fluorescent antibody technique. Immunoglobulins are classified into G, M, A, D and E (Table 3.2). All B-cells carry CD 19 and 20 markers and MHC II marker. Pre-B-cells (immature B-cells) carry CD9 and 10 markers. CD5 carrying B-cells are responsible for autoantibody production.

Once the antigens enter the body, they are processed by macrophages and then recognized by the antigen sensitive lymphocytes. Antigens synthesized within a cell,

TABLE 3.2

Characteristics of immunoglobulins					
Class	IgG	IgA	IgM	IgD	IgE
Heavy chain	gamma	alpha	mu	delta	eta

Secondary response	+	+	–	–	–
Placental crossing	+	–	–	–	–

such as viral polypeptides are externalised and associated with MHC (major histocompatibility) Class I molecules and beta-2 microglobulin. Class I molecules are present on all nucleated cells. The complexed antigen is then presented to the CD8 T cells. By contrast, antigens that have been endocytosed are associated with MHC Class II molecules, and these are then presented to the CD4 T cells. The lymphocytes recognise the antigen by means of the receptors present on their surface. The T-cell antigen receptor (TCR) is part of the CD3 complex. Antigen recognition receptors on B-cells are made up of partly by surface immunoglobulins. When the antigen is recognised by receptor, the lymphocytes undergo morphological alterations (blast transformation) and after a series of divisions form a clone of cells which react against the specific antigen. These committed cells differentiate into plasma cells which secrete specific antibodies. Some of the remaining cells are responsible for *immunological memory*. Many infections and vaccinations lead to prolonged immunity due to persistence of immunological memory.

Most animals start producing specific antibodies within 10 days of injection of antigen. Initially these antibodies are mainly of IgM variety. This is the *primary response*. When the same antigen is again introduced, the *secondary immune response* is elicited. The reaction occurs at a faster and augmented rate and lasts longer. This time IgG antibodies predominate. Sometimes even large quantities of antigen may not produce immune response. This is called *tolerance*, which again will be specific to that particular antigen. Tolerance acquired in postnatal life usually fades away with the passage of time. However, tolerance induced *in utero* tends to be permanent.

The effector mechanisms involved in the immune response are as follows:

1. Cell-mediated immunity,
2. Humoral immunity,
3. Antibody dependent cell mediated immunity,
4. NK cells-Natural killer cells mediated immunity, and
5. Macrophage-mediated immunity.

Cell-mediated immunity: This is mediated by the *T-lymphocytes* which form *T-helper cells*, *T-suppressor cells* and *natural killer cells*.

(A) **Immunity against infections** Effective immunity against bacteria such as mycobacteria and listeria, certain viruses and almost all parasites is mediated by T-cells. T-cells from sensitised individuals lyse the target cells bearing the viruses.

(B) **The rejection of allograft and destruction of tumour cells** These are also mediated mainly by T-cells, although other mechanisms are also involved.

(C) **Helper function** Some of the T-cells express CD4 antigen on their cell surface. These are called CD4 positive cells or T-helper (TH) cells. They also carry receptors for the Fc portion of IgM. They form about 50% of the T cells of peripheral blood. They are necessary for the optimal antibody production by plasma cells and for generation of cytotoxic T-cells. Moreover, they produce cytokines needed to stimulate immune response. These cytokines act in an autocrine manner on the CD4 cells themselves and in a paracrine manner on other cells. Human immunodeficiency virus (HIV) specially infects CD4+ cells with consequent destruction of these cells leading to acquired immunodeficiency syndrome (AIDS).

(D) **Suppressor function** The suppressor cell (TS) subgroup which constitutes 10% of the total can be distinguished by the presence of surface receptors for Fc portion of IgG (Tr). They carry CD8 antigens. They regulate the activities of both T- and B-cells. The TS activity is depressed in many autoimmune diseases and in some of the human malignancies.

(E) **Production of soluble mediators** Cytokines are biologically active molecules released by specific cells that elicit a particular response from other cells on which they act. Several lymphokines and monokines (products of monocytes) are known. T-cells stimulated by antigens liberate certain soluble substances called *lymphokines*.

These molecules produced in an antigen specific manner can act in an antigen nonspecific manner to recruit, activate and regulate effector cells with the potential to combat infectious agents.

Lymphokines include *macrophage migration inhibition factor* (MIF), *macrophage activation factor* (MAF), *leukocyte migration inhibition factor* (LMIF), *leukocyte adherence inhibition factor* (LAIF), *chemotactic factor*, *interferons* (IF) and *interleukins* (IL). The MIF and MAF help in accumulation of macrophages at the site of reaction. The resulting erythema and induration form the basis of skin tests. Administration of transfer factor to nonsensitized individuals leads to specific sensitisation.

Chemokines (chemotactic cytokines) mediate inflammatory reaction. The attraction of leukocytes to the site of inflammation is central to the process. More than 40 cytokines have been identified. These are grouped mainly into 4 families. Alpha chemokines attract neutrophils, while beta chemokines act on monocytes, eosinophils and lymphocytes with variable selectivity. C5a (complement activation product) and leukotriene (LTB₄) are generated at the site of bacterial infection and they attract macrophages and mast cells. Chemokines induce cell migration by attachment to specific G-protein controlled cell surface receptors on target cells. These chemokine receptors also act as co-receptors for infective agents such as *Plasmodium vivax* and HIV to get entry into host cells.

Interferons (IF) inhibit viral multiplication in host cells, modulate cell differentiation and inhibit oncogene expression.

The major types of IF are alpha, beta and gamma derived from leukocytes, fibroblasts and activated T lymphocytes respectively. Gamma interferon is antiviral in activity. It also increases cytotoxic activity of T-cells, enhances B-cell differentiation and induces respiratory burst in macrophages. Interferon is useful in the treatment of hairy cell leukemia and chronic myeloid leukemia in addition to several viral infections.

Interleukins (IL) are growth factors secreted by lymphocytes, monocytes and macrophages. There are 15 different interleukins described so far. They are biological mediators which control the amplitude and duration of immune response. IL-1 stimulates production of receptors for IL-2 on lymphocytes. Moreover IL-1 induces production of acute phase proteins, such as C-reactive protein from liver, which in turn produce fever and leukocytosis. IL-2 stimulates T-cells and NK cells so as to become lymphokine-activated killer (LAK) cells. Such specific LAK cells are being used for immunotherapy in cancer patients with promising results. IL-3 is colony stimulating factor for T- and B-cells. IL-4, 5, 6 and 7 are produced by T-helper cells; all of them help in B-cell differentiation. IL-5 stimulates eosinophils; IL-6 enhances myeloid cells

and IL-7 increases platelet production. IL-8 is produced by monocytes and is chemotactic for neutrophils. IL-9 and 10 are general growth factors for lymphocytes.

Leukotrienes (LTs) are derivatives of arachidonic acid. The arachidonic acid may be converted to (A) cyclooxygenase products (prostaglandins and prostacyclin), and (B) 5-Lipoxygenase products (leukotrienes and lipoxins). In myeloid cells leukotrienes A₄, B₄, C₄, D₄ are formed; the last mentioned two are components of the slow reacting substance (SRS) of anaphylaxis. LTs are chemical mediators of allergy and inflammation. LTs play important role in increasing vascular permeability and diapedesis of leukocytes. They produce bronchoconstriction, bronchial mucosal edema and mucous secretion in asthma. They have a role in pathogenesis of acute respiratory distress syndrome (ARDS) and ulcerative colitis.

(F) **Delayed hypersensitivity:** When tuberculin or a similar antigen is injected intradermally in a sensitised individual, an erythematous indurated lesion develops slowly, reaching its maximum within 48-72 hours. This is called delayed type of hypersensitivity. Hypersensitivity is the abnormal over-reaction of the immune system and it usually results in unwanted tissue destruction. This is responsible for caseation in tuberculosis, granulomatous skin lesions in tuberculoid leprosy, rashes in smallpox and measles, skin lesions in herpes simplex and contact hypersensitivity to chemicals and plants. Hypersensitivity reaction mediated by T-cells is called Type IV reaction.

Humoral immunity: Antibodies are produced by plasma cells. These are immunoglobulins, belonging to the class IgG, IgA, IgM, IgD, and IgE. All except IgA are present in plasma mainly. IgA is also present in body secretions and hence present in mucosal surfaces as well. The immunoglobulins consist of specific heavy chain and light chains. IgG is present in maximal amounts in plasma. It is mainly responsible for humoral immunity against microbial infection. Primary response produces antibodies of IgM type, while IgG antibodies predominate in secondary response. IgG can cross placental barrier. Natural antibodies (e.g., antibodies against ABO system of RBC) are of IgM variety; they cannot cross placental barrier, and so the fetus is protected. Anti-Rh antibodies, being IgG type, can cross the placenta, leading to Rh isoimmunization and consequent fetal distress.

The characteristics of immunoglobulins are given in Table 3.2.

Complement system: This consists of plasma and membrane proteins (globulins) that play a major role in host defence against microbes and in several other immunological processes such as hemolysis. They function in two major ways. (1) Opsonization of microbes and alteration in their surface membrane leading to disruption. (2) Promotion of inflammatory response by

TABLE 3.3

Characteristics of complement components

	Serum concentration (µg/mL)	Thermal reaction	Site of synthesis
C1q	100-200	labile	Epithelial cells of small intestine

C1s	20-120	labile	-Do-
C2	20-40	labile	Reticuloendothelial cells (RE cells)
C3	1200	stable	Hepatocytes
C4	250-400	stable	RE cells
C5	75-100	labile	Macrophages
C6	20	stable	Hepatocytes
C7	—	stable	-Do-
C8	10	labile	-Do-
C9	2	labile	-Do-

altering vascular permeability and attracting inflammatory cells to the site of injury. Several of them have been named. These are C1q, C1r, C1s, and C2 to C9. Their properties are given in Table 3.3.

Acquired and inherited abnormalities of the complement system predispose to microbial infections and autoimmune disorders. For example, when antigen-antibody complexes are deposited in kidney glomeruli, complement components are activated, inflammatory cells are attracted and immune mediated glomerulonephritis develops. Complement components are used up differentially in several immune mediated diseases and, therefore, measurement of serum levels of complement components gives diagnostic and prognostic information.

The complement system is activated sequentially when antibody attaches to antigen components on the cell surface. The final products create microscopic holes on

the cell membrane. Osmotic entry of water through these holes results in lysis of the target cells. The complement products also activate phagocytosis, chemotaxis and immune adherence. Capillary permeability is also increased. Inhibitors of the complement are present naturally, which check the uncontrolled activity of the complement.

Apart from the classical sequential complement pathway, some microbial polysaccharides can activate an alternate system (properdin system), thereby bypassing the initial complement components. Since this does not require specific antibodies, the alternate pathway acts as a first line of defence against invading micro-organisms. However, the nonspecific nature may sometimes prove disadvantageous as in the case of complement activation by immune complexes leading to widespread tissue destruction as in type III hypersensitivity reaction.

Humoral immunity plays a great role in conferring resistance to bacterial infection. The antibodies destroy the target cells by several mechanisms.

1. Classical complement pathway,
2. Antibody dependent cell-mediated cytotoxicity,
3. Agglutination, and
4. Opsonization of target cells, thereby making them more susceptible to phagocytosis. Characteristic features of various immunological effector arms are shown in Table 3.4.

Antibody dependent immunity: Hypersensitivity reactions mediated by antibodies fall into different types which are described below:

Type I. Anaphylactic reaction Introduction of the antigen (e.g., penicillin) leads to the production of cytophilic antibodies (mainly IgE) in sensitive persons. These are attached to the surface of mast cells. Unlike the other

TABLE 3.4

Characteristic features of various immunological arms

	T-cells	B-cells	K-cells	NK-cells	Macrophages
Cell surface marker	Sheep RBC receptor	Complement receptor and surface Ig	Fc receptor	Fc receptor	Fc receptor and complement receptor

immunoglobulins which circulate in the plasma, IgE is bound to receptors especially to FC ϵ R which is a distinctive receptor for ϵ chain, present more on basophils and mast cells, and probably on eosinophils as well. Cross linking of cell-bound IgE with the multivalent antigen excites cellular processes which culminate in the liberation of chemical mediators such as histamine and serine proteins into the circulation. This brings on the anaphylactic reaction.

On subsequent exposure the antigen reacts with the preformed antibodies, causing mast cell degranulation and release of histamine, serotonin, and slow reacting substance of anaphylaxis (SRS-A). This may lead to asthma due to bronchoconstriction, or anaphylactic shock due to widespread capillary dilatation.

Allergens such as pollens, house dust and fungi react with cell bound IgE of the respiratory tract leading to bronchial asthma or hay fever. Allergens from food may cause urticaria.

Type I hypersensitivity reaction occurs within 30 minutes of exposure to the allergen. Such reaction can be abolished by drugs like adrenaline and disodium cromoglycate which prevent the release of histamine. Antihistamines compete with the released histamine for effector sites. Repeated introduction of the allergen in small doses results in hyposensitization.

Type II. Cytotoxic hypersensitivity Certain drugs may complex with membrane proteins of blood cells leading to production of autoantibodies. These antibodies can lyse the blood cells through the action of complement. Hemolytic anemia caused by alpha-methyldopa, agranulocytosis produced by amidopyrine and thrombocytopenia induced by chlorothiazides are examples of this mechanism.

Type III. Immune complex mediated tissue damage The continued presence of antigen causes persistent antibody production. Antigen-antibody complexes form and circulate in the blood. These heavy molecules are entrapped in blood vessels, renal glomeruli, lungs, skin and joints. Complement system is activated through the alternate pathway. The complement degradation products attract polymorphs and macrophages and an inflammatory reaction sets in with resultant damage to the tissues.

Platelet aggregation occurs and these microthrombi lead to vascular occlusion and ischemia.

If the antibody is in excess, the complexes are rapidly precipitated and tend to be localized at the site of entry of antigen. This leads to Arthus type reaction. If an antigen is injected intradermally into a hyperimmunized animal, erythema and edema occur at the site of injection. This reaction reaches a peak in 3-8 hours, and is referred to as intermediate type skin reaction. Farmer's lung is the classical example of localized type III reaction. On the

other hand, if antigen is excess, soluble complexes are formed which precipitate in all tissues giving rise to the serum sickness type of reaction. The lumpy granule precipitates seen in renal glomeruli in post-streptococcal glomerulonephritis are due to systemic type III reaction.

Type IV. T-cell-mediated hypersensitivity reaction: This is mediated by T-lymphocytes and it has been described earlier.

Type V. Stimulatory hypersensitivity Thyroid cells are normally stimulated by TSH through a membrane associated receptor. The *long acting thyroid stimulator* (LATS), otherwise known as *thyroid stimulating immunoglobulin* (TSI) is an antibody against some components of the receptor for TSH. The LATS produces TSH like activity, but the action is more prolonged. The continued stimulation by LATS leads to hyperthyroidism. Similarly, antilymphocyte globulin (ALG) is stimulatory to lymphocytes in appropriate conditions. It is used therapeutically in immune mediated aplastic anemia.

Type VI. Antibody dependent cell-mediated cytotoxic mechanism (ADCC) This mechanism does not require complement activity. The effector cells are neither T- or B-cells but are called K-cells. The specificity of this reaction resides in the antibody molecule. Only very small amounts of antibody are required to produce this reaction and, therefore, this mechanism is effective in areas where antibody concentration may be minimal, e.g. at the site of solid tumours. The full significance of this mechanism is not known.

In certain circumstances, more than one mechanism may be operating. Thus in autoimmune damage to endocrine glands, e.g. type I diabetes mellitus, type II and IV hypersensitivity reactions are involved. Autoantibodies against insulin secreting cells, insulin molecules and insulin receptors were described. The clinical features of the hypersensitivity reactions are shown in Table 3.5.

AUTOIMMUNE DISEASES

The autoimmune diseases result from immunologically mediated tissue destruction where the antigens involved are autologous. These are broadly classified into two:

(A) **Organ specific diseases:** The antibodies associated with Hashimoto's thyroiditis react only with thyroid tissue, so the lesion is highly localized. Other examples of organ specific diseases include those of stomach (pernicious anemia).

(B) **Non-organ specific diseases:** In contrast, the serum from patient with systemic lupus erythematosus (SLE) reacts with many tissues in the body; the dominant antibody is directed against cellular double stranded DNA. Although non-organ specific, some autoimmune diseases

TABLE 3.5

Common hypersensitivity disorders

	<i>Skin diseases</i>	<i>Kidney diseases</i>	<i>Lung diseases</i>	<i>Diseases of other sites</i>	<i>Skin test</i>
Type I Anaphylactic, IgE mediated, histamine dependent	Urticaria and rashes due to bacteria, viruses, parasites, food and drugs, atopic dermatitis		Rhinitis and asthma due to pollen dust, feathers, etc.	Penicillin reaction food allergy	Wheal and flare reaction within 30 minutes, immediate type
Type II Cytotoxic antibody mediated complement dependent	Bullous pemphigoid (basement membrane), pemphigus vulgaris (desmosomes)	Goodpasture's (anti GBM) syndrome	Goodpasture's syndrome	Transfusion reactions, isoimmunization (Rh), drug-induced hemolytic anemia, thrombocytopenia, leukopenia	
Type III Immune complex mediated complement and phagocyte dependent	SLE	Post-streptococcal glomerulonephritis, nephrosis of quartan malaria	Farmer's lung due to dusts from hay, bagassosis, cereal grains, etc.	Arthus reaction serum sickness SLE	Erythema and edema, polymorphs predominate, maximum at 3-8 hr intermediate group reaction
Type IV T cell mediated cytotoxic	Contact allergy to chemicals, granuloma in leprosy	Chronic and membranoproliferative glomerulonephritis	Granuloma and caseation in tuberculosis	Hashimoto's thyroiditis	Erythema and induration, lymphocytes predominate maximum at 72 hr, delayed type
Type V Stimulatory antibody mediated				Thyrotoxicosis due to long acting thyroid stimulator	

preferentially involve certain organs; examples are rheumatoid arthritis (joints), scleroderma (skin) and dermatomyositis (skin and muscle). Removal of preformed antibody by plasmapheresis is a therapeutic tool in the management of some of these disorders.

Several mechanisms have been proposed to explain the pathogenesis of autoimmune diseases.

a. Forbidden clone theory: All the clones which react with self antigens are destroyed during intrauterine life, but such a clone may be generated by somatic mutation in later life.

b. Sequestered antigen theory: Antigens exposed to lymphoid system during intrauterine life are recognized as self. But some tissues (e.g., lens, thyroid, CNS) are anatomically sequestered or guarded from the lymphocytes. In adult life, when such antigens are exposed, the immune system reacts against them.

c. Suppressor cell deficiency: Small quantities of thyroglobulin (and other antigens) are seen in circulation even in normal persons, but they are below the threshold level

for immunostimulation. The suppressor cells also inhibit sensitization. In persons with deficient T-cell activity, inappropriate immune reactions are produced.

d. Genetic effect: Autoimmune diseases show familial distribution and female preponderance. Many of them are associated with particular HLA types. These suggest that genetic predisposition may play a role in their pathogenesis.

e. Cross reacting antibodies: Antibodies produced against exogenous antigens can cross react with tissue proteins, e.g. post-rabies vaccine encephalitis, and post-streptococcal rheumatic fever. In any given instance one or more of the above mechanisms may be operative. Some of the immune-mediated disorders are listed in Table 3.6.

Diagnostic Procedures

The tests used in immunology range from simple tests such as agglutination, flocculation, precipitation,

TABLE 3.6

Some important immune-mediated disorders

Diseases	Auto-antigen	Diagnostic test
I. <i>Organ specific diseases</i>		
Pernicious anemia	Parietal cells of stomach, intrinsic factor	IFT
Ulcerative colitis	Lipopolysaccharides of mucous membrane of colon	Neutralization
Acute post-streptococcal nephritis	Streptococcal antigen	IFT
Sympathetic ophthalmia	Uveal protein	CFT and IFT
Bullous pemphigoid	Basement membrane	Skin test
Pemphigus vulgaris	Desmosomes	IFT
Hashimoto's thyroiditis	Thyroglobulin microsomes	IFT
Thyrotoxicosis by LATS	Cell surface receptor proteins	CFT
		Bioassay
II. <i>Affecting two or more organ systems</i>		
Goodpasture's syndrome	Glomerular and lung basement membranes	IFT
Autoimmune hemolytic anemia	Membrane proteins of RBC	Coombs' test
Immune thrombocytopenia	Platelet components	Demonstration of antibody
Myasthenia gravis	Acetylcholine receptors in nerve endings	IFT
Primary biliary cirrhosis	Liver and kidney mitochondria	IFT
Rheumatic fever	Streptococcal antigen cross reacting with heart and joint tissues	IFT
III. <i>Systemic or generalized diseases</i>		
Rheumatoid arthritis	Immunoglobulins, especially IgG	Latex agglutination
Sjögren's disease	Ducts, mitochondria of glands	IFT
Systemic lupus erythematosus	Nuclear DNA and nucleoproteins	IFT
Systemic sclerosis (scleroderma)	Nuclear proteins	IFT

IFT = Immunofluorescence test; CFT = Complement fixation test.

hemagglutination, reverse passive hemagglutination, complement fixation and immunofluorescence to the more advanced tests such as immunoelectrophoresis, enzyme-linked immunosorbent assay (ELISA), immunoblotting, e.g., Western blot, and the use of specific monoclonal antibodies.

Enzyme-Linked Immunosorbent Assay (ELISA) Test

This is one of the most frequently performed immunological tests in most of the laboratories in India to detect antigens and antibodies. The test is useful even when they are present only in minute quantities. Specific pre-prepared antibody or antigen is employed to fix the corresponding antigen or antibody, respectively, present in the patient's serum. The antigen-antibody complex is detected by appropriate colour developing techniques. Though the original test was a complicated one, at present test kits are available for most of these estimations. Therefore ELISA tests are available even in laboratories which do not undertake high level work, e.g.

detection of antibody—hepatitis B and C, HIV

detection of antigens—alphafetoprotein, carcino-embryonic antigen.

Serum Sickness

Syn: Systemic immune complex disease

This is produced as a result of circulating immune complexes. The biological and inflammatory potential of circulating immune complexes depend on the nature of the antibodies and antigens as well as the molar ratio of the two reactants. The magnitude and duration of antigen exposure is also important. The manifestations are transient if the exposure to the antigen is short, but if supply of the antigen is continued, immune complexes are continuously formed and serum sickness like reaction follows. Main lesions are in the glomeruli, choroid plexus, synovium, skin and uveal tract, which are the sites of inflammation due to deposition of immune complexes.

Apart from the introduction of external protein antigens and viral infections, drugs like penicillin and other drugs are more often responsible for this condition in man.

The antibodies are initially of IgG type and a Type III reaction occurs. Later IgE antibodies are formed and a Type I reaction may also occur.

Clinical features: About 7-14 days after the injection of serum or exposure to the offending drug, the disease starts

with fever, arthralgia, peri-arthritis, urticarial or morbilliform rashes and lymphadenopathy. Myocarditis may occur rarely. Glomerulonephritis is rare in humans. Peripheral neuropathy is a late sequel. The condition generally is self-limiting.

Treatment: Withdrawal of the offending agent gives relief in mild cases. Prednisolone in a dose of 1 mg/kg body weight may be required in severe cases. Prednisone or other corticosteroids are indicated if there is myocarditis and peripheral neuropathy.

Serum sickness may be partially prevented by giving large doses of cyproheptadine (0.7 mg/kg per day) or hydroxyzine (5 mg/kg/day) along with the serum.

Immunodeficiency States

Immunodeficiency may be congenital or acquired. In many of these cases, the defect may differ and the susceptibility to get infection also varies.

Severe forms of immunodeficiency states are so incompatible with life that they are rarely seen in clinical practice. The disorders are classified as:

1. Combined immunodeficiency states,
2. Deficiency of humoral immunity,
3. Deficiency of cellular immunity,
4. Deficiency of phagocytes,
5. Deficiency of complement system, and
6. Secondary immunodeficiency states.

1. Combined immunodeficiency: There is deficiency of both cellular and humoral immunity. This is produced as a result of block of maturation of the stem cells which give rise to immunocytes. Severely affected children are incapable of limiting bacterial, viral and fungal infections and they die in childhood.

Several subtypes have been described, e.g., sex-linked recessive types (thymic type) and autosomal recessive (Swiss) types. Relatively benign types are the Wiskott-Aldrich syndrome (sex-linked) and ataxia telangiectasia (autosomal recessive). In both, lymphoreticular malignancies are more common. *Adenosine deaminase* (purine catabolizing enzyme) deficiency, an autosomal recessive disorder leads to severe combined immunodeficiency. Gene transfer therapy has been tried recently with promising results in a few of such cases. Adenosine deaminase gene from normal lymphocytes was introduced by gene splicing and recombinant technology into the defective lymphocytes. The cells are grown in culture and reintroduced into the patient.

2. Humoral immunodeficiency: This may be a selective primary deficiency affecting only one of the G, M or A classes of immunoglobulins. In IgG deficiency the affected persons suffer from repeated pyogenic

infections, especially by encapsulated organisms such as *H. influenzae* and *Strep. pyogenes*.

In IgA deficiency, respiratory and atopic allergies are also common. IgA deficiency also lowers the resistance to gut commensals leading to malabsorption syndrome.

Congenital hypogammaglobulinemia may be sex linked (Bruton type) or autosomal dominant. In these cases, severe depletion of B-cells and circulating immunoglobulins are noticed with consequent severe bacterial infections. Incidence of autoimmune diseases such as hemolytic anemia are high in primary agammaglobulinemia. Immunodeficiency may occur in presence of normal quantity, but functionally deficient immunoglobulins, e.g., *Job's syndrome*.

3. Cellular immunodeficiency: Primary deficiency of T-cells leads to severe viral and monilial infections and affected children usually succumb within the first few years of life. The lymphocytes of the patients are unable to respond to mitogens *in vitro*. The thymus may be almost absent (*Nezelof's syndrome*), or aplastic (*Di George syndrome*) or in some cases it may be normal, e.g., chronic mucocutaneous candidiasis.

4. Defect of phagocytosis: *Chronic granulomatous disease* is a sex-linked inherited condition where hydrogen peroxidase is deficient inside the phagocytes, leading to decreased microbicidal activity. Recurrent suppurative granulomas due to catalase positive and peroxidase negative organisms (*Staph. aureus* and *Proteus*) are common in this condition. In myeloperoxidase deficiency, infections by peroxidase positive bacteria such as hemophilus are common. In *Chédiak-Higashi syndrome*, the neutrophils show defective degranulation and sluggish motility with consequent predisposition to pyogenic infections.

5. Deficiencies in complement system: *Hereditary angioneurotic edema* is inherited as an autosomal dominant disease. It is characterized by absence of the enzyme which normally inhibits the activity of C₁ esterase. This results in unrestrained C₁ esterase activity which activates the complement cascade reactions leading to liberation of kinins and vasoactive peptides. Recurrent attacks of edema of skin and mucosa are very common and edema of glottis may sometimes be life-threatening.

Deficiency of C₃ is inherited as an autosomal recessive character. Deficiencies of other complement components, though reported, are very rare. Generally, the clinical conditions mimic immunoglobulin deficiency states.

6. Secondary immunodeficiency: The transplacental transfer of immunoglobulins takes place mostly in the last few weeks of pregnancy. Premature infants, therefore, may suffer from mild hypoglobulinemia. Secondary defects in lymphocyte functions are seen in many conditions such

TABLE 3.7

Immunocompromised hosts

Predisposing cause	Effect on immune system	Types of infections
Immunosuppression by drugs Viral infections; measles, EB virus, HIV	Humoral and cellular immunity diminished Impaired T-helper activity	Infections of lung, urinary tract, bacteremias, fungal infections Secondary bacterial infections, opportunistic infections
Tumours of immune system e.g., lymphomas, myeloma, leukemias	Replacement of immune competent cells	Bacteremia, pneumonia, urinary tract infections
Malnutrition	Lymphoid hypoplasia, decreased lymphocyte and phagocyte activity	Measles, TB, respiratory infections, GI infection
Breakdown of tissue barriers, burns, wounds, injury, foreign body, etc.	Local effect	Local and systemic infections

as burns, malnutrition, leukemias, lymphomas and uremia. In multiple myeloma, though total immunoglobulins are increased, the biologically active ones are depressed, leading to functional deficiency. Acquired immunodeficiency may be due to primary causes such as infections (especially HIV), drugs or malignancies. These are listed in Table 3.7.

Treatment of immunodeficiency states as a whole is unsatisfactory. Immunoglobulin injection (0.25 g/kg/week) may abort recurrent pyogenic infections in hypogammaglobulinemia. Treatment of cell-mediated immune deficiency states is still more difficult.

Immunocompetent cells can be restored by bone marrow transplantation.

Immunization

Immunity in the human body against disease can be induced by several methods.

1. **Active induced immunity:** This is induced by immunization with toxoid, or killed or attenuated organisms. Table 3.10 for immunization schedule.
2. **Active natural immunity:** This is the immunity produced by exposure to clinical or subclinical infections.
3. **Passive induced immunity** Temporary protection against the infecting organism can be conferred on the susceptible host by giving preformed antibodies obtained by immunizing heterologous or homologous hosts. Such passive immunization is recommended for the post-exposure prophylaxis in the following conditions:

Along with the induction of passive immunity to tide over the incubation period, active immunization using vaccine should also be started simultaneously for conferring lasting immunity.

Passive immunization by preformed antibodies

Hepatitis A	Human hyperimmune serum 0.2 ml/kg IM
Hepatitis B	Hepatitis B immunoglobulin (HBIG) 0.5 ml IM
Varicella	Varicella zoster immunoglobulin (VZIG) 125-625 units IM
Tetanus	Tetanus immunoglobulin human 500-3000 units IM
Rabies	Rabies immunoglobulin-human (HRIG) 20 IU/kg. 50% IM and the rest infiltrated around the wound
Measles	Human immunoglobulin 0.25 ml/kg IM

Therapeutic use of preformed antibodies

Infective conditions	Non-infective conditions
Tetanus	Myasthenia gravis
Botulism	Guillain-Barré syndrome
Diphtheria	Immune thrombocytopenia
Anthrax	Some cases of aplastic anemia
The dose of IgG given is moderate	The dose of IgG in these conditions is very large.

4. **Passive natural immunity** Transfer of immunoglobulins (especially IgG) to fetus takes place *in utero*. These antibodies remain in the circulation of the child for 3-6 months of postnatal life.

Immunization for Indian subjects is given in Table 3.10.

HLA System in Humans

Several diseases are known to have intimate association with disease susceptibility shown by distinctive HLA types (Tables 3.8 and 3.9). HLA system stands for human leukocyte antigen system which is the human version of the major histocompatibility complex (MHC).

TABLE 3.8

Association of HLA system with diseases—global data					
Diseases	Associated HLA type	Relative risk	Diseases	Associated HLA type	Relative risk
Ankylosing spondylitis	B-27	81	Multiple sclerosis	DW2	5
Reiter's syndrome	B-27	48	Psoriasis	B-13	4.3
Coeliac disease	B-8	9.5	Pemphigus	A-10	4.3
Rheumatoid arthritis	DW4	8	Sjögren's syndrome	B-8	3.2
Addison's disease	B-8	6.4	Graves' disease	B-8	2.5
Chronic active hepatitis	B-8	6	Hodgkin's disease	B-18	2
Myasthenia gravis	B-8	5	Diabetes mellitus (insulin dependent)	B-8	1-9

Note: Relative risk is the chance of developing the disease compared to controls who do not possess the particular HLA types.

TABLE 3.9

HLA association with diseases commonly seen in India	
Ankylosing spondylitis	HLA B-27
Reiter's disease	HLA B-27
Acute anterior uveitis	HLA B-27
Rheumatoid arthritis	HLA DR4
Juvenile RA	HLA DR5, DR8
Insulin dependent diabetes	HLA B-8, B-21, DR3
Graves' disease	HLA DR2, DQ2
Rheumatic heart disease	HLA DR3
Myasthenia gravis	HLA B-21, B-8
Tuberculoid leprosy	HLA DR2, DR6
Lepromatous leprosy	HLA DQW1
Pulmonary tuberculosis	HLA DR2, DR6

HLA system plays a role in very different situations such as:

1. Transplant rejection,
2. Chronic inflammatory diseases such as rheumatoid arthritis and ankylosing spondylitis,
3. Coma in cerebral malaria,
4. Immunodeficiency states, and
5. Advanced hepatic cirrhosis with iron overload.

HLA complex is mainly represented on chromosomes 6 and it contains over 200 genes. More than 40 of them encode leukocyte antigens. The HLA genes that are involved in the immune response fall into classes—I and II which are structurally and functionally different. The class I genes code for the alpha polypeptides of the class I molecule. The beta chain of class I molecule is encoded by a gene on chromosome 15—the beta 2 microglobulin gene. There are about 20 class I genes in the HLA region. Three of them—HLA-A, B and C are the main actors in the immune response. These are called the classic or class I genes.

The class I genes code for both the alpha and beta polypeptide chains of the class II molecules.

Their position on chromosomes 6 is identified by the three letters given below:

D—this indicates the class

M,O,P,Q or R—this represents the family

A or B—the chain that is affected.

The three main class II molecules are HLA, DP, DQ and DR. The individual genes of the HLA system are represented by Arabic numerals.

Class I genes are expressed by most somatic cells. In contrast class II genes are expressed selectively on a subgroup on cells concerned with immunity such as B cells, activated T cells, macrophages, dendritic cells and epithelial cells of the thymus.

The A, B and C loci can be identified by serologic tests. The D locus which controls lymphocyte antigens is detectable by mixed lymphocyte culture. The products of HLA genes are proteins which are found on all tissues including leukocytes and platelets but not on erythrocytes. HLA molecules are dimers of two different polypeptide chains, designated as alpha and beta. The variable amino acid sequences in these chains produce distinct three dimensional structures which will allow the identification of foreign cells. HLA typing of A, B and C loci is done by *complement mediated cytotoxic test* utilizing a panel of reference antisera. The D locus is typed by the mitogenic effect using a panel of lymphocytes. Inheritance of certain alleles confer susceptibility to particular diseases when exposed to suitable environment. Table 3.8 gives the association of HLA system with some of them.

The HLA antigens play a central role in cell-to-cell interaction in the immune process. The MHC molecule interacts with antigens and presents them to T-cell receptors for recognition and further action.

The HLA antigens play a great role in identifying self from non-self and in giving rise to rejection, when HLA incompatible tissues are transplanted into an individual. Histocompatibility is defined as the similarity between tissues of two different individuals. Organ transplantation

TABLE 3.10

Immunization schedule for Indian conditions

Vaccine	Description
A. OBLIGATORY	
1. DPT	1st dose - 6-12 weeks 2nd dose - 17-21 weeks 3rd dose - 36-38 weeks Tetanus toxoid IM or SC Diphtheria toxoid Pertussis-killed organisms
BOOSTER DT	1st dose - 18-24 months 2nd dose - 5-6 years Purified components of B. pertussis (acellular vaccine) is available either singly or in combination as DTaP. The DTaP is safer in children who have febrile convulsions.
2. POLIO	
a. ORAL POLIO VACCINE (OPV-Sabin)	1st dose - 3rd month Thereafter 3-4 doses at 2-6 wk. intervals. Fifth dose later Live attenuated human diploid cell vaccine oral
BOOSTER	Booster doses in the 2nd and 5 years
b. INACTIVATED POLIO VACCINE (IPV Salk)	1st dose 3-4 months The next two at 4-6 weeks interval Killed organisms SC This is rarely used in selected situations
BOOSTER	4th dose 6-12 months later At 4-6 years
3. MEASLES (Solid immunity occurs when vaccine is given after the 1st birthday. If the vaccination is done earlier, booster dose is necessary)	12-15 months Live attenuated SC
B. ADVISABLE	
BCG	During neonatal period or any time during childhood. Live attenuated Intradermal
MUMPS RUBELLA	Along with measles vaccine. Booster not required if given after first birthday. Live attenuated SC
Rota virus (Note: Combined MMR vaccines are available)	2, 3, 4 months Live attenuated Oral
C. VACCINATION NECESSARY UNDER SPECIAL CIRCUMSTANCES	
HEPATITIS-B VACCINE VACCINE (rDNA)	Pre-exposure prophylaxis: Special health care professionals, hemodialysis patients, hemophiliacs Travellers going to endemic areas, homosexual individuals, contacts of HBV carriers. Dose: 1 mL IM over deltoid 3 doses—2nd dose one month and 3rd dose six months after the 1st dose
	Post-exposure prophylaxis: -infants of HBV carrier women, contacts of HBV hepatitis, -victims of needle stick injuries from HBsAg positive patients or recipients of blood products. Give Hepatitis B Vaccine and Hepatitis B immunoglobulin at birth
RABIES VACCINE HUMAN OR OTHERS DIPLOID CELL VACCINES (Killed vaccine)	Pre-exposure prophylaxis: lab workers, veterinarians, etc. 1 mL IM over deltoid on days 0,7,28. Booster depending on serology
	Post-exposure prophylaxis: (a) those previously immunized 2 doses 1 mL over deltoid (IM) on days 0 and 3. Rabies immunoglobulin (RIG) should not be administered.

Contd...

Contd...		
Vaccine		Description
	(b) those not immunised	1 mL over deltoid (IM) on days 0,3,7,14 and 28. RIG 20 IU/Kg body wt half infiltrated at bite site and rest IM if the risk is severe
JAPANESE ENCEPHALITIS (Killed vaccine)	To be given to communities exposed to risk of encephalitis	0.5-1 mL SC. Two doses at 7-14 days interval, and booster within 12 months Revaccination at 3 yearly intervals
VACCINATIONS DESIRABLE UNDER SPECIAL CIRCUMSTANCES		
(For detail see appropriate sections)		
ENTERIC FEVER	:	Phenol and heat killed. 2 doses 0.5 mL SC. 4 weeks apart, or live oral vaccine, 4 oral doses, boosters every 4 years.
CHOLERA	:	0.5 mL IM or SC. Phenol killed vibrio vaccine, 2 doses 1 week to 1 month apart, at least 10 days before travel.
YELLOW FEVER	:	Immunized before going to endemic areas of Africa and South America.
TETANUS	:	In immunized persons, 2 doses of 0.5 mL toxoid, boosters every 10 years.
INFLUENZA	:	<i>H. Influenzae</i> type B polysaccharide conjugated to diphtheria toxin, primary 1 dose 0.5 mL.
MENINGITIS	:	Meningococcal polysaccharide vaccine, tetravalent, primary 0.5 mL SC given before going to endemic area.
PNEUMOCOCCUS	:	Polyvalent vaccine
VARICELLA	:	Live attenuated.
H. INFLUENZAE	:	a b c d e f strains.
HEPATITIS A	:	rDNA vaccine
JAP ENCEPHALITIS	:	During epidemics.

can be successfully carried out only if the donor and recipient are at least partially, if not completely matched. Since identical twins have identical HLA loci, they are the most suitable for tissue transplantation. Next in order of compatibility are parents and siblings, near blood relatives and others. Since exact HLA matching is not available in the vast majority of cases, one has to satisfy with as close a match as possible.

The difference in HLA constitution between a donor and recipient results in immunological reactions against the graft (*host vs graft disease—HVG*D) or the graft against the host (*graft vs host disease—GVH*D). This can be suppressed to a great deal by continuous use of immunosuppressants like corticosteroids, cyclophosphamide, cyclosporine and antilymphocytic serum.

Modulation of Cellular Behaviour

Chaperones in cells: The term chaperon denotes a person who modulates behaviours properly. All cells in the human body maintain a complete set of functionally competent

proteins, even in the presence of stress and injury, by the action of various mechanisms, including systems of proteins called molecular chaperons. The function of a chaperon is to assist a nascent polypeptide chain to attain functional information as a new protein and to assist its arrival at the site of its action in the cell. Chaperones also assist damaged protein molecules to regain their functional conformation. In the absence of chaperon function protein molecules become denatured, insoluble and functionless. They precipitate and appear as inclusion bodies within cells. e.g. Parkinson’s disease, Huntington’s disease, Alzheimer’s and others. Stresses which damage a cell include physical agents like heat, oxygen free radicals, changes in pH, osmotic changes, nutritional disorders, drugs, mechanical injury, infections and inflammation. Diseases such as Alzheimer’s dementia, inclusion body myositis, cataracts, von Hippel-Lindaus’ disease and others are considered to be due to dysfunction of molecular chaperones. Chaperonopathies may impair immunological function. It is likely that genetic disease may cause abnormalities of chaperones.

4

Principles of Drug Administration

1

Aswini Kumar, K.V. Krishna Das

Chapter Summary

Drug Metabolism	29
Pharmacogenetics	31
General Principles of Drug Administration	31
Drug Related Adverse Effects	32
Prescription of Drugs	34

Drugs are generally employed as replacement therapy, as agonists, or as antagonists. Drugs are used as replacement for conditions in which there is deficiency of a natural substance-endogenous, e.g., hormones, or exogenous, e.g., nutrients.

Agonist drugs produce a pharmacological effect, e.g., hypotensives, analgesics.

Antagonist drugs prevent the action of natural substances like anticholinergics or counteract the action of other drugs, e.g., nalorphine.

Drugs produce their effect by interacting with specific receptor sites on the cell membrane. At the receptor sites the action may be positive (e.g., agonists) or opposite to those of agonists (e.g., antagonists). Initially there is physical interaction between the drug and the receptor and this drug receptor complex *produces the therapeutic response*.

Routes of drug administration This may be oral, sublingual, topical or parenteral. Parenteral routes are subcutaneous, intramuscular, intravenous, intra-arterial, intrathecal, intraventricular (cerebral ventricles), intra-articular, intracavitary (into viscera like pleura or peritoneum or abscess cavities), and intra-amniotic.

Drug Metabolism**Absorption of Drugs**

The amount of drug that reaches the systemic circulation intact and is available to the target tissues for effective function is called the “*bioavailability*” of a drug. The rate of absorption, and the metabolic processes which tend to

eliminate or inactivate the drug determine the bioavailability of the ingested drugs. Absorption from the gastrointestinal tract depends upon lipid solubility, degree of ionization, and molecular weight of the drug. Low molecular weight substances and alcohol are absorbed passively, while other drugs are absorbed by active processes requiring energy, e.g., alpha methyl dopa. Lipid-soluble drugs are absorbed easily. Since drugs have to be in solution to facilitate absorption, formulations which disintegrate rapidly, are more easily absorbed. Due to the variability of physical properties, bioavailability of the same drug may vary when administered in different formulations and therefore it is important to avoid frequent changes in formulations from time-to-time. Other factors influencing gastrointestinal absorption are the availability of surface area for absorption, motility of the gut, pH within the gut, local blood flow, and presence of other substances in the gut lumen.

Drug interactions in the gut may alter absorbability. For example, antacids reduce the absorption of iron by changing the pH and anticholinergics reduce the absorption of other drugs due to delay in gastric emptying. Absorption of drugs may be altered by the presence of food in the stomach. In many instances the absorption is delayed, whereas it is facilitated in the case of others. It is important to know this aspect in order to optimise the timing of drug administration. For several drugs, administration with water on an empty stomach ensures maximum absorption. In malabsorption states drug absorption is erratic. In congestive heart failure venous stasis occurring in the intestines impairs absorption. Drug absorption is unpredictable in the elderly.

Drugs which are better absorbed from the buccal mucosa are preferably given sublingually. Some drugs like nitroglycerine and isoprenaline are destroyed by the gastric acid and hence sublingual administration is ideal. Usually, the clinical effect is evident within minutes. Another advantage of sublingual administration is that drug toxicity can be avoided by removing the drug from the mouth or swallowing it as soon as the desired effect is achieved.

Topical routes include the skin and the mucous membranes of the nose, rectum and lungs. Preparations for topical application include inunctions (e.g., nitroglycerine), suppositories into the rectum (e.g., pitressin) and aerosols which are inhaled. Rate of absorption of topically applied drugs depends on the concentration, lipid solubility and local blood flow. Absorption is lower from keratinized epithelium. The size of the particle is important when drugs are applied as aerosols. Only particles below 2 nm in size reach the alveoli. Absorption from the respiratory epithelium is rapid and the effect is immediate. The portion deposited in the oropharynx is later swallowed and absorbed to produce mild and delayed effect. Considerable attention to details is necessary for ensuring proper administration of the aerosol.

Parenteral administration is resorted to when more rapid action is desired and when patient's cooperation cannot be relied upon. Local vascularity influences absorption from sites of intramuscular or subcutaneous injections. Aqueous formulations are absorbed rapidly whereas oily preparations are absorbed only slowly. Local warmth and massage favour absorption.

Intramuscular injections are usually given into the deltoid, rectus abdominis or gluteal muscles. Certain drugs like diazepam and phenytoin may be erratically absorbed, so that oral administration may be more reliable than intramuscular doses.

The subcutaneous route is to be preferred when the volume of drug is small and the drug is non-irritant. The rate of absorption is slightly lower than the intramuscular route. When the peripheral circulation is insufficient, as is seen in shock, subcutaneous and intramuscular routes are unreliable. Intravenous route should be resorted to when the drug action has to be immediate, or large volumes of drugs have to be given. Since the onset of action is immediate, the pharmacological effect can be adjusted by controlling the rate of intravenous infusion. At present several devices such as programmable infusion pumps which can deliver the required quantity over prolonged periods are available, and these are employed in critical care departments and intensive care areas. For management of conditions like diabetes where insulin has to be administered round the clock at varying rates, implantable devices are available. Certain drugs like digoxin take several minutes to exert their full effect even after intravenous administration. Even highly irritant drugs like nitrogen mustards can be given into a rapidly flowing drip since the drug is diluted and the venous walls are relatively resistant. Local damage to vein can be avoided by releasing the drug into more central portions of the circulation, e.g., inferior vena cava. Intra-arterial infusions are indicated when a large dose of drug has to be given in a high concentration to a particular organ.

At present the pharmaceutical industry is bringing newer forms of drug presentation and delivery systems

in order to reduce the toxic effects, acceptability, absorbability and timed release in the body. Encapsulation within a lipid vesicle (liposome) or attachment to a polymer greatly increases safety profile and permits the use of higher dosage. Newer degradable materials which act as vehicles for drugs, intelligent drug delivery systems and newer routes of drug administration are all being actively pursued.

Drugs are transported with the aid of transport proteins and they exert their effects through specific receptors. Genetic factors modify the absorption, transport, receptor mechanisms, distribution, therapeutic effects, toxicity and the elimination of drugs. At the blood-brain barrier, P-glycoprotein in the choroid plexus limits the accumulation of several drugs in the brain.

Drug distribution In the circulation, the drugs are reversibly bound to plasma proteins. Entry into the tissues depends upon the blood flow and the ability of the drug to enter the tissues. Easy entry into the tissues depends upon lipid solubility, and the concentration gradient across the cell membranes. Major proportion of any drug is distributed to the tissues where it has no pharmacological action. In conditions like 'shock' when tissue perfusion is poor, the drug remains in the plasma in high concentrations without entering the tissues and this leads to toxicity. Specialized tissues take up drugs selectively. Most tissues of the central nervous system restrict the entry of polar (ionized) compounds. Lipid soluble substances enter easily down a concentration gradient, while sugars and amino acids are actively transported. This blood-brain barrier breaks down when there is meningeal inflammation. At conditions of equilibrium the drug is distributed among the plasma water, plasma proteins and tissues. Since lipid soluble drugs enter cells more readily, their concentration in the plasma is lower compared to water soluble drugs. By hemodialysis water-soluble compounds can be removed from circulation, but this is not effective for lipid-soluble drugs. Magnitude of response of any drug depends on the level of free drug available at the receptor site. The level of free drug in the plasma depends upon two factors: plasma protein binding and ease of distribution to other tissues.

Plasma protein binding Plasma proteins, especially albumin forms reversible complexes with drugs in circulation. The degree of absorption depends upon the plasma pH and affinity of the drug to the protein. When many drugs compete for absorption, the high affinity drug displaces the ones with weak affinity. Acidic drugs will be displaced from protein complex when acidosis develops.

Liver Since most of the absorbed drugs pass through the liver, they are either bound, metabolized or excreted in the bile. Hepatic metabolism of drugs occurs in two stages; stage I reactions include oxidation, reduction, and hydrolysis; and stage II reactions involve conjugation of

the original compound or its metabolites by acetylation, sulphation, O-methylation, and glycine-conjugation. These products are water-soluble and hence are excreted.

The metabolism of drugs in the body is governed by enzymes belonging to the class cytochrome P-450 (CYPs) cyp1, cyp2 and cyp3) which play important roles in the biosynthesis and degradation of endogenous compounds such as steroids, lipids and vitamins. There are more than 30 families of drug metabolizing enzymes in humans. All have several genetic variants which determine the functions of the proteins encoded. They metabolize drugs and several chemicals found in foods and environment. They also participate in their elimination. In humans more than 57 cytochrome P-450 enzymes have been identified, each with substrate specificity. Liver is the major site of cytochrome P-450 metabolism, next in importance is the enterocytes lining the small intestine. Enzyme Cy p3 A7 is an important enzyme present at both these sites. It is involved in the metabolism of more than 50% of the drugs administered.

Lungs Basic compounds are selectively taken up and sequestered from the general circulation.

Transplacental transfer The placenta behaves like a selective barrier. Lipid soluble drugs of molecular weight lower than 1000 diffuse freely from the maternal to fetal circulation, while water soluble drugs diffuse only slowly. Since the drug elimination systems of the fetus are immature, serious toxicity will ensue. The mechanism to remove the drug from the fetal circulation is diffusion back to the maternal side. Direct approach to the fetus by surgical techniques is feasible in a few hospitals.

Elimination of drugs: Drugs are eliminated from the body by (1) metabolism in the liver and kidney, and (2) excretion as the parent drug as such or its metabolites by the kidneys predominantly, but also by the gut, skin, lungs, sweat glands, breasts, and salivary glands. Urinary excretion depends upon the processes of: (1) glomerular filtration, (2) active tubular secretion and reabsorption, and (3) passive diffusion.

Pharmacogenetics

The influence of genetic factors in drug effects was recognized as early as the 1950s. Enzyme defects may give rise to arrested metabolism of drugs, thereby leading to unexpected drug effects.

For example, Cytochrome P 450 2D6 (CYP2D6) influences the metabolism of codeine, dextromethorphan, metoprolol and nor-typtaline.

Deficiency of the enzyme N-acetyl transferase leads to slow acetylation of INH, hydralazine and procainamide. At present genetic tools are available for identifying such genetic alterations.

Pharmacogenomics is the study of genes encoding the drug metabolizing enzymes and genome-based approaches to drug-behaviour in different persons.

Molecular diagnostic methods to determine the genotypes of individuals are becoming more freely available. At present it is possible to get genotype analysis from single blood samples and about 5000 genes and 20000 single nucleotide polymorphisms can be studied in a single assay. It can help more individualised selection of drugs with better efficiency and safety.

General Principles of Drug Administration

The effective and safe dose of any drug should be determined by considering the body mass or surface area. Though general instructions regarding dose are available, each dose should be tailored to the individual patient, based on his weight, status of vital organs like kidneys and liver, the severity of the infection and the immune status of the host. Though a long course of therapy is ideal for effecting cure, yet chances for toxicity limits the total dose.

Seriously ill patients should be treated by injection since this ensures predictable serum levels. Intravenous injection is more effective in giving peak serum levels and is less painful than intramuscular or other routes. This is the route of choice when large volumes of drugs have to be given and that too continuously. Though polyethylene cannulas are handy and convenient for use, steel needles are better to avoid infection. Ideally, the needles have to be re-sited at least every 48 hours to avoid venous thrombosis and infections.

Parenteral preparations are more likely to produce anaphylactic reactions than oral preparations. Topical application of drugs for general antibacterial action except to the eye and ear should be discouraged, since they produce local reactions and also give rise to emergence of resistant strains. Intrathecal injection of antibiotics is potentially hazardous and is often unnecessary except in the case of resistant meningitis, unresponsive to systemic therapy.

Chemoprophylaxis: Use of antibiotics for chemoprophylaxis is controversial. Bacteria resistant to the antibiotics may be selected out to multiply, and the possible toxicity of drugs may also occur. Chemoprophylaxis does not guarantee prevention of infection. The aim of chemoprophylaxis is to prevent a known organism from reaching a target tissue and if it reaches, to abort infection. Chemoprophylaxis is employed in special situations such as prevention of active tuberculosis in special groups, prophylaxis against *Pneumocystis carinii* in AIDS patients, accidental needle stick injuries in laboratory workers, newborns of HIV positive mothers and other similar circumstances. If an antibiotic is

intended to give coverage during a surgical procedure, it should be given intramuscularly 30 minutes before operation, or intravenously during the surgery and for a short period thereafter.

Severe infections Life-threatening infections such as septicemia, pneumonia, peritonitis, meningitis, etc. have to be treated even before microbiological results are available, especially so, if the patient is neutropenic. Helpful investigations include microbial identification, determination of antibiotic sensitivity and serum levels of the drug.

DRUG ADMINISTRATION IN SPECIAL GROUPS

1. Children The action of drugs differs quantitatively and qualitatively in children compared to that in adults. Before embarking on therapy it is absolutely essential to take into consideration the following points:

- Is the drug absolutely essential?
- Is it safe for the age group?
- Which preparation is best, most palatable and convenient for administration?
- Which is the best drug with least side effects?

The absorption, distribution, breakdown and elimination of drugs depends upon the maturity and relative size of body tissues. Other than age and size, genetic constitution, maturity of the kidneys, enzyme development in the liver, protein binding of the drug, organ sensitivity, distribution of the drug in the body and development of the central nervous system affect drug response and toxicity in infants and children. Changes in body composition, development of blood-brain barrier with increasing age, and metabolic disturbances such as acidosis affect the distribution of drugs. The rate of drug elimination is greatly diminished in neonates, especially premature infants. Topically applied drugs are significantly more absorbed in infants and children, particularly in prematures. Drugs excreted in breast milk during the early postnatal period may influence the baby. Proper education of the parent and child is important to ensure drug compliance.

2. Drug administration during pregnancy: The fact that the drugs may harm the mother, fetus or both should be borne in mind. The main dangers to the growing fetus include:

- Destruction of the embryo and abortion, e.g., quinine, cytotoxic drugs.
- Congenital defects and disorders of organ development are particularly common with drugs like thalidomide, radioactive drugs, anticonvulsants and anticancer drugs. Almost all drugs including large doses of some vitamins are associated with embryotoxicity in varying degrees at specific periods of gestation.

3. Incorporation into the tissues of the fetus, e.g., tetracycline into the teeth.

4. Pharmacological effects on the fetus by drugs which cross the placenta, e.g., antithyroid drugs may cause thyroid dysfunction in the newborn. Hormone administered to the mother may affect the fetus.

Apart from the damage caused to the embryo, the mother is more susceptible to the toxic effects of several drugs during pregnancy, e.g., tetracyclines are more likely to produce hepatic damage during pregnancy.

In general it is a golden rule to withhold medication to a pregnant woman unless absolutely indicated.

3. Drug administration in the elderly: Old subjects are likely to have multiple pathological lesions and hence they are susceptible to the cumulative adverse effects of several drugs which are concurrently administered. Elderly persons behave erratically to drugs. Since their weight is low, the ordinary doses may prove to be toxic. Absorption from the alimentary tract may not be predictable. Moreover, impairment of functions of the liver and kidney lead to their accumulation in the body. In addition, the organ systems may also show increased sensitivity, e.g., aged persons are more prone to develop cardiotoxicity of digitalis and ototoxicity of the aminoglycosides. Adverse effects of drugs constitute a major cause for morbidity in old persons and, therefore, great care is required for prescribing drugs to them. Aged women with history of allergic diathesis are particularly susceptible to develop drug toxicity. An early sign of drug toxicity is mental confusion and disorderly behaviour which should not be ignored.

Drug compliance is generally poor in the older age groups due to their physical disability, mental confusion and economic dependence. Particular care, therefore, is to be taken to ensure that drug schedules are followed.

Hospitalization should be avoided as far as possible since older persons cannot adapt to the hospital environment. As a consequence they develop confusion and disorientation. Moreover, hospitalization and immobilization lead to complications like respiratory infection, urinary retention, fecal and urinary incontinence, falls, venous thrombosis, embolism, and strokes. Confinement to bed should be kept to the minimum and the patient should be ambulated as early as possible.

Drug Related Adverse Effects

Adverse drug reactions are extremely common in present day medical practice. There are two types of adverse drug reactions, A and B. Type A is the result of an augmented or exaggerated pharmacological action of a drug given in the therapeutic doses (Table 4.1). These are primarily dependent upon the intrinsic biodynamic properties of the

TABLE 4.1

Types of adverse drug reactions

	Type A	Type B
Drug response	Augmented	Bizarre
Pharmacologically predictable	Yes	Bizarre
Dose-dependent	Yes	No
Dependence on host	Often independent	Usually dependent
Incidence	High	Low
Morbidity	High	Low
Mortality	Low	High
Treatment	Dose adjustment	Stop and antidotes

drug, often host-independent, dose-dependent and usually reproducible in animals. They are sometimes called predictable reactions which include overdosage, side effects, drug-caused disease and drug interactions.

e.g., Beta-adrenergic blockers produce bradycardia.
Ephedrine causes tachycardia and insomnia.

Type B reactions are totally bizarre unpredictable or aberrant effects that are not to be expected from the known pharmacological effects of a drug when given in usual therapeutic doses and with no alteration in pharmacokinetic processes. They are “idiosyncratic”, host-dependent, often apparently dose-independent and difficult to reproduce in animals.

Type A reactions: The factors involved in Type A reactions are divided into pharmaceutical, pharmacokinetic or pharmacodynamic causes.

Pharmaceutical causes	factors that affect drug dose and release from the formulation.
Pharmacokinetic causes	factors which alter absorption, distribution, metabolism and elimination.
Pharmacodynamic causes	factors which depend on dose-response relationship, drug receptor status, homeostatic mechanisms and disease state of the individual.

Type B reactions : Type B reactions, which are characterized by the existence of some qualitative difference either in the drug or in the patient or possibly in both, are classified as intolerance, idiosyncrasy and allergy. The causes of Type B reactions could be pharmaceutical, pharmacokinetic or may lie in a target organ response.

Table 4.1 shows the salient differentiating features between the two types of adverse drug reactions.

Rational therapeutics is defined as the use of the least number of drugs to obtain the best possible effect in the

shortest time, and at a reasonable cost. In general about 25% of hospitalized patients suffer from DRAs which may prove fatal. Risk of adverse events increases at the rate of 6% for every additional day of hospitalization. It is likely that about 5 million persons may suffer from serious ADRs. Aggressive drug therapy, particularly poly-pharmacy (concurrent use of several different classes of drugs) increases the risk, 50% of these are preventable if the physician and his staff are careful to avoid DRAs and to take early remedial steps.

Medical errors include the following:

Adverse event (AE): A definable injury caused at least in part by medical management, the injury must have prolonged the hospital stay or caused disability at the time of discharge.

Adverse drug event (ADE): AE related to the administration of drugs.

Negligent adverse event: An injury caused by failure on the part of the doctor to meet standards expected of an average doctor in his settings.

Drug related problem (DRP): An event or circumstance that involves patient’s drug treatment that actually or potentially interferes with achievement of an optimal outcome.

The spectrum of ADEs include following types:

1. Wrong choice of drug,
2. Wrong dose, frequency and route of administration,
3. Drug-drug interaction,
4. Inadequate instruction to nursing staff,
5. Allergic reactions.

Failure to use a life-saving drug when indicated does also amount to negligence on the part of the doctor.

While prescribing antimicrobial agents the full duration of therapy should be insisted upon even though symptomatic relief is achieved early. In India the most common causes of medical errors arise from inadequate information for the doctor (29%), wrong diagnosis (18%), wrong administration, and failure to recognize ADEs early.

The need to monitor ADRs and to prevent them has been realized by the medical fraternity in India. The common defects in prescription detected by limited surveys included:

1. No mention of the dose of the drug	-60%
2. Absence of information on the route and method of administration	-99%
3. Administration of antibiotic for inadequate duration	-60%
4. Information of the dose was given only partly	-11%

Some of the State Governments in India including the Govt. of Kerala supply drug formularies to their doctors which provide factual data on drugs.

Suggestions to Reduce the Frequency of ADEs

- 1. Use of check lists, protocols and computerized aids for writing prescriptions.
- 2. Improved access to information using computerized programmes.
- 3. Error proofing using customised computer software so that overdose, suboptimal drug doses, improper duration and allergic reactions can be avoided.
- 4. Training of doctors, nurses and other staff on safe prescribing practice.
- 5. Informing the public on adverse drug reaction and their remedy.

It is a golden rule to use a limited number of drugs, about which the doctor has full information as far as possible. The Government of India has accepted an essential drug list containing 279 drugs which are adequate to manage most of the common ailments.

The adage “*there are no biologically safe drugs; there are only safe physicians*” holds good even now; and it will continue to be so forever.

Prescription of Drugs

- 1. Medicines should be prescribed only when absolutely indicated. Once prescribed, the dose, route of administration, relationship with food and duration of therapy should be clearly specified. The total quantity of each drug to be dispensed should be separately specified.
- 2. As far as possible generic names should be specified. Proprietary names should be used only when it is unavoidable.
- 3. Avoid decimal points as far as possible, e.g. 3 mg instead of 0.03 g or 3.0 mg.
- 4. Quantities below 1 mg should be given as micrograms (mcg or µg) or smaller units, e.g. instead of 0.1 mg write as 100 mcg.
- 5. When decimals are unavoidable, use the format as 0.5 mL and not as 5 mL.

- 6. The prescription should be authenticated by legible signature of the prescriber, and his address.

The legal responsibility of a prescription rests on the prescriber.

The *drugs and cosmetics* ACT of 1945 has included drugs into different schedules.

- 1. Drugs in schedule G should be administered only under the supervision of a Registered Medical Practitioner (RMP).
- 2. Drugs in schedule H should be dispensed only on the prescription of RMP.
- 3. Drugs included in schedule X include psychotropic drugs and all prescriptions should be made in duplicate and authenticated by the full signature, address and registration number of the practitioners.

Patient education which is a very important responsibility of the prescribing doctor should include information on the following aspects.

- drug
- time
- dose
- intervals
- duration of treatment
- and cost

The patient should be instructed to report adverse reactions promptly after stopping the drug. On no account should the doctor shy away from the responsibility of having prescribed the drug. He should view the situation with empathy and confidence. Almost all the adverse drug reactions (ADRs) are remediable if detected early. Prompt handling of the situation will increase the confidence of the patient. Irresponsible behaviour on the part of the prescriber often leads to legal complications.

The availability of a vast number of antimicrobial drugs with specific actions, the problems in diagnosis and management created by the changing nature of the microbial flora, development of resistance by organisms and the emergence immunosuppressed hosts have necessitated the creation of the subspeciality of Infectious Diseases.

Chapter Summary

Antibacterial Agents 35
 Antiviral Drugs 43
 Antifungal Drugs 47
 Drug Resistance of Microbes 48
 The Compromised Host 49
 Fever in Immunocompromised Host 50
 Rational Use of Antibiotics 50

Introduction

The initial specific antibacterial drugs, sulphonamides were introduced in the early part of the 20th century. Discovery of penicillin and its introduction into therapeutics in the first half of the 20th century leading to dramatic cure of infections, acted as a stimulus for intense research to discover further antimicrobial drugs. As a result many types of antibiotics were introduced in succession.

Table 5.1 gives the site of action of the commonly used classes of antibacterial drugs.

Antibacterial Agents**Penicillins**

Penicillin discovered by Alexander Fleming in 1928 was the first effective antibiotic to be produced commercially, marketed widely and accepted with great zeal all over the world on account of its efficacy, safety and affordable cost. Introduction of penicillin ushered in the “antibiotic” era in the therapy of infective diseases.

The basic nucleus is 6 amino penicillanic acid which contains a thiazolidine ring linked to beta lactam ring. Further derivatives of penicillin contain the beta lactam ring and all such members are included under the term beta lactam antibiotics. Many bacteria develop resistance by producing beta lactamase. Penicillin and its derivatives block the synthesis of the bacterial cell wall peptidoglycan. Penicillin and its derivatives hold their pride of place among the most powerful antibiotics against susceptible bacteria. They are the drugs of choice in the appropriate

TABLE 5.1

Principal types of antibacterial drugs with their main site of action

Drug	Site of action	Mechanisms
Penicillin	Cell wall	Inhibits cell wall synthesis
Cephalosporins	Cell wall	"
Other beta lactams	Cell wall	"
Glycopeptides		"
e.g., Vancomycin	Cell wall	"
Tetracyclines	Ribosomes	Inhibit protein synthesis
Chloramphenicol	Ribosomes	"
Aminoglycosides	Ribosomes	"
Macrolides	Ribosome	"
Lincosamides		"
e.g., clindamycin		"
lincomycin	Ribosomes	"
Fusidic acid	Ribosomes	"
Rifamycin		"
e.g., rifampicin	RNA synthesis	Inhibit DNA or RNA synthesis as the case may be
Sulphonamides	Folate metabolism	"
Diimidopyrimidines		"
e.g., Trimethoprim, pyrimethamine	Folate metabolism	"
Quinolones	DNA synthesis	"
Nitrofurans	DNA synthesis	"
e.g., nitrofurantoin, nifurtimox		"
Nitroimidazoles	DNA synthesis	"
e.g., metronidazole, tinidazole		"

situations on account of their proven bactericidal activity, wide availability, safety profile and relatively lower cost.

Susceptible organisms: *Strep. pyogenes*, *pneumococci*, *susceptible gonococci* and *meningococci*, *spirochetes* such as *T. pallidum*, *T. pertenuis* and *leptospira*, *anaerobes* such as *Cl. tetani*, *Cl. botulinum*, *Cl. perfringens*, *peptococci*, *peptostreptococci*, *bacteroides*, *B. anthracis* and *Staphylococci* which are sensitive, respond well to penicillin. *Strep. viridans*, the organism causing infective endocarditis is susceptible in many cases.

Safety: Penicillins are generally safe. Most important adverse side effects are allergy and Jarisch-Herxheimer reaction. Anaphylactic shock and cardiac arrest may occur in unexpected situations. So any history of allergy to penicillin, however mild it is, is an absolute contraindication to even testing for drug sensitivity. In the absence of any history of allergy, allergy can be tested by a scratch test on the forearm using a weak solution (1000 units/mL) of penicillin.

Antacids reduce the absorption of orally administered penicillin. Penicillins are mainly eliminated in the urine. Probenecid reduces the urinary excretion when given in a dose of 250-500 mg bd orally along with penicillins. It helps to keep the blood levels of penicillin higher for longer periods.

Resistance to penicillins: Several microbes such as staphylococci, gonococci, meningococci, pneumococci and others have developed resistance in a big way and this has posed major problems in the management of life-threatening infections.

Mechanisms of Resistance

1. *Production of beta lactamases:* e.g. staphylococci, gonococci. This can be overcome by the concurrent use of beta lactamase inhibitors such as clavulanic acid, sulbactam or tazobactam.
2. *Reduction in the permeability of the outer membrane,* e.g. gram-negative bacteria.
3. *Alteration in the binding sites for betalactams,* e.g. methicillin resistant staphylococci.

Dosage of benzyl penicillin congeners

	dose
Benzyl penicillin-penicillin G	4-6 lac units 6 h
Phenoxymethyl penicillin-penicillin V	4-6 lac units 6 h oral tablets
Procaine penicillin	6-12 lac units once or twice a day IM injection
Benzathine penicillin	12-24 lac units IM (1.2-2.4 mega units once in 3 weeks)

Beta lactamase resistant penicillins: These are less potent than benzyl penicillin, but they are effective against penicillinase producing staphylococci and other mixed infections.

Cloxacillin

It is available as capsules of 250 and 500 mg and as injections of 0.5 and 1.0 g.

Dose: Oral-500 mg-1 g 6 h; later maintenance dose of 250-500 mg 6 h, given one hour before or 2 hours after food.

Parenteral: IV or IM injections 250-500 mg 6 h.

Cloxacillin is available as combination preparations along with ampicillin or amoxycillin.

Other members of this group are methicillin and nafcillin which are not freely available in India.

Broad Spectrum Penicillins

The antimicrobial activity covers gram-negative organisms such as *H. influenzae*, *E. coli* and *Proteus* in addition to the spectrum of penicillin. These are also inactivated by beta lactamase.

Ampicillin

Preparations available include capsules of 250 and 500 mg; injections containing 250 mg to 1 g and pediatric syrup and drops.

Dose: 250-500 mg 6 h.

Parenteral: 0.5 to 2 g IM or IV 6 h, depending upon the severity of the infection.

Cross sensitivity with penicillin may occur, but allergic reactions are generally milder. In patients with infectious mononucleosis, ampicillin worsens the clinical condition. Administration of probenecid helps to maintain blood levels higher for longer periods.

Amoxycillin

This drug resembles ampicillin in actions and antimicrobial spectrum. When given orally the blood levels are twice as high as that of ampicillin.

Preparations available: Capsules 125, 250 and 500 mg and injections containing 250 and 500 mg.

Dose: 250-500 mg oral or IM or IV 8 h.

Other members of this group include bacampicillin, pivampicillin and talampicillin. These are not freely available in India.

Extended spectrum penicillins: The additional spectrum includes pseudomonas, enterobacteriaceae and proteus. Carbenicillin, ticarcillin, azlocillin, piperacillin and mezlocillin come under this group. Piperacillin and mezlocillin are active against *Klebsiella* also.

Carbenicillin

Preparations available include injections of 1g and 5 g.

Dose: 2-6 g 6h IM or slow IV infusion.

Mixed infections including *Pseudomonas* and *Proteus* especially in immunocompromised hosts are special indications for carbenicillin.

Special risk: Due to the high sodium content it may precipitate cardiac failure in susceptible subjects.

OTHER BETA LACTAM ANTIBIOTICS

Imipenam (Carbapenam)

This is a very powerful bactericidal antibiotic with a very broad spectrum including gram-positive and gram-negative aerobic and anaerobic organisms. It is enzymically inactivated in the kidney and therefore concurrent administration of cilastin which inhibits the enzyme helps to potentiate the antibacterial activity.

Dose: 500-700 mg 8 h IM or IV up to 2 g/day in divided doses.

Meropenam: 500 mg IV or IM 3-4 times a day.

Aztreonam

This is a monocyclic beta lactam antibiotic. It is active against gram-negative aerobic bacteria including *Pseudomonas aeruginosa*.

Cephalosporins

These are among the most popular and widespread antibiotics at present. They contain 7-aminocephalosporanic acid nucleus, which bears structural resemblance to 6-amino penicillanic acid and the beta lactam ring. They are listed arbitrarily as first, second, third and fourth generation mainly on the basis of their antimicrobial activity and also on the period of their introduction as well as structure.

The first generation members resemble penicillin in antibacterial activity. Successive inclusion in the second, third and fourth generations depends upon their wider antimicrobial coverage and effectiveness on resistant strains.

The list is very long and several newer drugs are being added from time to time. The important and easily available members are listed here (Table 5.2).

First Generation

They resist beta lactamase. They do not penetrate into CSF. This group includes:

Cephalexin	oral	250-500 mg	6 h	Tab or cap 150, 250, 500 mg
Cephadroxyl	oral	1-2 g	12 h	Tab or cap 125, 250, 500 mg
Cephadrine	IV or oral	1-2 g	4-6 h	vials 1, 2 g
Cephazolin	IV or IM	0.5-2 g	8 h	vials 125, 250, 500 mg
Cephalothin	IV	1-2 g	4-6 h	vials 1 g, 2 g
Cephaloridine	IV	0.5 g	6 h	vials 0.5, 1 g

TABLE 5.2	
List of cephalosporins and their route of administration	
Oral	Parenteral
First generation	
Cephalexin	Cephazolin
Cephadroxyl	Cephalothin
Cephadrine	Cepharin
	Cephaloridine
Second generation	
Cefaclor	Cefuroxime
Cefuroxime axetil	Cofoxitime
	Cefhamandole
	Cefotetan
Third generation	
Cefixime	Ceftizoxime
	Cefoperazone
	Ceftazidime
	Cefotaxime
	Caltriaxone
	Cefsulodin
Fourth generation	
	Cefipime

Second Generation

They have expanded spectrum of activity against gram-negative bacilli, especially ampicillin resistant *H. influenzae*. Penetration into CSF is poor. Activity against gram-positive cocci is less than that of the first generation.

Cefaclor	oral	150-500 mg	8 h	275 or 350 mg tablets
Cefuroxime axetil	oral	250 mg	12 h	125, 250, 500 mg tablets
Cefuroxime	IM or IV	750 mg- to 1.5 g	8 h	250, 750 or 1500 mg vial
Cefoxitime	IM or IV	1-2 g	4-8 h	1 g, 2 g vial
Cephamandole	IM or IV	1-2 g	4-6 h	1 g, 2 g vial
Cefotetan	IM or IV	1-3 g	12 h	1, 2 and 10 g vial

Third Generation

These are effective against most of the gram-negative beta-lactamase producing bacteria, especially enterobacteriaceae and pseudomonas for gram-positive cocci is less compared to the first generation. Except cefoperozone, penetration into CSF is good.

Cefixime	200-400 mg	oral	12-24 h	Tablet of 200 and 400 mg
Ceftizoxime	1-2 g	IM or IV	8-12 h	0.5 and 1 g vial

Cefoperazone	1-2 g	IM or IV	8-12 h	0.5 and 2 g vial
Ceftazidime	1-2 g	IM or IV	8-12 h	0.5 and 1 g vial
Cefotaxime	1-2 g	IM or IV	8 h	0.5 and 1 g vial
Ceftriaxone	1-2 g	IM or IV	12-24 h	0.5 and 1 g vial
Cefsulodine	0.5-1 g	IM or IV	6 h	0.5 and 1 g vial

Fourth Generation

This includes drugs which have got extended spectrum of activity compared to the third generation drugs. They are also more resistant to the action of beta-lactamase. Their special use is in the treatment of aerobic gram-negative bacilli resistant to the other drugs.

Cefepime	2 g	IV	12 h
Cefepirome	1-2 g	IV	12 h

Aminoglycosides

These are bactericidal antibiotics. They derive their name on account of the presence of aminosugars in glycoside linkage in their structures. They have to be given parenterally, since they are not absorbed from the gut. Their distribution is mainly in the extracellular fluid, higher concentrations in renal cortex and endolymph and perilymph of the internal ear. These organs are more liable to suffer from toxic effects, especially in the elderly. At both extremes of age and in the presence of renal insufficiency the dose has to be modified to avoid toxicity. Diffusion into CSF and ocular structures is poor. Bacteria develop resistance rapidly, especially if administered singly. Administration along with other antibacterial agents reduces the chances for development of resistance. When combined with betalactam antibiotics such as penicillins or cephalosporins the action is synergistic. The important members in this group are streptomycin, gentamicin, amikacin, kanamycin, tobramycin, netilmycin, neomycin, framycetin and paromomycin (Table 5.3).

Antibacterial Spectrum

Streptomycin: Gram-negative bacteria, *Str. viridans*, *Y. postis*, *F. tularensis*, *brucella*, *M. tuberculosis*. Until two decades ago this was among the first line drugs for the treatment of tuberculosis. With the availability of rifampicin, streptomycin has been moved down to be a second line drug.

Gentamicin: Gram-negative bacteria esp *E. coli* and *proteus*, *Ps. aeruginosa*, *Klebsiella*, *acinobacter*, *mycoplasma*, Group A *Streptococcus* and *Staphylococcus* are susceptible. It is very effective in mixed infections such as peritonitis, empyema, urinary tract infection and others.

TABLE 5.3

Therapeutic details of aminoglycoside

Drug	Dose	Route	Preparation
Streptomycin	15-25 mg/kg/day	IM single dose	1 g or 0.75 g vials
Gentamicin	2-5 mg/kg/day	IM or IV divided doses 8 h	80 mg or 60 mg vials
Amikacin	15 mg/kg/day	IM or IV 8 h	50 mg to 500 mg vials
Kanamycin	15 mg/kg/day	IM 8 h	500 mg to 1 g vials
Tobramycin	3 mg/kg/day	IM 8 h	40 mg and 80 mg vials
Netilmycin	5 mg/kg bw	IV/IM 8 h	vials of 10-200 mg/mL

It is one of the very reliable and powerful bactericidal antibiotics to be used in combination in serious life-threatening infections, even before the microbiological results are available. Preparation for topical use are available, e.g. eyedrops. In view of the risk of development of resistance it is advisable to minimise their use.

Amikacin: *Serratia*, *proteus*, *pseudomonas*, *Klebsiella*, *enterobacteriaceae*, *E. coli* nonsocomial *Gram negative infections* and *atypical mycobacteria* are susceptible. This is one of the very powerful antibiotics available for use in life-threatening conditions.

Kanamycin: Gram-positive and gram-negative organisms causing urinary tract infections, septicemia, meningitis, bacterial endocarditis and pelvic infections respond to the drug. It is an “add-on” drug with other broad spectrum antibiotics.

Tobramycin: It is more active against *pseudomonas*. It is usually given along with ampicillin or ceftazidime.

Netilmycin- This drug is effective in serious infections of the respiratory tract and other locations such as intra-abdominal infections. It is also used as a prophylaxis for bacteremias in a dose 5 mg /kg bw 8 h. It is available as IV injection vials in strengths ranging from 10 mg-200 mg/mL.

TETRACYCLINES

These are in existence for over six decades. They are bacteriostatic. They act by inhibiting protein synthesis in the microbe. Though they are not considered as the first line of drugs for the common bacterial infections, they retain their pride of place for several infections such as *rickettsiae*, *mycoplasma chlamydia* and others. They are active against a wide range of microorganism.

Antimicrobial Spectrum

They are the drugs of choice for *rickettsiae*, *mycoplasma*, *ureaplasma*, and *chlamydia*.

They are effective against gram-positive cocci, gram-negative bacteria, *H. influenzae*, *Klebsiella*, *E.coli*, *brucella*, *Y. pestis*, *F. tularensis*, *B. recurrentis*, *C. jejuni* and *H. pylori*. Their adverse side effects include diarrhea, drug rashes, photosensitisation and hepatic and renal damage in susceptible individuals. Tetracycline orthophosphate gets deposited in the developing teeth of fetuses and young children and also in bones. The teeth may become permanently discoloured yellow. In patients on marginal nutritional status, destruction of the colonic bacterial flora may give rise to overt deficiency of the B. complex vitamins. It has therefore been a practice to prescribe B. complex vitamins along with tetracyclines. Tetracyclines can be given orally on an outpatient basis. Absorption is better if given on an empty stomach. Parenterally they can be given IM or IV. The popular preparations in this group are tetracycline, oxytetracycline, and colortetracycline which are short acting (6 hours) and doxycycline and minocycline which are long acting (up to 24 hours).

Dose	Oral	Parenteral	Preparations
Tetracycline	250-500 mg 6h	250-500 mg IM or IV 8-12 h	Tablets and capsules 250 mg and 500 mg injections 100-500 mg vials

Chlortetracycline and oxytetracycline resemble tetracycline in dose, efficacy and toxicity.

Doxycycline: 200 mg oral on first day followed by 100 mg once or twice a day for 5-10 days. Capsules and tablets of 100 mg are available.

Minocycline Dose: 100 mg bd.

MACROLIDES

These antibiotics derive their name due to the presence of many numbered lactone ring in the nucleus. They are very popular and safe drugs which can be given orally. Side effects include gastrointestinal upsets, allergy, hepatic damage and Stevens Johnson syndrome. Antimicrobial spectrum includes *Gram positive cocci*, *Gram negative bacilli*, *C. diphtheria*, *campylobacter*, *Legionella*, *leptospira*, *borrelia*, *nocardia*, *mycoplasma* and *Chlamydia (trachoma)*. Macrolides interact with several drugs and therefore great care has to be taken when prescribing them along with other drugs. The important members in this group are erythromycin, roxithromycin, azithromycin, clarithromycin, oleandomycin and spiramycin (Table 5.4).

Ketolides- e.g. Telithromycin. These are drugs with spectrum of action similar to macrolides. They inhibit

TABLE 5.4 Dosage of macrolides			
	Dose	Route	Preparation
Erythromycin	250-500 mg 6 h	oral	Tablets and capsules of 100 and 500 mg
Roxithromycin	150 mg bd or 300 mg od	oral	150 and 300 mg tab, capsules
Azithromycin	250-500 mg od	oral on empty stomach	100 and 250 mg tablets, capsules
Clarithromycin	250-500 mg bd or tds	oral	250 and 500 mg tablets
Spiramycin	3 miU bd	oral	tablets 3 miU
Note: Clarithromycin is useful for the prophylaxis and treatment of atypical mycobacteria, eradication of <i>H. pylori</i> and as an add-on drug for treating resistant malaria.			

protein synthesis in the microbe. Though the antibacterial spectrum resembles that of other macrolides, it is more potent than erythromycin. It is active against multi-drug resistant *Pneumococcus*, *H. influenzae*, *M. catarrhalis*, *N. gonorrhea*, and *N. meningitides*. It is not active against enterobacteracea, acinitobacter and *Ps. aeruginosia*.

Dose 800 mg oral od for 7-10 days for community acquired pneumococcus. The course is for 5 days for other respiratory pathogens. Adverse effects include gastrointestinal upsets, elevation of liver enzymes and prolongation of QT interval in the ECG. Mitochondrial damage has been reported.

Chloramphenicol

It is a bacteriostatic drug active against gram-positive and Gram-negative organisms, rickettsiae, chlamydia and *mycoplasma*. Since it diffuses into CSF it is an excellent drug for the treatment of meningitis especially due to meningococci, pneumococci and *H. influenzae*. It held its pride of place as the antibiotic of choice for treatment of enteric fevers till three decades ago. Development of resistance by salmonella against chloramphenicol and other drugs has been rapid and widespread and therefore at present it is used as a second line drug for the treatment of enteric fevers only under special circumstances. Major toxic effects include allergy, peripheral neuropathy, optic neuritis, dose related reversible anemia, fatal bone marrow depression, and permanent aplastic anemia (in 1/30000). When chloramphenicol is given to newborn infants whose hepatic and renal functions are still immature a toxic state may develop in which the baby becomes listless, pale and grey in colour. This is called 'grey baby syndrome'. Continuation of the drug may lead to death due to circulatory failure.

Dose of chloramphenicol	Tablets or capsules
250-500 mg oral 6 h	125 to 500 mg
Parenteral IV or IM same as oral dose vials	500 mg and 1 g

Due to the possibility of fatal bone marrow depression, chloramphenicol should be used with caution.

SULPHONAMIDES

These were the first group of antibacterial drugs introduced for the therapy of infections. The commonly used sulphadugs, in vogue from time to time include sulphadiazine, sulphaguanidine, sulfamethoxazole, sulphasoxazole, sulphadoxin, sulphacetamide, silver sulphadiazine and salicyclazosulpha pyridine (salazopyrin). Sulphonamides are bacteriostatic. Sulphamethoxazole in combination with trimethoprim (co-trimoxazole), salazopyrin, sulphadoxin and silver sulphadiazine are currently in wide use. The other members in this group have been largely replaced by newer drugs, on account of the greater efficacy and safety of the latter.

Co-trimoxazole

This is a combination of 1 part of trimethoprim with 5 parts of sulphamethoxazole 80 mg and 400 mg respectively. The action is bactericidal. The antimicrobial spectrum includes *gram-positive cocci*, *proteus*, *brucella*, *yersinia*, *E. coli*, *klebsiella*, *H.influenzae*, *shigella*, *salmonella*, *pneumocystis carinii* and others. Adverse side effects include allergy, leukopenia, megaloblastic anemia and bone marrow suppression.

Dose: 160 mg trimethoprim with 800 mg sulphamethoxazole twice a day orally for the usual infections.

For the treatment of *Pneumocystis carinii* pneumonia and its prevention in immunocompromised hosts larger doses have to be employed. Intravenous preparation is available. This may be combined with carbenicillin for the management of infections in neutropenic patients.

Trimethoprim

This has antibacterial property on its own. It is active against *E. coli*, *proteus*, *klebsiella*, *enterobacter* and *staphylococci*.

Dose: 100 mg oral bd or 200 mg od.

Toxic effects include rashes, gastrointestinal upsets and bone marrow suppression.

Sulphadoxine

This has a serum half-life of six days. It is used as an antimalarial against resistant *P. falciparum* infections. The

compound Fansidar tablets containing sulfadoxin 0.5 g and pyrimethamine 25 mg are given in a dose of 3 tablets orally as a single dose.

Salazopyrin

This is used as an antiinflammatory and immunomodulatory drug in ulcerative colitis, rheumatoid disease and reactive arthritis. It is not used as an antimicrobial drug.

Silver sulphadiazine: Is used as 1% drops or cream for topical use, especially in burns to prevent bacterial colonization.

OTHER ANTIBIOTICS

Vancomycin

It is a glycopeptide antibiotic used for the treatment of multidrug resistant *Staph. aureus* (MRSA) and pseudomembraneous colitis caused by *Cl. defficile*. It is bactericidal. It can be given orally or parenterally.

Dose: Oral—125-500 mg 6 h (7 mg/kg bw) for pseudomembraneous colitis.

Parenteral: Intravenous infusion of 500 mg to 1.0 g over one hour at intervals. It is available as 50 mg tablets and vials of 0.5 and 1 g.

Teicoplanin

It is a related antibiotic similar to vancomycin in action, but with a longer duration of activity. This drug is active against potentially serious gram + infections including *Staph aureus*, especially MRSA. The drug is available as Targacid (Aventis) as vials containing 200 and 400 mg. The dose is 400 mg IM or IV single dose on the first day followed by 200 mg daily. In severe infections the dose is 400 mg IM/IV 12 hourly for the first 3 days followed by 400 mg daily.

Lincomycin

It is a lincosamide antibiotic active against organisms which are penicillin resistant. Its use is limited to acute and chronic osteomyelitis, respiratory infections, septic arthritis and endocarditis.

Dose: Oral—500 mg 6-8 h or 600 mg IV or IM 12 h.

Preparations available: Capsules of 500 mg and injections of 600 mg in 2 mL.

Clindamycin

It is a derivative of lincomycin useful in infections caused by mixed bacterial flora, malaria and toxoplasmosis. It can be given orally or parenterally.

Dose: Oral—150-300 mg 6 h.

Parenteral: 600 mg to 2.7 g as IV infusion or IM over 24 hours in divided doses. This drug is available as 150 mg capsules and vials containing 150 mg/mL.

Oxazolidinones: e.g. Linezolid. These are newer synthetic antibacterial antibiotics which inhibit protein synthesis in the microbes. Linezolid is 100% bioavailable on oral administration. The antibacterial spectrum is wide against gram positive bacteria. It is especially useful against MRSA, and vancomycin resistant *Enterococcus faecium*.

Dose: oral- 600 mg 12 h or IV 600 mg 12 h for 10-14 days. When giving IV, linezolid should not be mixed with other drugs. Adverse side effects include pain at the site injection, elevation of liver enzymes, renal impairment and thrombocytopenia.

Daptomycin is a cyclic lipopeptide antibiotic that is rapidly bactericidal for most of the gram positive bacteria including *S. aureus*.

Dose: 6 mg/kg bw given IV once a day. It has been tried to treat MRSA bacteremia with encouraging results.

Fusidic Acid

Sodium Fusidate (Fucidin) is obtained from the parasite fungus *Fusicidium coccinimum*. It has a steroid structure and it is active against gram+ organisms. All strains of staphylococci are sensitive. Streptococci and pneumococci are relatively resistant.

Dose: 500-1000 mg oral 8 h. Milk reduces the absorption of this drug. The available parenteral preparation is diethanolamine fusidate 580 mg IV 8 h. Sodium fusidate is also a general purpose local antiseptic, available as ointment. Fucidin shows bactericidal synergism with penicillin and erythromycin.

Spectinomycin

This is effective in gonococcal urethritis.

Dose: IM or IV 2-4 g single dose or 2 g bd for 3-5 days.

Quinespristin-Dalfopristin

This group of drugs which belongs to the class streptogramins is active against gram+ organisms, vancomycin resistant MRSA, resistant enterococci and atypical organisms.

Dose: Quinpristin/dalfopristin mixture (30/70%) is given IV 8 h at 7.5 mg/kg bw.

Nitrofurantoin

This is a synthetic nitrofuran with activity against gram-negative bacteria of the urinary tract. It is used for the

prophylaxis and long-term treatment of urinary tract infections.

Dose: Oral—for prophylactic use 50-100 mg at hs.

For therapy of established infection 200-400 mg/day is divided doses.

The drug has to be used with caution in the presence of renal impairment.

QUINOLONES

The fluoroquinolones are synthetic bactericidal agents related to the parent drug nalidixic acid. The popular drugs in this group are norfloxacin, ciprofloxacin, pefloxacin, ofloxacin, lomefloxacin and sparfloxacin. The parent drug nalidixic acid is still in use. The antimicrobial spectrum is wide including gram-negative cocci and bacilli such as *enterobacteriaceae*, *H. influenzae*, *shigella*, *campylobacter*, *neisseria*, *gonococcus*, *pseudomonas* and others.

Ciprofloxacin one of the most potent among the quinolones is bactericidal for salmonellae and at present this is the drug of choice for enteric fevers. It is also used to eradicate the carrier state for *meningococci* and *S. typhi*. It is particularly active against *pseudomonas*.

Ofloxacin has action against multidrug resistant staphylococci, chlamydia and legionella.

Lomefloxacin has action similar to ciprofloxacin.

Sparfloxacin has action against anaerobic organisms. Lomefloxacin and sparfloxacin are long acting and therefore once a day dosage is adequate. Some of quinolones are available for local application such as eyedrops. Quinolones are generally contraindicated during pregnancy and lactations.

Levofloxacin: This is available as tablets of 250 and 500 mg to be given orally once or twice a day for up to 14 days. It is also available as an IV infusion containing 5 mg/mL, 100 mL vials, to be given as a slow infusion over 60 minutes, once or twice a day for up to 14 days. Side effects include QT prolongation in ECG, cardiac arrhythmias, hepatic impairment, tendon inflammation, and polyneuropathy. The drug is contraindicated in children and pregnant and lactating women.

Gatifloxacin and **moxifloxacin** are newer fluoroquinolones are powerful antibacterial drugs. They act by inhibiting the enzyme DNA gyrase (topoisomerase: II and IV) which are required for DNA replication, transcription, repair and recombination. Both are active against a wide spectrum of gram + and gram- bacteria, *Chlamydia pneumoniae*, *Mycoplasma pneumoniae* and penicillin resistant pneumococcus. They are less effective than ciprofloxacin against *Pseudomonas aeruginosa*.

Adverse effects include dizziness, nervousness, precipitation of seizures, erosion of cartilage in weight

TABLE 5.5

Dosage of quinolones

<i>Norfloxacin</i>	400 mg bd	oral	Tablets 100 to 800 mg
<i>Ciprofloxacin</i>	250-750 mg bd 200-400 mg bd	oral IV infusion	Tablets 100-750 mg
<i>Pefloxacin</i>	400 mg bd 400 mg	oral IV infusion 1 hour	Tablets 400 mg IV infusion 4 mg/mL 100 mL
<i>Ofloxacin</i>	200-400 mg/bd 200-mg infusion	oral IV in 30 minutes	Tab 100 and 200 mg infusion 2 mg/mL 100 mL
<i>Lomefloxacin</i>	400 mg o.d	oral	Tab 400 mg
<i>Sparfloxacin</i>	400 mg first day Then 200 mg/day	oral	Tab 200 and 400 mg
<i>Levofloxacin</i>	250-500 mg	oral IV infusion	Tab 250 and 500 mg 500 mg vials
<i>Gatifloxacin</i>			
<i>Moxifloxacin</i>	400 mg od	oral	400 mg tablets
<i>Nalidixic acid</i>	1 g qid	oral	Tab 250 mg to 1 g

bearing joints in young subjects and prolongation of QT interval in the ECG. Gatifloxacin may produce hypoglycemia and at times, hyperglycemia with symptoms requiring urgent attention.

Dose: 400 mg daily po for 5-10 days. The drug has to be given with caution in diabetes (Table 5.5).

The Imidazole Derivatives

Two drugs, **metronidazole** and **tinidazole**, originally developed as antiamebic drugs have potent antibacterial properties and therefore they are used widely for that purpose as well.

Metronidazole: This drug has anti-protozoal activity against amebae, giardia and trichomonas. It has wide antibacterial activity against the anaerobic organisms bacteroids, clostridium, fusobacterium, peptococcus, peptostreptococcus and eubacteriaceae. In combination with clarithromycin and a proton pump inhibitor it is bactericidal to *Helicobacter pylori*. Metronidazole is available as tablets of 200 and 400 mg, suspensions containing 200 mg/ 5 mL and vials of 100 mL containing 500 mg of the drug for IV use.

Dose: Amebiasis 400-800 mg tds po × 5-10 days.

For trichomoniasis, giardiasis and others 400 mg tds × 5 days.

For anaerobic infections, loading dose of 15 mg/kg bw IV infusion over 30-60 minutes followed by maintenance dose of 7.5 mg/kg bw 6 h for 7-10 days.

Metronidazole can be used as a primary drug for *Clostridium difficile* in dose of 400 mg tds oral for 5-7 days.

Tinidazole is available as tablets containing 500 mg and 1 g. It is effective against protozoa such as ameba, giardia and trichomonas.

Dose: Amebic dysentery-2 g/day/po in single or divided doses for 3-5 days.

Amebic liver abscess – 2 g/day in divided doses for 5 days or more.

Giardiasis and trichomoniasis – 2 g/day for 1 day as single or divided doses.

Anaerobic infections-treatment and prophylaxis -2 g initially, followed by 500 mg bd po for 5-7 days.

For preoperative sterilization - 2 g single dose po 12 hours prior to surgery.

Ulcerative gingivitis and bacterial vaginosis 2 g po single dose.

Rifampicin

This is a bactericidal antibiotic with a wide antibacterial spectrum. It is very effective against *M. tuberculosis* and *M. leprae* and therefore almost exclusively used for treating them.

Dose: 10 mg/kg bw orally daily as a single dose.

Capsules of 150-600 mg and tablet of 450 and 600 mg are available.

Absorption is best when given an empty stomach. Any food or drink should be given only an hour later. Resistance develops very rapidly if given alone. All forms of tuberculosis respond. The course of treatment should continue uninterrupted for six months or more.

For the treatment of leprosy supervised monthly doses of 450-600 mg are given depending upon the clinical status.

Other indications include infections by staphylococcus, legionella and gram-negative bacilli. It is effective as a prophylactic agent against *H. influenzae* and meningococcal meningitis in contacts.

Rifabutin

It is an antimycobacterial antibiotic, used for the prophylaxis and treatment of *M. avium complex*.

Dose: 150 mg/day oral for 6 months. In AIDS patients the dose is 300 mg/day to be given indefinitely. For multidrug resistant tuberculosis, rifabutin is effective in a dose of 300-450 mg day.

Rifapentine: This is a rifamycin derivative with excellent activity against *M. tuberculosis*. Compared to rifampicin its half-life is longer (10-15 hours vs 2-3 hours). Therefore it can be given at longer intervals. Regimens such as rifapentin 600 mg once a week with INH 900 mg weekly have been tried in non-cavitating pulmonary tuberculosis in HIV negative persons, with success.

POLYENE ANTIBIOTICS

These are all polypeptide antibiotics. These include bacitracin, polymyxin B, and colistin. They are less widely used for systemic diseases due to their non-availability, higher toxicity and higher cost.

Bacitracin

The antimicrobial spectrum includes *Gram-positive organisms meningococcus, gonococcus, treponemes* and *H.influenzae*. For systemic use it has to be given IM or IV.

Dose: 1000 units/kg/day in divided doses.

For local use it is available as eye ointment of 500 units/g, and powder in combination with polymyxin-B and neomycin.

Polymyxin-B

This is active against gram-negative organisms, especially *Ps. aeruginosa*. It is used systemically as well as for topical use in the eye and skin. It is available as injections (500,000 units vials), eyedrops (5000 u/mL) and ointment (5000 u/g).

Dose: IM injection 15-20000 units/kg bw/day in divided doses.

Colistin

The antimicrobial spectrum resembles that of polymyxin B, but the action is weaker. It is available for oral use as syrup containing 2.5 mg/mL (i.e.) 50,000 units/mL.

Dose: 3-5 mg/kg/day in divided doses.

Table 5.6 for choice of antibiotics.

Antiviral Drugs

Antiviral drugs are available at present for specific treatment and prophylaxis of many viral infections although several others have to be managed only symptomatically. From time-to-time antiretroviral drugs for the prophylaxis and treatment of acquired immunodeficiency syndrome (AIDS) are being introduced. Some of them have activity against other viruses as well. Availability of specific antiviral drugs has necessitated virological diagnosis of infections, in order to get best results (Tables 5.8 to 5.10). Antiviral drugs may be broadly classified based on their clinical effectiveness.

1. **Drugs for herpes group viruses:** acyclovir, valacyclovir, gancyclovir, famciclovir, pancyclovir, foscarnet, vidarabin and idoxuridine.
2. **For influenza A virus and other respiratory viruses:** amantadine, rimantadine, ribavirin, zanamivir, ostelamivir.
3. **Anti-retroviral drugs:** At present several drugs are available for the treatment of Human Immunodeficiency virus (HIV). Mainly they belong to four classes, based on their pharmacological effects. These include:
 - A. *Nucleoside Reverse Transcriptase Inhibitors (NRTI) and Nucleotide Reverse Transcriptase Inhibitors- NtRTI*
 - B. *Non-Nucleotide Reverse Transcriptase Inhibitors (NNRTI)*
 - C. *Protease Inhibitors- PI and*
 - D. *Entry inhibitors (EI)*
4. **Nonselective Human alpha interferons.** antiviral agents (Table 5.7)

Acyclovir (Acycloguanosin): This is a potent drug which inhibits the multiplication of herpes simplex types 1 and 2, varicella zoster and EB virus. Acyclovir is given intravenously in a dose of 5 mg/kg as an infusion running over 1 hour and repeated every 8 h for 5 days. Side effects include allergy, renal impairment, local necrosis of tissues, and hepatic dysfunction. The dose should be reduced in patients with impaired renal function. This is one among the most effective and widely used antiviral drugs. It inhibits replication of herpes viruses. Infected cells concentrate the drug 40-100 times higher than uninfected cells. It is the most active agent in HSV₁, HSV₂ and varicella zoster virus. Preparations for topical use are also available for herpes simplex and herpes zoster lesions.

TABLE 5.6

Choice of antibiotics for common infections

Disease	Proven value (conventional antibiotics)	Cephalosporins group
Respiratory tract infections		
Pharyngitis	Benzylpenicillin	Cephadrine
Otitis media	Amoxycillin	Cefaclor
Necrotising otitis	Ticarcillin	Cefsulodin, ceftazidime
Sinusitis	Amoxycillin	
Pneumonia		
<i>Strep. pneumoniae</i>	Benzylpenicillin	First generation cephalosporins
<i>H. influenzae</i>	Ampicillin	Cefuroxime, cefotaxime, cephamandole
<i>Staph. aureus</i>	Nafcillin, cloxacillin	Cephalothin, cefazolin
Klebsiella	Cefazolin	Cefotaxime, moxalactam
Pseudomonas	Ticarcillin	Ceftazidime
Anaerobic organisms	Penicillin, clindamycin metronidazole	Cefoxitin, moxalactam
Urinary tract infections		
Domiciliary	Ampicillin	
Hospital-acquired enterobacteriaceae	Aminoglycosides	Cefotaxime, moxalactam
Pseudomonas	Aminoglycosides	Ceftazidime
Meningitis		
Neonatal	Ampicillin, gentamicin	Cefotaxime, moxalactam + ampicillin
<i>Strep. pneumoniae</i>	Benzyl penicillin	Cefotaxime
<i>N. meningitidis</i>	Benzyl penicillin	Cefotaxime
<i>H. influenzae</i>	Ampicillin, chloramphenicol	Cefotaxime, moxalactam
Enterobacteriaceae	Aminoglycosides	Cefotaxime, moxalactam
Bone and joint infections		
<i>Staph. aureus</i>	Nafcillin, cloxacillin	Cefazolin
Enterobacteriaceae	Aminoglycosides	Cefotaxime, moxalactam
Pseudomonas	Ticarcillin + aminoglycosides	Cefsulodin, ceftazidime
Diarrheal disease		
Shigella		
Salmonella	Ampicillin	None
Campylobacter		
Gynecological infections		
Endometritis, salpingitis	Clindamycin + gentamicin	Cefoxitin, cefotaxime, moxalactam
Sexually transmitted disease		
Gonorrhea	Penicillin	Cefoxitin, cefotaxime
Intra-abdominal infections		
Septicemia	Clindamycin + gentamicin Ampicillin + aminoglycosides Ticarcillin + aminoglycosides	Cefoxitin, cefotaxime, septicemia Cefotaxime Moxalactam
Leptospirosis	Penicillin, tetracycline, doxycycline	

Dose:

Genital herpes	200 mg oral 5 times a day—
curative	10-12 days
	or IV 5 mg/kg 8 h for 5 days
suppression	400 mg bd for long periods.
HSV encephalitis	10 mg/kg IV 8 h for 10-14 days
Neonatal HSV	IV 10 mg/kg 8 h for 10-14 days
Varicella zoster	800 mg qid or tds for 10-14 days

Gancyclovir: This drug is effective against cytomegalovirus (CMV) and is indicated for the treatment of life-threatening lesions such as colitis and pneumonias in immunocompromised host and for retinitis which may lead to blindness. The dose is 5 mg/kg given as intravenous infusion within one hour, repeated twice daily. The initial course extends for three weeks after which the maintenance dose is 5 mg/kg/day for several weeks. Drug

TABLE 5.7			
Antiretrovirals approved for use			
NRTI	NNRTI	PI	Entry inhibitor
Zidovudine (ZDV)	Nevirapine (NVP)	Saquinavir (SQV)	Enfuvirtide* (T-20)
Stavudine (d4T)	Efavirenz (EFV)	Indinavir (IDV)	
Lamivudine (3TC)	Delavairidine* (DLV)	Ritonavir (RTV)	
Didanosine (ddI)		Nelfinavir (NFV)

*Drugs not available in India. Several newer drugs which are in the process of development are likely to be introduced from time to time in the near future.			

toxicity includes neutropenia and thrombocytopenia. It is available in vials of 500 mg.

Phosphonoformate (Foscarnet): This is a pyrophosphate analogue that inhibits DNA polymerase of all herpes viruses and RNA polymerase of influenza viruses. Topical application is found to be beneficial in herpes labialis and herpes genitalis. It is being used parenterally in AIDS and CMV infections.

Vidarabine: This is a derivative of adenine arabinoside. It inhibits DNA synthesis and is active against several herpes group viruses. It is used therapeutically in herpes simplex, varicella zoster and cytomegalovirus infections. The drug has to be given intravenously as a 12 hr infusion in a dose of 5-15 mg/ kg/day for 10 days. Toxicity occurs in a few cases and this includes nausea, vomiting, diarrhea and tremors. For the treatment of herpes simplex encephalitis and neonatal herpes simplex infections, vidarabine has to be given intravenously. Adenine arabinoside is available as a 3% ointment for topical use in herpetic keratoconjunctivitis.

Idoxuridine: This is effective against herpes simplex infections, although the organisms develop resistance rapidly. The drug is given as local application to the eye as 0.1% drops and as 0.5% ointment. Toxic effect include irritation and local allergy.

TABLE 5.8	
Mode of action of antiviral agents

Stage of viral replication	Effective drug
Attachment	Antibody to virion-binding Antibody to cell receptors
Penetration/uncoating	Amantadine
Viral macromolecular synthesis	Nucleoside analogues Vidarabine, acyclovir, ganciclovir, ribavirin, zidovudine, foscarnet, Interferons

Note: The details of anti-retroviral drugs is given in Table 5.10

Amantadine hydrochloride (Symmetrel): It is active against RNA viruses such as myxoviruses, paramyxoviruses and togaviruses. The drug is effective particularly against influenza A virus, but not against influenza B. The drug is mainly used for the prophylaxis against influenza A in vulnerable groups. There is a 50-60% reduction in attack rates. For prophylaxis after exposure it should be given within 24-48 hours. It is given orally 100 mg twice a day. Toxic effects include confusion, hallucinations, anxiety and insomnia. It may produce embryopathy when given in pregnancy. This drug is also used in parkinsonism. Rimantadine is an analogue.

Ribavarin: It is a synthetic triazole nucleoside with wide spectrum of activity both against DNA and RNA viruses. It is useful in the treatment of influenza and respiratory syncytial virus (RSV) when given as an aerosol. When given orally or intravenously the drug is effective against Lassa fever, hepatitis B and C, viral hemorrhagic fevers caused by hantan virus and Argentinian and Congo-cremean hemorrhagic fevres.

Lamivudine has also suppressive action on hepatitis B virus (in a dose of 100 mg oral daily). Several others anti-retroviral drugs have also been produced and they are under different stages of trial.

TABLE 5.10

Antiviral drugs, their antiviral activity, preparations and toxicity

Name	Antiviral activity	Preparation	Indication	Main toxicity
Idoxuridine	Herpes virus (HSV), Superficial lesions	0.1% solution or 0.5% ointment for eye	HSV keratitis	Local irritation
Trifluridine	HSV keratitis	1% eyedrops	-do-	
Vidarabin	DNA viruses esp. Herpes group, HSV, VZV, CMV	eye ointment, IV infusion 5-15 mg/kg/day for 10 days	HSV keratitis, HSV encephalitis, disseminated varicella zoster, CMV infections	GI toxicity, tremors
Acyclovir (Zovirax)	HSV, VZV, BB virus	Local cream 5% IV 15-30 mg/kg/day oral tablets 800 mg 4 h	Herpes labialis, Herpes encephalitis EB virus infection	Allergy, renal and hepatic damage
Ganciclovir (Cymevene)	CMV infections	IV 7.5 mg/kg/day	Systemic congenital or acquired CMV infections	
Zidovudine (Azidothymidine)	HIV	250 mg oral 6 h	AIDS and AIDS related disorders	Bone marrow suppression
Ribavirin	Lower resp. tract viruses esp. syncytial virus, Lassa fever virus hepatitis B and C virus	Aerosolized ribavirin, oral tablets 600-1200 mg/day	Influenza, Resp. syncytial virus, Lassa fever HBV, hepatitis C virus	Hemolytic anemia Neoplasia
Amantadine and Rimantadine	Influenza A virus	200 mg/tab. orally	Prevention of Influenza A	Neurotoxicity
Zanamivir and Ostelamivir	Influenza A and B	Zanamivir 5 mg inhalation Ostelamivir 75-100 mg bd oral	Do treatment	—
Phosphonoformate (Foscarnet)	Herpes viruses and influenza virus	Topical	Recurrent herpes labialis	
Alpha interferon	Rhinoviruses HBV, non A non B hepatitis, delta virus hepatitis	Nasal spray parenteral preparation up to 20 mega units/day	Prevent rhinovirus infections Hepatitis B,C,D	Fever

Note: Several newer anti-retroviral drugs are being developed with a view to improve the results in AIDS. Many of these are given along with the chapter on AIDS

Neuroaminidase inhibitors: They inhibit the growth and release of influenza virus from the infected cell. The available drugs are zanamivir and ostelamivir. They inhibit both influenza types A and B. They are used for chemoprophylaxis and curative treatment.

INTERFERONS

Interferons are cytokines produced by host cells in response to viral infection or other stimuli. They are glycoproteins in structure.

Three types of interferons are available-*alpha* interferon produced by lymphocytes and monocytes, *beta* interferon produced by fibroblasts, and *gamma* interferon produced by sensitized T-helper (TH1) lymphocytes. Alpha interferon has two subtypes 2a and 2b which slightly differ in activity. Interferons are commercially produced by rDNA technology, and they are widely used for a large variety of unrelated conditions. Alpha interferon is the most widely used. The antiviral spectrum

includes *hepatitis B, C and D, herpes zoster, EB virus* and *juvenile laryngeal papillomatosis*. Interferon exerts its action possibly by interfering with the translation function in the host cell.

Neoplastic conditions such as chronic myeloid leukemia, hairy cell leukemia and multiple myeloma respond well to alpha interferon.

Alpha interferon is given SC, IM or IV in doses of 5 million units daily or on alternative days for prolonged periods depending upon the indications. Adverse side effects include flu-like symptoms, somnolence, confusion, paresthesia, motor neuropathy, alopecia, leukopenia and thrombocytopenia. *Pegylated interferon* is available. Adverse side effects are less and the preparation is more acceptable. It is more expensive too.

A single dose costs Rs. 1500-2000 and therefore the treatment becomes very expensive.

Beta interferon is used to reduce the frequency and severity of relapses in multiple sclerosis. Gamma

interferon is immunomodulatory in action. It takes part at different stages of the immune mechanisms of the host, including activation of macrophages and NK cells and regulation of antibody production by lymphocytes.

Inosiplex (Inosine pranobex): This drug stimulates B-lymphocytes to produce antibodies, promotes the differentiation of T-lymphocytes and increases macrophage and interleukin activity. Its use is beneficial in hepatitis, subacute sclerosing panencephalitis (SSPE) and herpes simplex virus infections.

At present specific antiviral drugs should be considered for the treatment of the following conditions:

- 1. Herpes simplex infections-severe mucocutaneous or generalized forms in an immunocompromised host, ophthalmic forms, genital herpes, lesions in neonate, meningitis and encephalitis,
- 2. Varicella-zoster infections in immunocompromised host,
- 3. Cytomegalovirus,
- 4. EB virus,
- 5. Hepatitis B, C and delta virus,
- 6. Respiratory viruses—influenza A, RSV, rhinoviruses, corona virus,
- 7. AIDS and HIV infection,
- 8. Lassa fever and other viral hemorrhagic fevers.

Antifungal Drugs

Fungal infections may take the form of superficial or deep systemic infections. With the increase in number of immunocompromised individuals as a result of disease or its treatment, systemic fungal infections have assumed more serious proportions. Several drugs are available for their treatment.

Refer Table 5.11.

Systemic Antifungal Drugs

Several groups of drugs have antifungal properties. These include:

- 1. Antibiotics, e.g: amphotericin B, nystatin, hamacin, griseofulvin.
- 2. Antimetabolites, e.g: flucytosine which impairs synthesis of fungal DNA.
- 3. Azoles, e.g: clotrimazole, econazole, miconazole, ketoconazole, fluconazole.
Voriconazole: This is a broad spectrum triazole compound active against aspergillus species. Dose is 4-6 mg/ kg bw IV bd for 7 days followed by 200 mg oral bd for maintenance.
Compared to amphoterecin B the results are superior.
- 4. Other topical agents, e.g: tolnaftate, terbinafine.

TABLE 5.11		
Antifungal drugs		
Drug	Dose	Main toxicity
Amphotericin B	0.5 mg/kg/day intravenous infusion daily or 0.8-1 mg/kg intravenous infusion in 5% glucose over 4-6 h	Phlebitis, vomiting, nephrotoxicity, anaphylaxis, hypomagnesemia, hypokalemia
Flucytosine	150 mg/kg/day in 4 divided doses orally for 6 weeks 200 mg/kg IV infusion daily	Nausea, vomiting, leukopenia, thrombocytopenia, hepatic dysfunction
Griseofulvin	125-250 mg qid oral with meals for 2 weeks-1 year	Photosensitivity, urticaria, gastrointestinal disturbance, hepatotoxicity
Itraconazole	100-200 mg oral/day	"
Ketoconazole	200-400 mg orally daily	Rashes, hepatotoxicity, gynecomastia
Miconazole	Oral gel 125-250 mg 6 h Parenteral intravenous 8 h; intrathecal 20 mg; topical 2% cream or 100 mg pessary	Mild local reaction, anaphylaxis, nephrotoxicity, hyponatremia, hyperlipidemia, acute psychosis
Fluconazole	50-200 mg/day oral or 200-400 mg/IV day	"
Voriconazole	4-6 mg/kg bw IV bd oral 200 mg bd	
Nystatin	Oral 50,000 U 6 h; topical 10,000 U/g ointment or vaginal tablet	Rash, lymphadenopathy, parotitis, lacrimation, dermatitis
Clotrimazole	1% cream or 100 mg vaginal tablet for 6 days	Mild local effects
Econazole	1% cream or powder	Nil
Miconazole		
Terbinafine	Oral 250 mg daily Cream for local use 10 mg/g	

Most important among them are amphotericin B and the azole drugs.

Mechanism of action: Antifungal drugs, especially the azoles are targeted against ergosterol which is the main sterol in the fungal cell membrane. The synthesis of ergosterol is inhibited. Ergosterol is required for the membrane integrity and growth of fungi. Respiration of the fungi is also inhibited in body tissues.

Spectrum of Activity

Amphotericin B: This is active against cryptococci, aspergillus, histoplasma, coccidioides, blastomyces and Candida. This drug is indicated in systemic infections by these fungi. The drug is contraindicated in renal failure.

Liposomal formulations are available. These permit higher dosage. Toxicity is less-but cost is higher.

Azoles: They are active against most of the organisms that cause systemic and deep-seated fungal infections. The sensitive spectrum includes:

Cryptococcus neoformans,
Candida albicans,
Coccidioides immitis,
Histoplasma capsulatum,
Blastomyces dermatitidis (miconazole is not effective against this organism),
Paracoccidioides brasiliensis, and
Sporothrix schenckii.

Voriconazole is active against aspergillus species.

Action against *Candida* and related yeasts and *Torulopsis glabrata* is weaker.

Ketoconazole inhibits cytochrome p-450 enzyme which is necessary for adrenal and gonadal steroids synthesis, thereby leading to inhibition of these glands in experimental animals, though this action is very weak.

Terbinafine is an orally and topically effective fungicidal agent. Its spectrum of activity includes mainly dermatophytes, and to a lesser extent, candida and pityriasis ovale. The drug is lipophilic and keratinophilic. Adult dose is 250 mg orally daily given for periods varying from 2-6 weeks depending upon the indication.

Echinocandins

Over 50% of candida species isolated from blood stream is formed by *Candida albicans*. Echinocandins are a new class of antifungal agents. They inhibit the cell wall synthesis of candida species. Candida species which are resistant to azoles may be susceptible to echinocandins. Drugs in this class include

Capsofungin (candide Merck) dose 70 mg IV 1st day thereafter 50 mg IV daily.

Micafungin (mycanine- Funguard, Fijisawa) dose 100 mg IV/daily.

Anidulafungin (Eraxis, Pfizer)

dose 200 mg IV initially, followed by 100 mg IV daily.

These drugs are not absorbed orally in effective doses. Adverse side effects include histamine like reactions, thrombophlebitis. These drugs are expensive. The dose for 20 days costs \$ 7000-8000. These drugs should be considered in candida bacteremia not susceptible to amphotericin B or fluconazole.

Further reading: J.E Bennet. Echinocandins for candidemia in adults without neutropenia N. Eng JI. Med. 2006. 355. 1154-1159.

Treatment of Specific Fungal Infections

Systemic candidiasis: Amphotericin B is the drug of choice. Combination of amphotericin B with flucytosine may be synergistic. Fluconazole given orally is almost as effective as amphotericin B.

Cryptococcosis: For cryptococcal meningitis, the conventional treatment is to give amphotericin B. Fluconazole is an attractive alternative, since it penetrates into CSF. Both the drugs are equally effective in cryptococcal meningitis complicating AIDS. Due to the chance of recurrence such patients should receive life-long maintenance therapy. A common regimen is to give amphotericin B in a dose of 1 mg/kg IV once a week and 200 mg fluconazole orally once everyday.

Endemic mycosis: Blastomycosis, coccidioidomycosis and histoplasmosis. Amphotericin B is very effective. Azole drugs are effective alternatives. Itraconazole is the drug of choice due to ease of administration and effectiveness, in these infections.

Invasive aspergillosis: Amphotericin B, itraconazole, echinocandins are effective.

Antifungal prophylaxis: This may become necessary under special situations like neutropenia, organ transplantation and others. The orally administered antifungal drugs are being tried for this purpose.

Antifungal drugs used for superficial mycoses: Superficial mycoses are treated generally by surface applications of the drug. These are described in Chapter 204.

Drug Resistance of Microbes

Failure to attain optimum response to a drug may be:

1. Due to wrong diagnosis of the disease and choice of the antimicrobial agent.
2. Inadequate dose and inappropriate route of administration.
3. Impotency of the drug due to several factors.
4. Resistance developed by the microbes against the therapeutic agent.

Drug resistance is a major problem encountered in present day clinical practice and at present several microbes are highly resistant to drugs which were very effective, when

they were introduced. Though some degree of development of resistance is an inescapable biological process evolved by the microbes, a great deal of this problem has been brought about by the widespread and often inappropriate use of the drug over prolonged periods.

The magnitude of drug resistance is given in table:

Staph aureus—80% of strains resistant to betalactam antibiotics

N.gonococci—more than 50% resistant to penicillin

S. typhi—more than 50% resistant to chloramphenicol

S. shigae—more than 80% resistant to tetracyclines

P. falciparum—more than 50% resistant to chloroquine.

Microorganisms develop drug resistance by several mechanisms. Important ones include:

1. Development of alternate metabolic pathways by enzymatic process. e.g. *Staph aureus*.
2. Mechanisms which inactivate the antimicrobial drug. e.g. beta lactamase.

The resistance developed in the microbe may be due to mutation of the microbial genome or acquisition of resistant genetic material from another organism. Four processes are important.

1. Transformation—The DNA of one organism is released during bacterial lysis and this is acquired by another.
2. Transduction—Gene transfer occurs between two organisms through the medium of bacteriophage.
3. Conjugation—Two organisms come close together and develop a bridge between them. Through this bridge genetic material is exchanged.
4. Plasmids—These are extra-chromosomal double stranded DNA occurring in circular form. These can replicate spontaneously. Gram negative bacteria contain plasmids. In gram-negative bacteria plasmids can be transmitted by conjugation between bacteria, whereas in gram+ve bacteria this does not happen.

Superinfection occurs when resistant strains proliferate and overgrow.

Other causes for resistance include.

- a. Absence of the target of action of the antimicrobial drug on the organism, e.g. chlamydia which lack cell wall are resistant to penicillin which acts on the cell wall.
- b. Inaccessibility of the drug to the target of action, e.g. penicillin cannot penetrate the outer membrane of gram-bacilli and reach the peptidoglycans, to exert its action.
- c. Efflux pumps develop, which remove the drug from the microbe e.g. gram -ve bacilli resist the action of tetracyclines.
- d. Modification of the target to resist drug action, e.g. resistance to quinolones is brought about by the point

mutation in DNA gyrase which prevents the binding of the drug to the target.

It is absolutely essential for the doctor to know about the prevalence of resistance in his area. Simple and most effective methods to prevent drug resistance are:

1. Use the antibiotic only if definitely indicated, thereby reducing widespread and unnecessary use.
2. Use the full dose at the recommended intervals and route for the full period, so that relatively drug resistant mutants are not left behind to proliferate.
3. Whenever possible, try to get the drug sensitivity of the microbes before launching therapy. Avoid unduly prolonged use of the same drug, unless definitely indicated.
4. Wherever necessary, use synergistic combination of antibiotics which will also prevent the chance for developing drug resistance.

At present several newer antimicrobial agents are being used as the first line drugs on an empirical basis to treat possibly resistant infections, e.g. ciprofloxacin for *S. typhi* infection.

The Compromised Host

A compromised host is defined as a patient with a defect in the normal defence mechanisms, which makes him vulnerable to infection. He is not only liable to get severe or recurrent infections with the usual pathogens, but also liable to attack by "opportunistic" microbes which otherwise have minimal pathogenic potential. Particular infections are common in each of the live categories of defects in the normal immune and inflammatory response.

i. **B-cell defect:** *Str. pneumoniae*, *Staph. aureus*, *N. meningitidis*, *H. influenzae*, *E. coli*, *Giardia lamblia*.

ii. **T-cell defect:** *Listeria monocytogenes*, *Mycobacterium sp*, *Candida sp*, *Aspergillus sp*, *Cryptococcus neoformans*, cytomegalovirus (CMV), herpes simplex, herpes zoster.

iii. **Combined B- and T-cell defect:** Combination of (i) and (ii).

iv. **Neutrophil defects:** This includes, neutropenias, defects of adhesion, defects in signalling, defects of intracellular killing and defects in the formation of cytoplasmic granules—gram negative bacilli, candida, *Staph. aureus*, *Streptococcus pyogenes*.

v. **Complement defects:** *Staph. aureus*, *Str. pneumoniae*, *Pseudomonas sp*, *Proteus sp*, *Neisseria sp*, *Salmonella sp*.

vi. Present day chemotherapy for cancer with anti-cancer drugs and several immune mediated diseases with immunosuppressants, monoclonal antibodies and others lead to severe immunodeficiency and susceptibility to opportunistic infections. They also increase the risk of development of secondary

neoplasms such as lymphomas. Infection with human immunodeficiency virus (HIV) leads to gradual depletion of CD4 T-lymphocytes and profound immunodeficiency when the patient develops acquired immunodeficiency syndrome-AIDS. Several opportunistic infections and specific neoplasms like Kaposi's sarcoma and lymphomas may develop.

In addition to systemic chemotherapy, an alteration or breach in the skin or mucosal defence barriers that permit micrograms to cause a local or systemic infection also makes the patient immunocompromised, e.g. burns, indwelling catheters, intravenous lines and others.

The type of immunosuppression and the duration of immunodeficiency partly determine the type of nosocomial or superinfection they acquire. Among the acquired causes of immunocompromise, cancer chemotherapy, use of corticosteroids and immunosuppressants, organ transplantations (both solid organ and bone marrow) splenectomy and AIDS from the major bulk.

Fever in Immunocompromised Host

At times fever may be the principal or even the only manifestation in the immunocompromised patient. The pattern of fever in such patients is nonspecific despite different pathogenic agents. In severely immunocompromised state fever may even be absent. Fever is the result of the release of proinflammatory cytokines, such as interleukins 1-alpha, 1-beta, 4,6, and tumour necrosis factor. Endogenous pyrogens are known to arise from polymorphonuclear leukocytes. These are also produced by macrophages, lymphocytes, fibroblasts, epithelial cells, and endothelial cells, as a consequence of infection or inflammation. Even in severe neutropenia fever may occur, the pyrogens arising from alternate sources.

Immunosuppressed patients rapidly deteriorate and die if infection is allowed to establish. Therefore empirical antimicrobial therapy may have to be started depending on the clinical state. In general neutrophil counts below 500/cmm predispose the patient to life-threatening infections. The clinical signs of infections may be minimal and therefore, misleading. Presence of multiple factors such as breaches in the epithelium, neutropenia, reduction in CD4+ lymphocytes and concurrent cytotoxic or immunosuppressant drugs worsen the condition. Neutropenia occurring after cytotoxic chemotherapy is much more dangerous compared to neutropenia occurring in aplastic anemia or following viral infection. Prolongation of neutropenia beyond 10 days adds to the risk of infection.

Severe depression of CD4 cell counts also predispose to infection. Reduction of CD4 cells to < 1500/cmm in the first year of life, < 750/cmm in children between 2 and 6 years of age and < 200/cmm in children above

6 years is associated with risk of life-threatening infection with *Pneumocystis carinii*, *Toxoplasma gondii* and cytomegalovirus. Patients with AIDS are susceptible to *tuberculosis* irrespective of the CD4 counts, whereas *M.avium complex* affects those with CD4 count < 50/cmm. The infective agents affecting the immunocompromised host vary widely. Virtually all organisms including avirulent ones can become pathogenic.

Acute infections are commonly due to *staphylococci*, *Ps. aeruginosa*, *E.coli* and *klebsiella*. Infections lower the immunity further. Infections such as *respiratory syncytial virus*, *adenovirus*, *parainfluenza virus* and *cytomegalovirus* are common. Multiple infections by bacteria, fungi, viruses and protozoa may occur. Fungal infection by *Pneumocystis carinii*, *cryptococcus*, *aspergillus*, *candida* and *mucor* are common. Protozoal infections include *toxoplasmosis*, *amebiasis* *cryptosporidiosis* and others.

Patients who had splenectomy or *autosplenectomy* in sickle cell disease are susceptible to develop infection by capsulated organisms such as *pneumococcus*, *H. influenzae* or *N. meningitidis*.

Management: Fever and infection in the immunocompromised host are managed based upon the nature of the hosts disability such as neutropenia, defective cellular immunity, or mucosal disruption. The guiding principle has been to treat severely immunocompromised febrile patients empirically for the major pathogens to which they are susceptible. Broad spectrum antibiotic therapy is given with a view to cover gram-positive and gram-negative aerobic organisms. Combination antibiotic therapy or monotherapy with third generation cephalosporins or carbapenams is given.

Rational Use of Antibiotics

Selection of Antibiotics

The drug has to be tailored to the need of the individual patient, site of infection and organism causing the infection. The following points are important:

1. Efficacy – to be given top priority.
2. Cost – must be affordable to the patient
3. Toxicity – potentially toxic drugs like aminoglycosides, chloramphenicol and others are to be used only when definitely indicated.
4. Availability.
5. Least disturbance to normal flora whenever possible.
6. Prevent development of drug resistance and super infections.
7. As far as possible try to get culture and sensitivity results to select the appropriate antibiotic. However, in special situations the laboratory results should not be the only criteria for deciding the treatment, clinical judgment may also have to play its role. If the

specimens are obtained from closed sites that are normally sterile, e.g. CSF, blood and pleural, peritoneal and joint fluids, isolation of a microorganism is definitely pathological. Isolation of a pathogen from areas such as skin, mucosa and the respiratory, alimentary and lower genito-urinary tract should be interpreted on the basis of the clinical picture as well.

Overuse of Antibiotics – is common in the following situations

1. Higher specialities – all branches
2. General specialists
3. General practitioners
4. Quacks
5. Chemists who dispense ‘over the counter drugs
6. Patients who resort to self medication

Misuse of Antibiotics

1. Use without evidence of bacterial infection.
2. Prophylactic antibiotics without indication.
3. Combination of drugs when single agent is sufficient.
4. Use of unscientific combinations.
5. Use of parenteral agents when oral medication is sufficient.
6. Use of expensive and newer drug - when simple and cheaper agents are equally effective.
7. Improper selection of antibiotics.
8. Duration and dose - not conforming to the standard recommendation.
9. Using single drugs when combinations have to be used e.g. Tuberculosis.

Overuse and misuse of antibiotics are commonly seen in the treatment of fever, upper respiratory tract infections, viral infections, poisonings, asthma, chronic respiratory diseases, amebic liver abscess, indwelling urinary catheters and the like.

Antibiotics are employed empirically without evidence of bacterial infection.

More than 75% of antibiotic prescriptions are without indication.

1. *Fever* - Short febrile illness is most commonly produced by self-limiting viral infections with no indication for antibiotics, but extensively used.
2. *Upper Respiratory Tract Infections (URTI)* – Almost always they are viral in etiology and there is no role for the routine use of antibiotics. The common adage “*If common colds are left alone they clear over the course of a week, whereas if treated vigorously they disappear within 7 days*” holds true even now.
3. *Influenza* - Routine antibacterial drugs are not indicated, but they have to be used in selected patients with severe COPD or heart disease.
4. *Poisoning* – Routine use of prophylactic antibiotics is not recommended, but extensively overused.

Appropriate antibacterial drugs are indicated only in selective situations.

5. *Asthma* – Usually the precipitating factor is viral infection. Para influenza and RSV in young children and rhinovirus and influenza virus in older children and adults. Bacterial infection may supervene and then the sputum becomes purulent. Rarely yellow sputum may be due to the presence of eosinophils even without secondary infection. Therefore the routine use of antibiotics is not indicated.
6. *Indwelling catheter* – Prophylactic antibiotic during the first 4 or 5 days reduces the risk of infection. Beyond 5 days there is no benefit, and hence antibiotic prophylaxis fails when the catheter is kept for longer periods. Infections have to be treated when they occur.

Prophylactic Antibiotics

Indications for Chemoprophylaxis

1. When there is a high risk of infection, e.g. wound infection after colonic surgery.
2. Risk is low, but consequences are severe if infection results e.g. insertion of prosthetic heart valves and prosthetic joints.

Observe the following principles

1. Risk of severe infection should be greater than the adverse effects of antimicrobials.
2. Antibacterials should be given only for the minimum period necessary to prevent infections.
3. The drug should be given before the onset of risk such as before starting surgery or as soon as possible after exposure to infection.

Common clinical situations requiring prophylactic antibiotics

1. Rheumatic fever
2. Infective endocarditis
3. Meningococcal meningitis
4. Recurrent cystitis
5. Surgical prophylaxis in selected situations
6. Recurrent cellulitis in conjunction with lymphedema
7. Severely neutropenic patients

Improper Selection of Antibiotics

This leads to poor clinical response, increased cost of treatment and adverse side effects.

Use of parenteral route when oral administration is effective

The route of administration should be preferably oral if the drug is suitable for oral use and the patient can tolerate oral medication. Since parenteral administration ensures

quicker and more reliable bioavailability, parenteral route should be preferred in severe infections such as meningitis, infective endocarditis or severe pneumonias. Intravenous route is preferable in patients with hypotension and circulatory depression. In those in whom repeated large doses are required for prolonged periods, an intravenous line or central venous line is the ideal route. When the patient improves, change to the oral route. Parenteral therapy is inherently more expensive, inconvenient and predisposing to the risk of nosocomial infection. Drugs which are effective when administered orally as single daily doses have better patient acceptance and compliance.

Use of combination drugs when single agent is effective, and using unscientific combinations

Infections are to be treated with single drugs if they are definitely effective. Combinations are definitely indicated in some situations.

- a. *When antimicrobial synergy is clearly advantageous:*
e.g. *Pseudomonas aeruginosa* – aminoglycoside + beta lactam (ceftazidime/piperacillin) more effective.
Enterococci – ampicillin + aminoglycoside like (gentamicin)
Brucellosis – aminoglycoside + doxycycline or doxycycline + rifampicin
Mycobacteria – Combination of 3 or more anti tuberculosis drugs – for preventing the development of drug resistance.
- b. *To broaden the spectrum of antibacterial action*
e.g. – *peritonitis following perforation* – Mixed infection is common. This may require a combination of β lactam antibiotics + aminoglycoside + metronidazole
- c. *Neutropenic patients with sepsis*

Combination therapy may lead to increased cost, change in microbial ecology and chances of superinfection.

Combination of amoxycillin/ampicillin with cloxacillin is marketed by many pharmaceuticals and extensively prescribed. Such fixed drug combination should be avoided as far as possible.

Use of costly and newer agents when cheaper conventional agents are effective

When many drugs with equal efficacy and toxicity are available, one should choose the least expensive drug. When an expensive drug is more effective and absolutely indicated, its use is justified. Newer agents generally cost more and they are promoted more vigorously. Older agents like penicillin G, amoxycillin, co-trimoxazole and doxycycline are relatively cheap, but quite effective against several organisms.

Duration of Therapy

Therapy has to be continued until cure is achieved as assessed by clinical and laboratory parameters. Most acute infections require treatment for 5-10 days. The key factors include – type of infection, location of infection and immunocompetence of the patient. The duration may vary from single oral dose for gonococcal cervicitis to 4-6 weeks of IV therapy for infective endocarditis. Most acute infections of the respiratory tract, ear, paranasal sinuses and GIT should be treated for 5-10 days.

For streptococcal pharyngitis/tonsillitis, 10 days treatment is indicated to ensure eradication.

Prolonged therapy is not only more expensive, it can also lead to adverse side effects and emergence of bacterial resistance.

Consequences of overuse and misuse

1. Emergence of drug resistance
2. Increased cost of treatment
3. Unwanted side effects
4. Disturbance of the normal flora and risk of superinfection.

Therapeutics of
Glucocorticoids

1

S. Bhasi

Chapter Summary

General Considerations 53

Common Indications 53

Adverse Side Effects 54

Management of Glucocorticoid Therapy 54

Inhibition of Hypothalamo-Pituitary Adrenal Axis 55

General Considerations

The initial therapeutic use of glucocorticoids in 1948 resulted in dramatic clinical improvement in a patient with severe rheumatoid arthritis. Today, glucocorticoids are extensively used in therapeutics to manage a wide variety of conditions. Presently available corticosteroid preparations are all synthetic.

Cortisol (hydrocortisone) is the natural glucocorticoid produced from adrenal cortex. The normal rate of endogenous cortisol production as evidenced by recent studies is only 8 to 15 mg/day. ACTH controls normal secretion. In healthy unstressed persons normal secretion shows a diurnal pattern – plasma cortisol is highest in the early morning hours and lowest in the evening. Less than 10% is in the free form which is biologically active. In stressful situations like infection, trauma, burns, surgery and others, cortisol secretion is increased 2 to 6 times in proportion to the severity of the stress. The diurnal variation is also lost.

Several formulations of corticosteroids are available for therapeutic use. They differ in their glucocorticoid and mineralocorticoid activities. In addition to cortisone and hydrocortisone other derivatives include prednisolone, methyl prednisolone, betamethasone, dexamethasone and triamcinolone which have increased glucocorticoid activity with less of mineralocorticoid activity. They have the following properties:

1. Higher affinity for glucocorticoid receptors
2. Less binding with cortisol binding globulin and therefore more of the drug remains in the free form
3. Higher potency

4. Longer duration of action and
5. Less salt- retaining property.

Comparison of commonly used Glucocorticoids

Compound	Anti-inflam- matory potency	Mineralo- corticoid potency	Biological half-life (Hours)	Equi- potent dose (mg)
Short acting				
Cortisol	1	1	8-12	20
Intermediate acting				
Prednisolone	4	0.25	12-36	5
Methyl- Prednisolone	5	< 0.01	12-36	4
Triamcinolone	5	< 0.01	12-36	4
Long acting				
Betamethasone	25	< 0.01	36-72	0.75
Dexamethasone	25	< 0.01	36-72	0.75

Therapeutic Effects

1. Anti-inflammatory effect. Glucocorticoid receptors suppress inflammatory activity
2. Immunosuppressive action
3. Membrane stabilizing effect
4. Modulates vascular responsiveness and permeability
5. Surfactant production in the lung.

Common Indications**1. Endocrine disorders - Physiological replacement**

A. *Hypoadrenal-corticism and hypopituitarism.* Hydrocortisone is ideal – 15 to 20 mg/day. Prednisolone is the convenient alternative - dose 5 mg/day – $\frac{2}{3}$ of the dose is given in the morning and $\frac{1}{3}$ in the evening. Doubling the dose is needed during concurrent minor acute illnesses. Further increase is required in severe stressful situations.

B. *Non-endocrine indications* – Steroids are given in pharmacological doses which are larger.

1. *Allergic diseases* – Anaphylactic shock, atopic dermatitis, asthma, drug reaction, urticaria and others.

2. *Autoimmune diseases*—Systemic lupus erythematosus, rheumatoid arthritis, systemic vasculitis, temporal arteritis, myasthenia gravis, mixed connective tissue disease.
3. *Hematological diseases*—Autoimmune hemolytic anemia, immune thrombocytopenia, leukemia, lymphoma, multiple myeloma.
2. *Gastrointestinal disorders* – Ulcerative Colitis Crohn's disease, autoimmune chronic active hepatitis
3. *Ocular conditions* – Acute uveitis, choroiditis, optic neuritis
4. *Respiratory diseases* – Asthma, interstitial lung disease, pleural effusion, chronic obstructive pulmonary disease
5. *Prevention of graft rejection* in organ transplantation
6. *Metabolic homeostasis* – Acute hypercalcemia
7. *Miscellaneous conditions* – Shock, cerebral edema, thyroid storm, myxedema coma and several others.

Unique Advantages of Glucocorticoids

In several life-threatening and serious diseases such as severe asthma, fulminant ulcerative colitis and systemic vasculitis, the relief brought about by glucocorticoids is dramatic. Maintenance dose helps to prevent exacerbation. Glucocorticoids produce mild euphoria and offers better quality of life. They are relatively cheap, widely available and often available even without prescription. Due to all these advantages glucocorticoids have been used extensively for prolonged periods, often empirically, even as self medication.

Glucocorticoids have several adverse effects. Therefore it is necessary to assess the benefits and adverse effects before starting therapy. In medical emergencies, often high doses may have to be administered for short periods even in the presence of minor contraindications, fully aware of the risk, e.g. severe asthma in diabetic patients. However they should never be administered for more than a few days in such patients without full evaluation and review.

ADVERSE SIDE EFFECTS

1. Iatrogenic Cushing's syndrome.
2. Growth retardation in children.
3. Flaring up of infection – especially tuberculosis and fungal infections.
4. Unmasking of latent diabetes and worsening of existing diabetes.
5. Osteoporosis – especially in elderly and post menopausal women, leading to compression fractures.
6. Hypertension.

7. Increased appetite, polyphagia, obesity, dyslipidemia.
8. Delayed wound healing, dehiscence of scars, striae over the skin.
9. Acid Peptic disease –hyperacidity, ulceration of the upper GI tract, exacerbation of peptic ulcer, gastroduodenal hemorrhage and perforation of the upper GI tract.
10. Ocular problems – cataract, glaucoma.
11. Myopathy – mainly proximal muscles.

Timing of Side Effect

Insomnia, euphoria, glucose intolerance and increased appetite may develop within hours. Psychotic symptoms may occur within hours or may develop later. Osteoporosis takes weeks to months to develop.

MANAGEMENT OF GLUCOCORTICOID THERAPY

Evaluation of Patient Prior to Glucocorticoid Therapy

Look for the following

1. Presence of TB or other chronic infections.
2. Evidence of glucose intolerance or frank diabetes mellitus.
3. Evidence of osteoporosis.
4. History of peptic ulcer, esophagitis, or gastritis.
5. Evidence of hypertension or cardiovascular disease
6. History of psychiatric disorder.

Management of patients on steroid therapy

- Diet with calorie restriction to avoid weight gain, high protein, low sodium and rich in potassium.
- Regular exercise to prevent muscle wasting and osteoporosis.
- Patients with acid peptic disease to be given H₂ receptor antagonists or proton pump inhibitors and antacids.
- Growing children should have regular monitoring of growth.
- Investigate for detecting diabetes or impaired glucose intolerance at monthly intervals. If these develop, consider withdrawal or at least substantial reduction of dose of the glucocorticoid. If the glucose does not come to normal start anti-diabetic therapy. If the glucocorticoid cannot be withdrawn, give it with concurrent anti-diabetic therapy – preferably insulin.
- Supplement Vitamin D 400 IU and calcium salts (gluconate, carbonate and others) 500 mg od or bd orally.

Routes of Administration

1. **Oral:** This is the most commonly used route for systemic effects.
Prednisolone is the commonly used drug, though all the others can be employed.
2. **Parenteral:** IM/IV: Acute severe asthma, craniospinal trauma, brain tumour with cerebral edema, transplant rejection, fulminant presentation of autoimmune diseases, septic shock with corticosteroid deficiency, acute adrenal crisis.
3. **Inhalation:** For relief of life-threatening asthma and for its long term prophylaxis.
4. **Intralesional:** Tenosynovitis, enthesitis, keloids, local painful inflammatory lesions and others.
5. **Intra-articular:** Inflammatory joint disease such as oligoarticular rheumatoid arthritis in 1-2 joints
6. **Topical to skin:** Many steroid responsive dermatosis
7. **Retention enema and foam:** ulcerative colitis.
8. **Ophthalmic indications:** Topical application in the form of eye drops or ointment is indicated for conditions like allergic conjunctivitis, and other inflammatory conditions.

Topical preparations of corticosteroids, especially betamethasone and its analogues may be absorbed from normal and inflamed skin, joints and the large intestine to produce systemic adverse effects if continued for long. Aerosol preparations also can give rise to systemic drug effects if used regularly over several months.

INHIBITION OF HYPOTHALAMO-PITUITARY ADRENAL AXIS

Glucocorticoids give rise to suppression of the hypothalamo-pituitary-adrenal axis (HPA) leading to reduction in corticotrophin releasing hormone (CRH) and adrenocorticotrophic hormone (ACTH). The degree of suppression depends on duration of treatment and the dose.

1. When used for long periods HPA suppression occurs at all doses. Pharmacological doses produce more severe suppression. There is individual variation in the suppressibility. Short courses may not produce marked suppression, but if given for more than three weeks the HPA axis is impaired.
2. Timing of dosing influences the suppression. Doses given in the morning are less harmful compared to doses in the afternoon. Alternate day drug administration is clinically effective, at the same time only less suppressive of the HPA axis.

Steroid withdrawal following long-term therapy. The following problems occur:

1. Worsening of underlying disease

2. Slow recovery of HPA axis
3. Secondary adrenal insufficiency

In the early stages of drug withdrawal, though adrenal cortical function may recover to be adequate at ordinary times, it may fail during stress. Complete recovery may take 6 to 9 months or even more. Many patients may remain steroid dependent.

Steroid Withdrawal Syndrome: This develops rarely in persons receiving prolonged glucocorticoid therapy, on rapid withdrawal of the drug. It is characterized by lethargy, anorexia, malaise, weight loss, arthralgia, myalgia, headache and sometimes fever. Since aldosterone secretion is not ACTH dependant, its level is maintained. Therefore blood pressure level and electrolytes remain normal.

Protocol for corticosteroid withdrawal: These should be followed for all cases where steroid therapy is given in doses above the equivalent of 20 mg of prednisolone daily for 2 weeks or more

- Step 1:** Taper steroid dose gradually to physiological level (i.e.) 5 mg/day
- Step 2:** Change to alternate day therapy for prednisolone and single morning dose for cortisone
- Step 3:** Measure serum cortisol level at 8 AM. Procedure to be followed is given below:

- a. Cortisol level below 3 mcg / d L—This indicates adrenal cortical insufficiency. Continue steroid at lower dose and re-test later in 2-6 weeks
- b. Cortisol level 3-20 mcg/d L— Reduce dose of steroid, re-test later.
- c. Cortisol level above 20 mcg/d L—HPA axis has recovered. Steroid can be withdrawn safely.

Stimulation of adrenal cortex by giving ACTH (tetracosactin depot) 1 mg. IM injection daily, prior to, during and following the period of glucocorticoid withdrawal helps to hasten recovery.

In patients who have been on long-term corticosteroid therapy recovery of the adrenal may take several months.

Glucocorticoids are life saving drugs in many serious clinical conditions even though they possess mild and severe, even life threatening, adverse side effects. On no account the fear of side effects should result in withholding in the drug is essential indications.

Glucocorticoids are life saving drugs in many serious clinical conditions even though they possess mild and severe, even life-threatening, adverse side effects. On no account the fear of side effects should result in withholding in the drug is essential indications.

Principles of Oncology

Chapter Summary

- General Considerations 56
- Tumour Markers 59
- Paraneoplastic Syndromes 60
- Metastasis 60
- Tumour Kinetics 60
- Prognosis in Cancer 60
- Therapy 61
- Palliative Care and Pain Management 66

General Considerations

The International Union Against Cancer has defined cancer as a disturbance of growth characterized primarily by excessive proliferation of cells without apparent relation to the physiological demands of the organs involved. Oncology deals with the prevention, diagnosis, treatment, and research aspects of cancer. Cancer is a leading cause of death all over the world, 7 million deaths occurred during 2001. Globally 35% of these are attributable to 9 potentially modifiable factors. 1/3 of cancer deaths occur in affluent, and 2/3, in developing countries. Among these 2/3 are men and 1/3 are women. The modifiable risk factors include obesity, low consumption of fresh vegetables and fruits, physical inactivity, tobacco smoking, alcoholism, unsafe sex practices, urban air pollution, indoor air pollution by burning bio-fuels and sharing of contaminated needles.

As the life expectancy increases, the incidence of cancer also increases. Table 7.1 shows the frequency of the common malignant neoplasms in India compared to the West.

The pattern of cancer has changed over the past decade in many parts of India. Figures of the hospital based tumour registry from Regional Cancer Centre, Trivandrum 1996 reveal the following. Oral cancers related to tobacco chewing habit still constitute the single largest group. Among the other leading cancers the frequency is given in Table 7.2.

TABLE 7.1

Comparison of incidence (age-standardised incidence rate per 100,000 persons) of common malignant neoplasms in India and the developed countries. (from Cancer Incidence in Five Continents, Vol. 7, International Agency in Cancer, 1997)

<i>In India*</i>		<i>In developed countries**</i>	
Cancer in male population			
Oral cavity	10.8	Prostate	79.1
Lung	10.6	Lung	62.1
Lymphoma	7.3	Colon	30.4
Cancers in female population			
Breast	18.8	Breast	93.3
Cervix	15.9	Lung	35.2
Oral cavity	5.9	Colon	21.6

*Regional Cancer Center, Trivandrum (data as on 1992)
**Connecticut, USA (data as on 1997)

TABLE 7.2

Frequency of cancer in different sites (Numbers denote the percentage out of total cancers) (Data as on 1996, from Hospital Cancer Registry, Regional Cancer Centre, Trivandrum, 1999)

Males		Females	
Oral cavity	16.3%	Breast	24.8%
Lung	12.6%	Uterine cervix	16.3%
Lymphoma	6.8%	Oral cavity	9.5%
Pharynx	6.2%	Thyroid	9.0%
Esophagus	6.0%	Ovary	7.0%
Leukemia	5.9%	Leukemia	4.2%
Larynx	5.8%	Lymphoma	3.5%
Stomach	3.8%	Brain	2.1%
Liver	2.7%	Esophagus	1.9%
Brain	2.6%	Body uterus	1.8%

This clearly shows that as the health conditions improve there is a change in the pattern of malignancy as well. Moreover, with improved facilities for early cancer detection and the mass education programmes launched by the Regional Cancer Centre, Trivandrum, a considerably higher proportion of cancer patients are seeking treatment at an earlier stage when chance for cure is much higher.

Etiology: Several factors operate to bring about carcinogenesis. These are genetic, hormonal, metabolic, physical, chemical and other environmental factors. During the course of cell division malignant mutants may be formed which proliferate to form tumours. Carcinogens increase the rate of mutation and thereby the possibility of malignancy is also increased. Cancer is more frequent in old age, since the occurrence of aberrant mutation is increased. Many mutants are destroyed by immunological mechanisms of the body.

Chemical carcinogens: These act cumulatively to bring about carcinogenesis. Food additives, coloring agents, aflatoxins and n-nitroso compounds are common carcinogens. The incidence of lung cancer is about 11 times more in cigarette smokers compared with non-smokers. Cancer may be produced: (a) at the site of exposure to the carcinogen, e.g., skin cancers in tar workers and buccal cancer in tobacco chewers; (b) at the site of metabolism, e.g. liver cancer in aflatoxicosis; or (c) at the site of elimination, e.g., bladder cancer in workers using aromatic amines.

Diet: Some dietary factors or aspects of life-styles are significantly associated with certain malignancies. Thus salt-cured and smoked foods are related with cancer of esophagus and stomach; high fat diet with cancer of breast and colon; alcohol with cancer of liver and esophagus; tobacco with cancer of lung and oral cavity. Vegetable fibres in the diet increase the intestinal motility and so reduce the incidence of colon cancers. Fresh vegetables, beans and fruits in the diet will reduce cancer incidence, especially of gastrointestinal tract cancers. Some of the important etiological agents are shown in Table 7.3.

Initiation and progression: It is postulated that a carcinogen produces a mutation, but it remains dormant unless acted upon by a promoter. Benzopyrine or croton oil applied alone will not produce skin cancer. But when benzpyrine is followed by croton oil, tumour develops. The benzpyrine acts as a carcinogen to produce a mutation. But the promoter (croton oil) gives the drive for unchecked cell division, which is the characteristic feature of malignancies.

Antimutagens are substances which will inhibit with tumour promotion. Vitamin A and carotenoids are shown to reverse precancerous conditions, especially oral leukoplakia. Butylated hydroxy anisol (BHA), vitamin E and vitamin C are antioxidants, which prevent the damage made by free radicals and superoxides. Curcumin, the yellow substance in turmeric is known to prevent mutations in experimental systems.

Viruses: Several viruses have been implicated in many cancers. Epstein-Barr virus has been identified as the causative factor for Burkitt's lymphoma in African children and for nasopharyngeal carcinoma in chinese

TABLE 7.3	
Important etiological agents of cancer	
Agent	Associated cancer
<i>Physical agents</i>	
Sunlight (UV)	Skin cancers
<i>Chemical agents</i>	
Tobacco smoking	Lung, mouth, esophagus, larynx, bladder
Tobacco chewing	Oral cavity
Alcohol	Oral, esophagus, liver
Polycyclic aromatic hydrocarbons (produced during deep frying)	Liver colon
N-nitroso compounds	Stomach, esophagus, bladder, liver
Aflatoxins (Fungal contamination)	Liver
<i>Microbial agents</i>	
<i>Helicobacter pylori</i>	Stomach
<i>Schistosoma hematobium</i>	Urinary bladder
<i>Viruses</i>	
Epstein-Barr virus	Burkitt's lymphoma; nasopharyngeal carcinoma
Hepatitis B virus	Hepatocellular carcinoma
Hepatitis C virus	Hepatocellular carcinoma
HTLV-1	T cell leukemia
HPV (human papilloma)	Uterine cancer
HSV-2 (herpes simplex)	Uterine cancer
HHV-6 (human herpes)	Lymphomas
HHV-8	Kaposi's sarcoma

population. Papilloma viruses (different types) and herpes virus type 2 have been shown to be associated with carcinoma cervix, hepatitis B and C viruses with primary carcinoma of liver, herpes virus type 6 with lymphomas and herpes virus type 8 with Kaposi's sarcoma. This virus is also associated with multicentric lymphoma and multicentric Castleman's disease.

Physical agents: Ionizing radiation cause a marked increase in cancer incidence in later life. Exposure to X-rays in fetal life increases the risk of developing leukemia in later life. The risk of developing cancer in a population exposed to ionizing radiation in a dose of 1 rad/year is 40 per million annually. Indiscriminate use of diagnostic X-rays constitutes a health hazard, and has to be avoided. Chronic irritation by heat (*kangri* in Kashmir and lighted cigarettes inside the mouth in Andhra Pradesh) lead to cancer of the abdominal wall and the palate in different populations. Bilharziasis is associated with higher risk of bladder neoplasms.

Genetic factors: Many neoplasms show evidence of genetic predisposition. For example,

1. Retinoblastoma, multiple polyposis of the colon, and carcinoma breast run in families.
2. Mongolism is associated with a ten-fold increase in the risk of leukemia.

3. Blood group A is associated with a higher risk of gastric carcinoma, compared to blood group B and O.
4. Hodgkin's disease is more frequent in subjects with HLA B 18.

Breast cancer shows a strong familial predisposition. Women with BRCA1 or BRCA2 mutations have a 60-85% cumulative lifetime risk of invasive breast cancer up to 70 years of age and 15-65% cumulative life time risk of invasive ovarian cancer. Prophylactic mastectomy reduces the risk of breast cancer. Salpingo- oophorectomy reduces the risk of both breast cancer and tubo-ovarian cancer.

Colonic epithelial cancers all also increased in patients with BRCA 1 and 2 mutations.

Several chromosomal changes have been demonstrated in malignant cells. Many of them are characteristic to be of diagnostic help, while others are not. For example, Ph1 chromosome is diagnostic of chronic myeloid leukemia. When chronic myeloid leukemia transforms into the acute phase diagnostic chromosomal rearrangement occurs. Myelodysplastic syndrome is characterised by specific chromosomal patterns. Several examples of chromosomal abnormalities in cancers are known at present.

Genetic studies have yielded rich dividends in understanding the initiation and progress of cancer. These include the identification of *oncogenes*, *proto-oncogenes*, *onco-suppressor genes*, genetic changes caused by *retroviruses* and several others.

Oncogenes are altered forms of normal genes called proto-oncogenes. More than 80 human proto-oncogenes are known. For example, erb-B is located in chromosome No.7, and it produces the receptor for epidermal growth factor (EGF-R). The sis gene, located in chromosome 22 produces platelet derived growth factor (PDGF). The abl, located in chromosome No. 9 and src, in chromosome No. 20 produce proteins with tyrosine kinase activity. The protein products of proto-oncogenes have essential roles in cell growth and differentiation. But the proto-oncogenes are under the control of other regulatory genes. When proto-oncogenes are activated there will be continuous expression of the gene leading to uncontrolled cell division and malignant transformation. A proto-oncogene may be activated by the following mechanisms:

(A) **Chromosomal translocation:** In all cases of Burkitt's lymphoma, translocation of chromosome 8 to chromosome 14 takes place with consequent activation of C-myc. In Non-Hodgkin's lymphoma, translocation of chromosome 14 to 18 is very common. The breaks on chromosome 18 occur either in major break point region (MBR) or at the major cluster region (MCR), both involving the bcl-2 oncogene. The bcl-2 product suppresses programmed cell death, leading to tumour formation.

(B) **Promoter insertion:** Virus promoter genes may be integrated upstream to the oncogene so that continuous expression of the oncogene takes place.

(C) **Mutation of proto-oncogene:** The ras gene produces a protein termed p-21 (mol. wt. 21,000), which suppresses the activity of adenyl cyclase and thereby, cell division. In human bladder cancers, a mutated p-21 is demonstrable, leading to continuous activity of adenyl cyclase. In many cases particular mutations leading to the formation of oncogenes have been identified.

Oncogenes are generally coded with a combination of three small letters, e.g., myc, L-myc, N-ras, C-abl, etc., while onco-suppressor genes are coded by two capital letters, e.g., RB-1, for retinoblastoma, WT-1 for Wilms' tumour, NE-1 for neurofibromatosis.

Oncosuppressor genes present in normal cells usually prevent cancer formation. For example, when both alleles of the RB gene are deleted, retinoblastoma results. An onco-suppressor gene called p-53 produces a phosphoprotein with molecular weight 53,000. It can complex with proteins generated by other oncogenes.

Most tumours have a complete absence of p-53 while others show mutant nonfunctional p-53.

Several different mechanisms may activate oncogenes. Thus viruses, chemical carcinogens, chromosome translocation, gamma rays and spontaneous mutation may activate oncogenes to produce malignancy.

Growth factors: These are humoural factors which generally cause mitosis or differentiation to target cells. More than 100 such growth factors are described. Epidermal growth factor (EGF) produced by fibroblasts stimulates growth of epidermal and epithelial cells. Platelet derived growth factor (PDGF) produced by platelets, accelerates wound healing and stimulates growth of mesenchymal cells. Nerve growth factor (NGF) produced by salivary glands stimulates growth of sensory and sympathetic neurons. Oncogene activation leads to imbalance in such growth factors.

Apoptosis: Programmed cell death is known as apoptosis. During the normal growth, old cells are to be removed, so that new cells can replace them. Hypoxia, reactive oxygen species, chemicals, irradiation, DNA damage, immune attack, malnutrition, tumour necrosis factor, and many other signals activate the apoptotic pathway. The final effectors of this pathway are a group of enzymes known as caspases (cysteiny peptidases with aspartate specificity). They are named 1 to 14 according to their order of identification. They activate nucleases and cause DNA to be fragmented into small fragments (step ladder pattern of DNA in agar gel electrophoresis). The apoptotic cells show chromatin condensation, shrinking of the cells, and finally disintegration. In normal organs, the number of cells produced by cell division will be equal to the

number of cells undergoing apoptosis. If the regulation of apoptosis is altered the cells in that tissue accumulate leading to neoplasms. Apoptosis promoting (suicidal) genes are c-fos, P53 and Rb: they are oncosuppressor genes. On the other hand, apoptosis inhibiting genes are cancer promoting genes, e.g. Bcl-2.

Clonal origin of neoplasms: It is widely accepted that most of the tumours arise from a single clone of altered cell, the clone having the potential to multiply and form the tumour. The biological history of a tumour shows several steps of progression. In the normal individual the aberrant cells tend to be destroyed by immune mechanism. When this breaks down, cells with malignant potential survive and proliferate. Initial progression of the tumour is very slow and it takes several years for an abnormal clone to multiply and become clinically recognizable. The early changes indicating dysplasia of the cells, can be identified and treatment at this stage can lead to arrest of the neoplasm and cure in many cases.

Immunological changes: Malignant cells show different degrees of de-differentiation. Several functional genes are present which are active in fetal life, but which are repressed in later life leading to the disappearance of several fetal antigens from the surface of the adult cells.

In malignant cells, embryonal antigens reappear on the cell surface due to derepression of these genes, and these are termed onco-fetal antigens, e.g., carcino-embryonic antigen (CEA) in colon cancer and alpha-fetoprotein (AFP) in liver cancer.

TUMOUR MARKERS

Tumour markers or tumour index substances are factors released from the tumour cells; these could be detected in blood and therefore indicate the presence of the tumour. They are useful (A) For follow up of cancer and to monitor the effectiveness of the therapy (B) To detect the recurrence of the tumour (C) For prognosis; serum level of tumour marker usually indicates roughly the tumour load, which in turn indicates whether the disease is advanced or not and (D) To facilitate detection of cancer. The presence of high levels of tumour marker suggests the diagnosis, but caution is to be taken to rule out other nonmalignant conditions. The levels of tumour markers are increased in inflammatory and other conditions as well but drastic elevation is suggestive of malignancies. The following are some of the commonly employed tumour markers:

1. Alpha-fetoprotein (AFP). It is a fetal albumin. It is increased in hepatocellular carcinomas, germ cell tumours, teratocarcinoma of ovary and in pregnancy with fetal malformations of neural tube.
2. Carcino-embryonic antigen (CEA). It is increased in colorectal and other gastrointestinal tumours.

3. CA-125 (ovarian cancer antigen) is a glycoprotein and is increased in ovarian cancers of epithelial origin.
4. CA-199 is another glycoprotein seen in circulation in cancers of stomach and colon.
5. Alkaline phosphatase (ALP) level is increased in bone and liver diseases; high level of heat-labile isoenzyme (bone isoenzyme) is seen in bone secondaries.
6. Placental isoenzyme of ALP (heat stable and inhibited by phenyl alanine) is found in normal pregnancy. It is also seen in certain cases of carcinoma of lung, liver and gut and testicular seminomas, then it is called Regan isoenzyme.
7. Acid phosphatase (tartrate labile isoenzyme) is increased in prostate cancers.
8. Prostate specific antigen (PSA) is produced by secretory epithelium of prostate. It is normally secreted into seminal fluid, where it is useful to liquify the ejaculate. It is a protease, and in serum it is seen complexed with alpha-1 antitrypsin. The PSA level, especially the complexed form is increased in prostate cancers.
9. Neuron specific enolase (NSE) level is raised in nervous system tumours.
10. Beta chain of human chorionic gonadotropin (hCG) is elevated in choriocarcinoma.
11. Big ACTH is seen in pulmonary oat cell carcinomas.
12. Vasoactive intestinal polypeptide (VIP) is elevated in apudomas (amine precursor uptake decarboxylaseomas).
13. Tissue polypeptide specific antigen (TPS) measures an antigenic determinant associated with human cytokeratin. TPS level is elevated in almost all solid tumours. It is a marker of tumour cell activity, in contrast to all other markers related to tumour burden. Although non-specific with reference to the site of origin of tumour, it is very useful in assessing the efficacy of the treatment, and also for early detection of recurrence.
14. Immunoglobulin levels are increased, and are seen as a monoclonal peak in electrophoresis, in multiple myeloma and in Waldenström's macroglobulinemia.
15. Vanillyl mandelic acid (VMA), metabolite of catecholamines, is excreted in increased quantities in urine of patients with pheochromocytoma and neuroblastoma.
16. Hydroxy indole acetic acid (HIAA), metabolite of serotonin, is raised in urine of patients with carcinoid syndrome.
17. Hydroxy proline excretion in urine is elevated in bone metastasis.

Malignant cells show several biochemical abnormalities compared to normal cells. Some of them have **59**

been beneficially exploited in cancer chemotherapy, e.g., use of L-asparaginase for acute lymphatic leukemia.

Paraneoplastic Syndromes

Tumours may produce signs and symptoms distant from the tumour site of metastasis; this is referred to as paraneoplastic syndrome. This is due to the production of hormones or metabolically active factors by tumours arising from non-endocrine tissues. The substances produced by the neoplasms are analogues of the natural hormones or their precursors. Several neurological manifestations may develop, such as neuropathies, myopathies, myasthenic reaction, myositis, and brainstem encephalitis. Antibodies against neuronal proteins may be demonstrable. These lesions may precede the overt manifestations of the tumour in many cases. Some of the important paraneoplastic syndromes are listed below:

1. **Ectopic ACTH syndrome** is seen in small cell carcinoma of lung, medullary cancer of thyroid and cancer of pancreas. These malignant cells may produce ACTH, leading to Cushing's syndrome.
2. **Syndrome with inappropriate antidiuretic hormone** (SIADH), where arginine vasopressin is synthesised by the tumour cells, leading to clinical manifestations of hyponatremia. It is seen in non-small cell lung cancers, lymphomas, leukemias, and head and neck cancers.
3. **Ectopic parathyroid hormone** (PTH) is produced by thoracic and intestinal solid tumours.
4. **Oncogenous osteomalacia** is seen in calcitonin secreting malignancies, usually cancers on thyroid and mediastinum.
5. **Human placental lactogen** (HPL) is commonly elevated in bronchial cancers and thyroid cancers.
6. **Polycythemia** is occasionally noticed in hypernephroma.
7. **Acanthosis nigricans** (brown plaques in neck, axilla and flexor regions) are seen in adenocarcinomas, especially of gastrointestinal origin.
8. **Hyperpigmented palms** are seen in some cases of gastric and lung cancers.
9. **Acrokeratosis** (acral hyperkeratosis) in toes, ears and nose is seen in squamous cell carcinomas.
10. **Hypertrophic osteoarthropathy** (digital clubbing) is noted in non-small cell cancers of lung and metastatic malignancies.
11. Symptoms of **limbic and brainstem encephalitis** may occur at times in testicular tumours.

It should be remembered that many typical or atypical endocrine manifestations can develop as a result of paraneoplastic manifestations of several neoplasms. It should be the endeavour to detect such lesions if the clinical manifestations are not classic.

METASTASIS

Cell membrane of the malignant cells show qualitative and quantitative changes resulting in an increase of the negative charge on the surface. This leads to mutual repulsion of the cells and increases the tendency to disseminate. Another phenomenon noted in malignant cells is loss of contact inhibition. When two normal cells come into contact this inhibits further cell multiplication. This property is lost in malignant cells which continue to multiply and grow. The tissue in which the metastasis develop is also conditioned to favour the growth of the metastatic cells.

Tumour Kinetics

Growth of the tumour depends on the balance between cell proliferation and cell loss. Cellular proliferation depends on: (1) the proliferation coefficient, i.e., the ratio of active to resting cells, and (2) the cell cycle interval.

Cell loss depends upon: (1) cell death by apoptosis aging, lack of oxygen and nutrition; (2) abortion, i.e., incapability of the cells to multiply; (3) escape, detachment of cells from the tumour mass; and (4) specific cell destruction by immunological mechanisms. All these parameters are important in deciding "tumour doubling time" (i.e. the time taken by a tumour to exactly double its mass), which will be constant for a particular growth over a long period. The tumour doubling time in human cancer varies widely between 10 to 450 days, with a median of about 100 days. In the case of a tumour with doubling time of 100 days, the time taken for the growth to reach 1 g from the initial mutation is about 8-10 years. It naturally follows that the tumour is present in the system for a considerable period before clinical detection. The same reason can explain the development of the secondaries several years after the treatment of primary growth. Modern treatment aims at reducing the tumour growth by increasing the cell loss coefficient. When this is achieved, the patient may remain apparently normal for many years. When referring to the management of cancer, the term 'control' is more appropriate than 'cure'. Five-year survival figures are usually taken for comparing the results of different forms of treatment in several neoplasms. It should be remembered that 5-year survival is not synonymous with cure of the lesion.

Precancerous lesions: Precancerous or preinvasive lesion is a stage where individual cells are abnormal but cancer cells have not yet invaded the surrounding normal tissues. About 5-10% of such cases develop invasive tendency within a few years, e.g., leukoplakia of oral cavity, hyperkeratosis of skin, papillomas of the urinary bladder, polyps of bowel, and stage 0 cancer of cervix.

Prognosis in Cancer

(1) The most important factor determining survival is early detection. The earlier the diagnosis, the better is the

curability. Mass screening of susceptible groups of persons by Pap smear and other methods can lead to early diagnosis, (2) Prognosis is better for slow-growing tumours, (3) Well differentiated tumours have a better prognosis than undifferentiated ones, (4) If the host can effectively mount an immunological attack against cancer cells, the outcome is more favorable. Prognosis is better in neoplasms where the immunological status of the individual is not depressed. (5) For several cancers modern treatment protocols are available, which are highly effective. In such lesions early diagnosis and proper therapy are curative.

Therapy

The aim of therapy is to reduce the tumour mass within the shortest possible time and to destroy the remaining cells and prevent them from multiplying and disseminating. This ideal is possibly achieved only in the case of very few cancers but in the majority of cases this is not possible due to: (1) late diagnosis, (2) presence of secondaries early in the disease, (3) surgical risk, and (4) toxic effects of radiation and chemotherapeutic agents. Cancer has emerged as one of the curable diseases among the serious chronic diseases. Modern radiotherapy has reached a high level of effectiveness in eradicating tumours, with minimal damage to normal tissues. In the management of solid tumours, multimodal therapy, combing irradiation with chemotherapy is employed, except in the case of very early tumours.

Surgery and radiotherapy are most effective to reduce the initial tumour load. These are the prime modalities of treatment in solid tumours. In the case of disseminated neoplasms like leukemia and myeloma and in the case of some rapidly growing tumours like trophoblastic tumours, chemotherapy has to be employed as the first line of treatment. The technical perfection and complexity of management of malignant neoplasms have resulted in the achievement of successful results in many case if detected early. Several sub-specialities such as radiation oncology, solid tumour oncology, hemato-oncology and others have developed.

Radiotherapy

Tumour cells are more radiosensitive as they proliferate faster than normal cells. Radiotherapy may be given as the only modality of treatment or combined with surgery and chemotherapy. With the advent of highly sophisticated equipment such as the linear accelerator, large doses may be focused on deep seated tumours with only minimal injury to adjacent tissues. Therapeutic efficacy of radiation is enhanced by exposure to hyperbaric oxygen and radiosensitizing drugs such as metronidazole.

Radiation produces ionization in its path. This causes physical and/or chemical changes. The nucleic acid in the cell is damaged, so as to arrest the next cell division. Radiotherapy mainly affects cells in the dividing phase. X-rays produce breaks in DNA. Break of 2 single strands of DNA lead to disruption of the integrity of the chromosomes and tissue destruction.

Depending on the sources of radiation, the radiotherapy may be (a) unsealed sources, (b) sealed sources or brachytherapy and (c) teletherapy. Unsealed sources are radioactive substances kept in liquid form. The beta rays are the main effective radiation in these sources. For treating primary and metastatic thyroid cancer, ¹³¹I (dose 50-100 mCi) is administered. Since iodine is preferentially concentrated in thyroid cells, the radioactivity is specifically taken up by these cells, and so they are destroyed. ³²P (dose 5 mCi) is given intravenously to treat polycythemia vera. Phosphorus is an essential constituent of DNA and so rapidly dividing cells take up the radioactive phosphorus. The dose may be repeated after 3 months, if necessary. Radioactive gold (¹⁹⁸Au) (75-150 mCi) may be instilled into serous cavities to reduce malignant pleural and peritoneal cavities. Commonly used radioisotopes are listed in Table 7.4.

Brachytherapy: The radioactive source is covered by platinum alloy to absorb alpha and beta radiation, so that only gamma rays are allowed to penetrate into the tissue. Alpha and beta rays if allowed to come out, will produce necrosis of tissue around the source within a short time.

TABLE 7.4 Widely used radioisotopes				
Element	Isotope	Half-life	Major radiation	Important applications
Carbon	¹⁴ C	5600 years	Beta	Research in metabolism
Phosphorus	³² P	14 days	Beta	Polycythemia treatment
Chromium	⁵¹ Cr	28 days	Gamma	RBC kinetic in diagnosis
Iodine	¹²⁵ I	60 days	Gamma	Radioimmunoassay
Iodine	¹³¹ I	8 days	Gamma	Thyroid cancer treatment
Radium	²²⁶ Ra	1600 years	Gamma	Implantation in tumours
Tantalum	¹⁸² Ta	115 days	Gamma	Implantation, bladder cancer
Gold	¹⁹⁸ Au	2.5 days	Beta	Instillation into serous cavities
Cobalt	⁶⁰ Co	5.3 years	Gamma	Teletherapy for cancer
Caesium	¹³⁷ Cs	30 years	Gamma	Teletherapy for cancer.

The sources are packed as needles inside small tubes with a length of about 2 to 5 cm and a diameter of about 2 mm. ^{137}Cs with a half-life of 30 years, is the preferred sealed source. Intracavitary application (for cancer of body of uterus, cancer of cervix uteri, cancer of vagina) and interstitial applications (for buccal cancer, tongue cancer) are very commonly used.

Teletherapy: Here the source of radiation is kept at a distance from the patient. The high penetration power of the gamma rays has an advantage. Maximum dose is received not on the skin, but on the underlying tissues, which reduces unwanted skin reactions.

Gamma rays from ^{137}Cs (Caesium) or ^{60}Co (Cobalt) are used for teletherapy. Here the energy equivalent is in the order of 2 MV (megavolt or million volts). Usual diagnostic X-ray works in the region of 80-150 KV (kilovolt or thousand volts). Since penetration power is dependent on the energy of the ray, better machines, called linear accelerators with energy levels of 5-12 MV are now being used. The present machines are able to provide programmed doses of radiation at specific targets in high doses, with minimal damage to surrounding tissues. The aim of radiotherapy in general, and teletherapy in particular, is to provide maximum destruction of tumour tissue, while retaining the regenerative capacity of surrounding normal tissues. The art of radiotherapy is to decide the most beneficial risk-benefit ratio. Radiation fields can be designed, using shielding blocks, computerized planning and automated tracking techniques.

Radiosensitivity: The effectiveness of radiotherapy varies with different tumours. In general, lymphomas, Hodgkin's disease and neuroblastoma are highly radiosensitive. Epithelioma, cancer of oral cavity, cancer of cervix, cancer of breast and lung cancer are moderately radiosensitive. Poorly radiosensitive tumours are osteosarcoma, and malignant melanoma.

Fractionation of doses: Radiation given in a single dose is not optimally effective, because only 5-10% of cells are in the dividing phase at any one time and the radiation kills only this fraction. If divided doses are given at programmed intervals which coincide with the cell division fresh cells are killed successively. Fractionation also helps to reduce the toxic effects of radiation. In general a total dose for many cancers is 5,000 to 6,000 rads (also called centigray-cGy) given in 15-20 fractions, administered over a period of 25-35 days. Recovery from radiation damage is quicker in normal cells than in cancer cells.

Adverse effects: The adverse effects of radiotherapy are due to the damage caused to normal tissues; some degree of which is inevitable. These are described below:

1. **Skin** Epilation, damage to sweat glands, erythema and blisters. These constitute the syndrome of acute

radiation dermatitis. These reactions are generally mild and acceptable in most cases, but overdosage may produce burn and sloughing of superficial tissues. Long-term effects include minor degrees of ischemia, atrophy, hypopigmentation, fibrosis and loss of elasticity.

2. **Mucous membranes** Mucosal surface cells are replenished very rapidly, about a third being formed everyday. Since radiation damages the dividing cells most, gastrointestinal problems are very common during radiotherapy. Minor manifestations include nausea, vomiting, and diarrhea. In severe cases, ulceration and bleeding may occur. Late sequelae such as adhesions, fibrosis, stenosis and luminal obstruction may develop several months after radiotherapy.
3. **Blood cells** Bone marrow and lymphoid tissues are highly radiosensitive because of the higher rate of cell division in the organs. Cytopenias are the most common adverse effects. Platelets, granulocytes and erythrocytes are frequently reduced. Continuation of the dose may lead to marrow aplasia. Leukopenia leads to infections and thrombocytopenia leads to hemorrhage. It is important to repeat blood counts before each successive dose of irradiation and modify therapy accordingly.
4. **Reproductive organs:** Complete sterility may result if 1000 rads are given over the pelvic region. Smaller doses of radiation may produce genetic effects in the offspring.
5. **Radiation sickness:** This depends on the radiation dose and the tissue volume irradiated. 100-150 rads given as a total body irradiation will cause severe illness which can be fatal, if untreated.

The maximum permissible dose (MPD) of radiation for whole body among radiation workers including doctors, is 5 mRem/year, and for general population is 0.5 mRem/year.

TABLE 7.5

Common malignant conditions in which combination chemotherapy is administered

Acute lymphatic leukemia	:	Vincristine + Prednisone + Adriamycin + L. asparaginase
Acute myeloid leukemia	:	Doxorubicin + 6-Thioguanine + Cytosine arabinoside
Hodgkin's lymphoma	:	Nitrogen mustard + Vincristine + Prednisone + Procarbazine
Non-Hodgkin's lymphoma	:	Cyclophosphamide + Vincristine + Prednisone
Multiple Myeloma	:	Melphalan + Vincristine + Prednisone
Ewing's tumour	:	Vincristine + Actinomycin D + Cyclophosphamide
Embryonal tumours	:	-do-
Breast cancer	:	5-Fluorouracil + Adriamycin + Mitomycin
Oral cancer	:	Mitomycin + Methotrexate + Bleomycin

TABLE 7.6

Commonly used anti-cancer drugs

Group of drug and mechanism of action	Name of drug	Dose and route	Most important side effects	Indications
Alkylating agents				
They form electrophilic lymphatic ions making covalent bonds (alkylation) with guanine residues leading to cross-linking of DNA strands and interference in DNA replication	<i>Cyclophosphamide</i>	100-150 mg oral daily	Cystitis and marrow	Acute and chronic
	<i>Endoxan</i>	or 1 g/m ² every 3 weeks		suppression
	<i>Cytosan</i>			lymphomas Ca. of
	<i>Nitrogen mustard (Mustargen)</i>	6 mg/m ² infusion intravenous	Local inflammation	ovary lungs and cervix
	<i>Phenylalanine mustard (Melphalan)</i>	6 mg/m ² /d oral for 5-10 days every 4-6 weeks	Marrow suppression	Several tumourus
	<i>Chlorambucil (Leukeran)</i>	0.1 mg/kg/day oral	-do-	Multiple myeloma
	<i>Busulfan (Myeleran)</i>	4-12 mg/day oral	Pulmonary fibrosis marrow suppression	CLL, lymphoma
				CML
Antifolates				
Inhibit dihydrofolate reductase; tetrahydro-folate is not produced; one carbon units are not available for DNA synthesis	<i>Amethopterin</i> <i>Methotrexate</i>	5 mg/day oral or 30 mg/m ² intravenous twice weekly	Marrow suppression; hepatic and renal toxicity, painless nodules over fingers	ALL, Ca. of breast, lung, head and neck sarcomas choriocarcinoma
Antipyrimidines				
Inhibit thymidylate synthetase and thus DNA synthesis	<i>5-Fluorouracil</i>	15-20 mg/kg/week intravenous: maximum dose is 1 g	Gastrointestinal disturbance; marrow suppression	Ca of brest, colon, stomach, ovary, head and neck
Inhibit deoxycytidine and DNA synthesis	<i>Cytosine arabinoside</i> <i>Cytosar, Ara-C</i> <i>Cytarabine</i> <i>Gemcitabine (Difluorodeoxy cytidine)</i>	100-200 mg/day intravenous 1000 mg/m ² IV infusion	-do- Hyperuricemia Myelosuppression hepatotoxicity	AML, ALL Advanced adenocarcinoma of pancreas
Antipurines				
Interfere with purine biosynthesis and interconversions	<i>6-Mercaptopurine</i> <i>Purinethol (Hypoxanthine analogue)</i> <i>6-Thioguanine (Guanine analogue)</i>	2.5 mg/kg/day oral 2 mg/kg/day oral	Hepatotoxicity marrow suppression marrow suppression	AML, ALL, CML, AML, ALL
Vinca alkaloids				
Derived from periwinkle (vinca rosea) plant. Interfere with microtubule assembly in mitotic spindle formation	<i>Vinblastine (Velban)</i> <i>Vincristine (Oncovin)</i>	5-15 mg/m ² every 1-2 weeks intravenous 0.5-2 mg/m ² every 1-2 weeks intravenous	Mental depression, local inflammation, marrow suppression. Peripheral and autonomic neuropathy; alopecia.	ALL, neuroblastoma Wilms' tumour lymphomas, Ca lung
Taxene group				
Inhibits microtubule assembly; mitotic block in metaphase/anaphase boundary	<i>Paclitaxel (Taxol)</i> <i>Docetaxel</i>	175/m ² IV infusion repeated every 3 weeks 60 mg/m ² IV infusion	Hypersensitivity Myelosuppression Hypersensitivity fluid retention	Breast cancer Ovarian cancer Advanced Breast carcinoma

Contd...				
Group of drug and mechanism of action	Name of drug	Dose and route	Most important side effects	Indications
Podophyllotoxins				
Semisynthetic drugs	<i>Etoposide (VP-16)</i>	100-200mg/m ²	Marrow suppression	Ca of lung, breast and testis lymphomas, AML, Kaposi's sarcoma
Selective inhibition of DNA topoisomerase, and inhibition of S and G2 phases of cell cycle	<i>Teniposide (VM-26)</i>	I. V. on alternate days 3-4 weeks	Late development of leukemia	
	<i>Irinotecan</i>	125 mg/m ² IV infusion	Diarrhea	Advanced cancers of colon and rectum
	<i>Topotecan</i>	1.5 mg/m ² IV infusion × 5 days	Myelosuppression	Ovarian carcinoma
Antibiotics				
Inhibiting DNA directed RNA synthesis	<i>Actinomycin</i>	12-15 mcg/kg/day	Marrow suppression	Wilms' tumour
	<i>Dactinomycin</i>	5 d for 2-4 weeks	local inflammation	Rhabdomyosarcoma
	<i>Cosmegen</i>	intravenous		
	<i>Bleomycin</i>	1-5 mg/d intravenous or intramuscular. maximum 300 mg/m ²	Pulmonary fibrosis with minimal myelosuppression.	Ca of head and neck, skin, lung, gut, and GIT
Inhibiting DNA synthesis	<i>Daunomycin</i>	60 mg/m ² intravenous	Cardiotoxicity	AML, ALL
	<i>Daunorubicin</i>	3-4 weeks		
	<i>Rubidomycin</i>			
	<i>Adriamycin (Doxorubicin)</i>	60 mg/m ² intravenous once in 5 days for 3-4 weeks. Maximum total dose 500 mg	Cardiotoxicity	Soft tissue tumour, lymphomas, ALL, Ca of breast, GIT, and gut
	<i>Mitomycin-C</i>	20 mg/m ² intravenous every 4-6 weeks	Local inflammation, marrow suppression.	Ca of stomach, cervix, colon, breast
	<i>Mutamycin</i>			
Enzymes				
L. asparaginase depletes L. asparagine availability: inhibits protein synthesis	<i>L. asparaginase</i>	6000 IU/m ² intravenous	Allergy; coagulation defects. Pancreatitis	ALL
Nitrosoureas				
Inhibit nucleic acid synthesis	<i>Cyclohexyl chloroethyl nitrosourea (CCNU)</i>	100 mg/m ² oral every 4-6 weeks	Delayed marrow suppression	
	<i>Bis chloroethyl nitrosourea (BCNU)</i>	200 mg/m ² intravenous every 4-6 weeks	-do-	-do-
Hydrazine derivatives				
Damage DNA through peroxide formation	<i>Procarbazine (Methylhydrazine derivative)</i>	50-100 mg/m ² daily orally for 10-14 days	Myelosuppression	Hodgkin's
Imidazole derivatives				
Mechanism uncertain, probably alkylation	Dimethyl triazenomidazole carboxamide (DTIC <i>Dacarbazine</i>)	150-250 mg/m ² intravenous for 5 days repeated every 3 weeks	Myelosuppression	Malignant melanoma
			Hepatotoxicity	Hodgkin's sarcoma
Platinum complexes				
Inhibit DNA synthesis by intrastand crosslinking	Cis-diamino dichloro platinum. <i>Cis-platin</i>	100 mg in 500 mL intravenous once a week in 3-4 weeks	Renal toxicity, Ototoxicity	Ca of head and neck, lung, cervix, oavary
	<i>Carboplatin</i>	300 mg/m ² IV infusion every 28 days	Peripheral neuropathy	Advanced ovarian carcinoma
	<i>Oxaliplatin</i>	130 mg/m ² IV infusion	Thrombocytopenia	
			GIT toxicity	Colorectal and liver cancers
			Myelosuppression	

Contd...				
Group of drug and mechanism of action	Name of drug	Dose and route	Most important side effects	Indications
Hormones				
Androgens	Testosterone	300 mg weekly deep intramuscular	Virilisation	Ca of breast
Antiandrogen	Flutamide	750 mg oral daily		Advanced prostate cancer
Estrogens	Diethylstilbestrol	5-15 mg oral daily	Feminization	Ca of prostate
Estrogen linked to nitrogen mustard	Estramustine	140 mg oral		Advanced prostate cancer
Progestogens	Medroxy progesterone acetate (Provera)	300 mg daily orally	Withdrawal bleeding	Ca of breast and endometrium
Antiestrogens	Tamoxifen (Nolvadex)	20-30 mg daily orally	Vomiting	Breast cancer
Adrenocorticoids	Prednisone	40-60 mg/m ² orally/ day	Cushingoid features	ALL
Thyroxine	L. thyroxine sodium	0.1-0.3 mg daily orally	Hyperthyroidism	Ca. thyroid
Biological response modifiers				
Interleukin-2		6 lakhs IU/kg, IV every 8 hr × 5 days	Hypotension Fever	Advanced renal cancer, AML
Interferon-Alpha		1-2 million U/day		Hairy cell leukemia CML, Kaposi's sarcoma
GMCSF (Granulocyte Macrophage Colony Stimulating Factor)		250 mcg/m ² IV daily	Fever, bone pain, hypotension	
Adjuvants used in cancer therapy				
Levamisole (immunostimulant)		150 mg/d/oral		Useful in 5-FU treatment
Amifostine (Radioprotector)		900 mg/m ² IV	Hypotension infusion	Prevents hepatotoxicity of cis-platin; reduces mucosal toxicity of radiation
Pamidronate (Bone resorption inhibitor)		60-90 mg IV infusion	Fever	Osteolytic bone lesions; Paget's disease of bone
Dexrazone (Radioprotector)		500 mg/m ²	Myelosuppression IV infusion	Prevents cardiotoxicity of doxorubicin
All trans retinoic acid (ATRA) (Vesanoid)		45 mg/m ² daily oral	Hypervitaminosis	Induced cytodifferentiation; adjuvant in acute promyelocytic leukemia, germ cell tumours
13-cis retinoic acid		1-2 mg/kg daily oral for 3 months		Oral leukoplakia, basal cell carcinoma, T cell lymphomas

In may cases surgery or radiation is used as the first modality to reduce tumour bulk. This can be followed or preceded by chemotherapy (Table 7.5).

Chemotherapy

Chemotherapy is the sheet anchor of therapy in leukemias, advanced lymphomas, choriocarcinoma and other widely disseminated malignancies. It is combined with surgery in embryonal tumours and used as the primary treatment

in advanced cancers not amenable to surgery or radiation. The effectiveness of cytotoxic drugs is directly proportional to the doubling time of the tumours, and is inversely proportional to the number of cancer cells. Prior reduction of tumour mass by surgery or radiotherapy augments the effectiveness of chemotherapy. Cytotoxic drugs are non-selective and affect all cells which are in certain phases of their proliferative activity (Table 7.6).

Cell destruction by a cytotoxic drug follows the first order kinetics, i.e. it reduces a constant percentage and

put in larger values not a constant number of cancer cells. Thus the same dose which reduces the cancer cells from 10^8 – 10^7 is required to reduce them from 10^3 – 10^2 . It is difficult, therefore, to eradicate the last portion of any tumour by chemotherapy alone without serious toxicity. Surgery, radiation and chemotherapy leave residual tumour tissue even after completion of therapy. These cells are generally destroyed by the immunological system of the body, but if the immune mechanism is weak, the residual cancer cells rapidly multiply and produce recurrence. It should be remembered that both radiotherapy and chemotherapy depress the immune status of the individual. From time to time attempts have been made to stimulate the immune status of the individual by nonspecific immunostimulants such as levamisole or specific immunizing agents such as tumour antigens or modified tumour tissue. Tumour infiltrating cells and LAK (lymphokine activated killer cells) specifically active against tumour antigens were used with limited success in advanced solid tumours. Monoclonal antibodies (immunoglobulin of known specificity produced by single clone of hybrid cells) conjugated with toxins or radioactive isotopes were used in hematological malignancies.

Human interferon obtained by recombinant DNA technology has been successfully used in hairy cell leukemia, chronic myeloid leukemia, cutaneous T cell lymphomas and Kaposi's sarcoma. Interleukin-2 has been tried in advanced cancers, especially in renal cell cancers with success. Interferons and interleukins are described in Chapter 3.

Palliative Care and Pain Management

The care for terminally ill cancer patients include (a) control of symptoms, (b) control of pain, (c) treatment of psychological disturbances, (d) maintenance of quality of life, and (e) preparation for a decent death. Moderate to severe pain is associated with 80-90% of advanced cancers. The pain may be somatic (soft tissue origin; dull, aching localised type) in 40% cases; visceral (due to compression of tissues; deep and poorly localised) in 20% cases; neuropathic (due to infiltration of nerve; severe burning type) in 10% cases; or a combination in the rest of the cases.

Palliative care is the active total care of the patient and their families by a multiprofessional team at a time when the patient's disease is no longer responsive to curative treatment and life expectancy is relatively short.

SYMPTOM MANAGEMENT

Pain

‘Pain is what the patient says hurts’.
Pain is an unpleasant *sensory* and *emotional* experience associated with actual or potential tissue damage or

Factors Affecting Pain Threshold	
Threshold lowered	Threshold raised
Discomfort	Relief of other symptoms
Insomnia	Sleep
Fatigue	Sympathy
Anxiety	Understanding
Fear	Companionship
Anger	Creative activity
Sadness	Relaxation
Depression	Reduction in anxiety
Boredom	Elevation of mood
Mental isolation	Analgesics
Social abandonment	Anxiolytics
	Antidepressants

described in terms of such damage. In other words, pain is a somatopsychic phenomenon.

The aim of management of pain in terminal cancer cases is to render freedom from pain. Treatment of cancer pain includes: (a) treatment of the underlying cause, if possible; (b) analgesic drug therapy; (c) anesthetics; (d) neurosurgery and (e) psychiatric consultations. Out of this, analgesic drug therapy is the main choice. Here, the aim is to make adequate pain relief with minimum side effects. Drug dose is to be titrated to individual needs. The basic principle is summarised as “by the clock, by the mouth, by the ladder”. Drug doses are titrated to individual needs, and doses are given every 4-6 hours, by the clock. Administration by mouth is preferred.

The WHO three-step analgesic ladder is briefly shown below (Fig. 7.1 and Table 7.7):

1. Start with non-opioid drugs individually or in combination. If necessary, adjuvant drugs may be added. This form of therapy produces no tolerance or physical dependence. The first step will be sufficient in about 20-40% patients.
2. If pain persists, as the second step, mild opioids are started, along with non-opioid drugs, with or without adjuvant drugs. Taper the opioid dose slowly, reduce by 25% every 2 days, until a suitable dose is reached. This strategy will be useful for another 20-40% patients.
3. If pain still persists, as the third step, strong opioids are used, along with non-opioids and adjuvants. Oral route is preferred, but severe pain may need continuous subcutaneous or intravenous administration.

Fig. 7.1: The World Health Organization 3-step analgesic ladder

4. As a last resort, as the step four, anesthetic drugs may be employed. Further, nerve block or even nerve root ablation may be tried. Metastasis in bone may produce severe pain, which may be treated by osteoclast inhibitors such as biphosphonate compounds (etidronate, 60 mg biweekly; pamidronate, alandronate), gallium nitrate, strontium and calcitonin (25 IU per day). Corticosteroids are used especially in pain associated with spinal cord compression.

TABLE 7.7

Drugs used to control pain in palliative care

1. Nonopioid drugs (oral administration)
Paracetamol, up to 4 g/day in divided doses
Naproxen, up to 1 g/day in divided doses
Ibuprofen, maximum 2 g/day in divided doses
Diclofenac, 50 mg 6 hourly
Ketorol, maximum 100 mg/day in divided doses
Aspirin, 500 mg 4 hourly (maximum 4 g/day)
2. Mild opioids (oral administration is preferred)
Codeine, 200 mg 6 hourly
Propoxyphene, 100 mg 6 hourly
Oxycodone, 30 mg 6 hourly
Tramadol, 50 mg 6 hourly
Buprinorphine (sublingual, not freely available)
3. Strong opioids
Morphine 30 mg/day, orally, in divided doses
Methadone, 10 mg orally (useful in morphine dependence)
Fentanyl, 25-100 mcg/hour, transdermal patch
Pethidine (Meperidine) 75 mg intramuscular
4. Adjuvant drugs
 - a. Antidepressants:
Amitriptyline, 50 mg at night
Benzodiazepines, diazepam, 10 mg at night
 - b. Antiemetics:
Domperidone, 30 mg/day
Metaclopramide, 3-5 mg/kg/day
Ondansetron, 8 mg/4 hourly
 - c. Anticonvulsants:
Carbamazepine, 200-400 mg/8 hourly
Sodium valproate, 200 mg/8 hourly
 - d. Corticosteroids, prednisolone, 15-30 mg/day or higher doses
5. Anesthetics:
Local anesthetics
Nerve block (peripheral, epidural, intrathecal)
Lumbar sympathetic/stellate ganglion block
Nerve root ablation (rhizotomy)

8

Organ Imaging Techniques

K.V. Krishna Das

Chapter Summary

Radiology 68
Ultrasonography 69

Isotope Imaging 69
Computed Tomography (CT) 70
Magnetic Resonance Imaging 70
Positron Emission Tomography 71

Deeper tissues in the body have been studied by different methods from time-to-time. Visualisation of organs and tissues by imaging techniques have reached a high degree of technical perfection. Production of newer machines and provision of more advanced facilities to help the physician to assess the state of the various organs with further precision and at greater speed with loss of discomfort to the patient, have been taken up by the industry. The subject of imageology has established as a major speciality in all modern medical establishments in India and abroad. The forerunner in this field is the introduction of X-rays and radiological procedures in the early part of the last century.

RADIOLOGY

The most time-honored and well-established method of imaging is radiology, which employs X-rays. Shadows cast on the photosensitive film by different tissues vary in density and this principle is used in interpreting the radiographs. Different techniques like plain radiography, contrast radiography, and tomography are employed. Radiological imaging gives details about anatomical and structural alterations in an organ e.g., foreign bodies in the bronchi, consolidation of the lungs, cardiac enlargement, abnormalities of bones, etc. Both the anatomic abnormalities and physiological functions can be studied by techniques using contrast radiography, e.g., *barium swallow*, *barium meal follow-through*, *cholecystography*, *contrast urography*, etc. Angiography elegantly reveals the vascular supply of an organ. Apart from visualizing occlusion and aneurysms, the vascular pattern gives indirect evidence of tumours, space occupying lesions and also the functional state of the organ. Angiography has been extensively applied in cardiovascular, neurological, renal, hepatic and other disorders. Angiography has been used with other methods like *computerized tomography* to improve the resolution of details further. Angiography has been applied to the arteries, veins and lymphatics.

A new development in the field is interventional radiology in which investigative or therapeutic procedures are done under radiological control. The technique is highly sophisticated, demanding very great skill and perfect team work. A few classical examples of *interventional radiography* are endoscopic retrograde cholangiopancreatography (*ERCP*) with removal of pancreatic or biliary calculi, renal artery dilation through a renal artery catheter, relief of coronary occlusion using a balloon catheter in the coronary artery, and use of devices such as vortablator, stents, and laser procedure.

Radiology is still a standard technique of imaging since this investigation answers many of the questions. Moreover, its universal availability and relatively low cost have helped to make it the most acceptable investigation.

only about 1/100. Repeated exposures lead to cumulative toxicity. Despite this the benefits arising from radiological procedures far outweigh the risk. Still it is prudent to avoid exposure to X-rays during early fetal development.

Chest X-ray remains the primary investigation of pulmonary, cardiovascular and other thoracic lesions involving the soft tissues and skeleton. Plain radiographs of the abdomen in different positions provide reliable evidence of visceral perforation, intestinal ileus, megacolon and abnormalities of solid organs.

Intravenous urography, retrograde urography and cystography have been replaced to some extent by ultrasonography, but still they are employed frequently before surgical procedures. Cholecystography has been almost replaced by ultrasound investigations. Contrast bronchography using iodinated dyes has been replaced to a large extent by computed tomographic and MRI procedures.

Conventional angiography using radiocontrast dyes is still the gold standard for detecting abnormalities of vascular lumen, e.g. coronary angiogram. Digital subtraction angiography (DSA) has modified the procedure to a great extent and made it less invasive and more diagnostic, in some situations. Barium contrast examination as a diagnostic procedure for esophageal gastric, duodenal and upper intestinal lesions has been replaced to large extent by endoscopy. Endoscopy gives direct visualisation and facilities for biopsy and therapeutic interventions. Barium procedures still hold their position where the motility of the gut structures, transit time of ingested material, multiple polyps, diverticulitis, foreign bodies, fistulisation and functional abnormalities are to be demonstrated. Barium enema procedures, especially double contrast enema are done frequently for the diagnosis of colonic lesions.

Though conventional radiography is noninvasive, contrast studies are invasive in varying degrees. X-ray contrast media fall under two categories—ionic and non-ionic, all containing organic compounds of iodine. When dissolved in water, the former dissociates into anions (benzoic acid) and cations (Na^+ , Ca^+ , Mg^+ or methyl glucosamine⁺). Their osmotic activity is 7 times that of plasma. The non-ionic agents do not dissociate in solution and therefore their osmotic activity is only 2.5 to 3 times that of plasma. Ionic contrast media are much more toxic, but less expensive. Toxic complications are caused by osmotic activity and chemotoxic effects. Osmotic effects give rise to feeling of warmth during injection, vasodilation, hypotension and rigidity to the erythrocytes. Chemotoxic effects lead to inhibition of enzymes, hemorrhagic states, neurotoxicity, renal failure and others. Contrast agents such as iodixanol which is a third generation isosmolar non-ionic iodinated dye is safer with less of nephrotoxicity.

The exposure to diagnostic X-rays, though small quantitatively, adds to cumulative irradiation received by the subject. It is well known that irradiation of the fetus *in utero*, especially during early pregnancy can be harmful to the baby. So also repeated radiographic studies can give cumulative toxicity due to X-ray. Though the dose and the field of exposure have been considerably reduced in modern machines, this risk should not be taken lightly and radiological studies should be undertaken only if properly indicated. Many radiological techniques are supplemented by the newer imaging techniques like ultrasonography, isotope scanning, computerised tomography, nuclear magnetic resonance and positron emission tomography.

ULTRASONOGRAPHY

This uses ultrasound which is nonionizing. The advances in this technique over the past two decades have been phenomenal. The earlier machines used '*M*' mode echography subsequent ones employed real time and two dimensional echography. Further improvements in technique such as colour coding, three-dimensional studies, and computerization have been introduced. Ultrasonography has been employed in the imaging of almost all organs, such as heart, abdominal and pelvic organs, retroperitoneal tissues, thyroid, scrotal structures, intracranial structures and others.

Ultrasonography is the method of choice in the diagnosis of jaundice where other diagnostic methods have failed to distinguish between medical and surgical jaundice. In kidney it distinguishes cysts and hydronephrosis from tumours. Abdominal masses can be distinguished with reasonable accuracy, so also the distinction of aortic aneurysm from other masses. Investigation of thyroid lesions employs ultrasonography very often.

Most widespread use of ultrasonics is in cardiological diagnosis. Ultrasound studies are the most valuable noninvasive methods for the study of anatomic abnormalities of pericardium, heart chambers, heart valves, cardiac muscle, and great vessels. Function of the myocardium can be assessed by echocardiography. Doppler ultrasound which uses the principles of reflection or scattering of the ultrasonic waves by moving objects, is used to assess the blood flow in superficial vessels. Advent of ultrasonography has obviated the use of invasive techniques like angiocardiography in many instances.

The practical management of obstetrics has been considerably influenced by the use of diagnostic ultrasound. *In vivo* measurement of fetal head diameter helps in assessing fetal maturity and growth. Diagnosis of early pregnancy and fetal abnormalities and location of the placenta are easily done with this technique.

Several additional facilities and newer probes have been introduced. These include:

1. Use of Doppler studies to assess the hemodynamics in the heart and major blood vessels, peripheral arteries and veins.
2. Use of colour coding to detect and quantify abnormalities of blood flow in the heart and arteries.
3. Use of esophageal probe during echocardiography to visualize the posterior chambers in the heart.
4. Intravascular probes mounted on suitable catheters, which can make direct observations of vascular lumen, thrombi, etc.
5. Vaginal probes which help to delineate abnormalities of the pelvis, tubo-ovarian structures and uterine cavity from different positions.

Ultrasonographic localization of hepatic abscesses, tumours, thyroid nodules, and cystic lesions, help to direct aspiration needles more accurately on to the target and thus get more reliable information.

Newer technological advances include high definition imaging, wide range of transducers, tissue specific imaging, harmonic imaging, integrated image management and use of contrast agents.

ISOTOPE IMAGING—NUCLEAR MEDICINE

Isotope imaging is based on the use of ionizing radiations emitted by radioactive isotopes administered into the system. The metabolic pathways taken up by the isotope are studied. Several isotopes are available, emitting different radiations and the appropriate radioactive source is employed for visualizing different organs e.g., ^{131}I for thyroid, $^{99\text{Tm}}$ technetium for brain, liver and kidney, ^{201}Tl thallium for myocardium, etc. Radioactivity is quantitatively recorded. The procedure is generally non-invasive. The radiation dose is kept small, so as not to produce a health hazard. Isotope images do not depict detailed anatomic structures, they are much more of a functional nature. If purely anatomical information is sought, isotope imaging is not the method of choice, but if the clinical problem requires an answer in terms of evaluation of function, then isotope imaging is the ideal. If demonstration of widespread metastatic lesions is desired isotope imaging is the method of choice, since whole body imaging can be simultaneously done and a total picture obtained. The patient can be followed up with repetition of the tests.

Some important techniques include the detection of pulmonary emboli, ventilation-perfusion studies of the lungs, assessment of thyroid function, studies on erythropoiesis and red cell life span, imaging of the liver, kidneys and brain, and study of the state of the myocardium in ischemic heart disease. Isotopic imaging is more sensitive than radiography in detecting early bone metastases. For brain lesions isotope scanning is less sensitive than computerised tomography. Functional imaging of the brain using isotopes has a clinical role in assessment of suitability for epilepsy surgery.

In the investigation of jaundice, ultrasonography is more rewarding than isotope studies.

The isotopes used in small doses in conjunction with monoclonal antibodies help to locate tumours and other lesions, *Immunoscintigraphy* is an accepted diagnostic tool with a high degree of sensitivity and specificity. Quantitative autoradiography studies can be integrated and correlated with positron emission tomography to study the distribution and function of cellular receptors. These areas are being actively investigated and expanded particularly in the field of tumour diagnosis and management.

COMPUTED TOMOGRAPHY (CT)

Godfray Hounsfield, an English physicist discovered computed axial tomography (CAT) in 1972.

The principle of this technique is that the resistance offered by different tissues such as skull, brain, CSF and blood vessels to the passage of more than thirty thousand, 2-4 mm beams of X-rays directed horizontally at different horizontal planes of the brain are computed and revisualized.

The differing densities caused by different tissues are clearly distinguishable in the resultant picture. The technique is noninvasive. The final picture gives an anatomical reconstruction of the part to be studied. Use of contrast agents such as metrizamide serves to bring out lesions more clearly. This technique has been most frequently used in the investigation of neurological disorders. Hemorrhage, tumour, abscess, softened and edematous areas, and blood vessels can be identified. Precise size and shape of the ventricles can be assessed.

Indications for CT scanning include traumatic lesions, stroke, space occupying lesions, spontaneous intracranial hemorrhage, arteriovenous malformations, hydrocephalus, herpes encephalitis, parasitic cysts, epilepsies, etc. Supratentorial lesions are detected more easily by CT scanning. Being a noninvasive method with high diagnostic efficiency, many invasive investigations like angiography and ventriculography can be avoided if CT scanning is undertaken as a primary investigation.

Machines are available for the examination of all parts of the body (*whole body scan*). This is a very useful non-invasive method to detect intrathoracic, intra-abdominal and pelvic lesions and to detect solid from cystic masses.

CT scanning exposes the patient to ionising radiation. Modern machine use X-ray source which sweeps 360°. Spiral CT is an advancement, which has reduced the imaging time to less than a minute (the earlier machines take several minutes). The requirement of contrast agent is also much less. Magnetic resonance imaging (MRI) is a technique which developed after the introduction of CT. Though it has several advantages over CT, CT still stands out as the investigation of choice in several specific situations.

MAGNETIC RESONANCE IMAGING (MRI)

The production of images depends on magnetic properties of the hydrogen ions (protons) in the nucleus and radiofrequency pulses. Also known as magnetic resonance (MR), this technique utilizes the phenomenon that the nuclei which contain water and other elements behave like magnetic dipoles and possess magnetic fields of their own. Each nucleus is spinning like a top in its magnetic field. The magnetic fields of different nuclei are in different directions. When a strong magnetic field is applied to this system all the nuclei tend to align parallel to the induced magnetic field. If at this stage a burst of radiofrequency is delivered to the tissue, the spinning nuclei are tilted or made to precess to 90° or even 180°, depending on the strength of the radiofrequency. After cessation of the induced magnetic field the precessed nuclei resume their original position. In doing so they emit the absorbed radiofrequency, which can be detected by suitable detectors arranged all around the organs under study. The energy given out in relation to the space is called "*spin-lattice time*" (T1) and that in relation to its own spin is called "*spin-spin time*" (T2). Using these parameters, the computer reconstructs the organ. All parts of the human body can be imaged by magnetic resonance imaging (MRI). Vertebrae, intervertebral discs, eyes, knee joints, upper and lower pelvic regions, and many other tissues can be clearly studied.

In the brain MRI can distinguish between grey and white matter, and thus detect plaques of demyelination in life, which was possible only by biopsy or autopsy. Posterior fossa lesions which are less clearly visualized by CT due to bone artifacts can be seen quite clearly by MRI. Due to this advantage, techniques such as pneumoencephalography and angiography can be avoided. MRI has been very useful in imaging CSF spaces, spinal canal, spinal cord, vertebral column, intervertebral discs, etc. without interference from surrounding bony structures.

In the case of liver, MRI provides detailed informations not available by other noninvasive methods. Various parenchymal liver diseases can be distinguished. The myocardium can be visualized without contrast medium, so also the cortex and the medulla of the kidney can be differentiated. MRI is rapidly enlarging in its scope and usefulness. MRI is capable of imaging the products of conception. No untoward reactions have been reported so far. Still it is used only with caution to delineate maternal parts like the uterus and cervix or the fetal anatomy.

Several newer facilities have been added on to conventional MRI studies. *MRI angiography* can delineate the vasculature in the brain without direct puncture of any major artery. *Chemical imaging* is a technique employed to identify intracytoplasmic lipids within the adrenal

cortex. This helps to distinguish adenomas from cancers. *MRI spectroscopy* gives information about cellular metabolism.

Functional MRI of the blood- oxygen level dependent (BOLD) contrast is increasingly used to lateralize language area before neurosurgery and to predict deficits in the temporal lobe before surgical resection.

MRI is devoid of the risk of exposure to ionizing radiation. Due to the powerful magnetic field, susceptible metal parts may be attracted by the magnetic source. This danger has to be taken care of. Implanted gadgets such as pace makers, metallic prosthesis and others should be taken into account before deciding upon MRI.

MRI machines are now available in India in several centers and in within reach in many towns.

The technology of CT scan is utilized also in MRI scans. The latter gives greater differentiation between tissues, such as the grey and white matter of the brain, renal cortex and medulla and so on. Ionising radiations are not used and therefore the risk to the patient is less. Both CT and MRI can study tissue sections as thin as 1 mm or even less. Pictures in all planes—sagittal, coronal and axial can be obtained. MRI is generally the more rewarding imaging modality for neurological diseases. MRI spectroscopy and diffusion/perfusion imaging are improvement on the parent modality.

POSITRON EMISSION TOMOGRAPHY

Syn: PET

Substances such as radioactive fluorine, oxygen, rubidium, etc. are positron emitters. Positrons are positively charged electrons. When positrons collide against electrons and annihilation takes place, two photons (or X-ray particles) fly out in opposite directions from this meeting point.

PET which is a sophisticated isotopic technique depends on isotopes with short half-lives and very high release of energy. These have to be prepared fresh in a cyclotron which forms part of the equipment. Commonly used isotopes for PET are ^{11}C (half-life 20 minutes) ^{15}O (2 minutes) and ^{13}N (10 minutes) and ^{18}F .

The principle of PET is to give positron emitters systemically and the photons emitted by the organ under study are detected by an array of detectors. Detection of these rays permits the reconstruction of the tissue

distribution of the tracer radionuclide through the organ, or in the body. By computer techniques the source and pattern of these photons can be reconstructed to give an image which lacks in anatomical details, but gives functional details. ^{18}F -labelled deoxyfluorine or other isotopes are given to the subject and metabolic function of the brain such as glucose utilization can be studied. Metabolic alterations in tumours can be detected. PET can distinguish between viable tumour tissues and necrosis and fibrosis after treatment of cancer. It can detect recurrence of tumour and metastases early. Dynamic changes occurring in brain metabolism can be followed up by serial studies.

Single Photon Emission Computed Tomography (SPECT)

This technique utilizes single gamma rays emitted by other radionuclides such as $^{99\text{m}}\text{Tc}$, ^{123}I and ^{111}In . Photographs are taken by a gamma camera and the distribution of tracer in the organ is visualized.

PET and SPECT can be employed to study the abnormalities or regional blood flow and metabolic derangements in the brain.

PET provides information on the biochemical processes. In addition to studies on cerebral blood flow and metabolism, PET is used for studies on the heart, distribution of receptors and others. PET is to be used complementary to CT scanning and nuclear magnetic resonance imaging, which provide excellent morphological details with pathological information as well. SPECT is useful in identifying epileptic foci in the brain and this may be needed in intractable cases where other methods fail to locate the lesion, especially so if surgery is necessary.

There are only a few PET machines available in India at present.

Diseases due to Arthropods Marine Animals and Snakes

9. Myiasis	74	11. Snake Bite	80
10. Arthropod Bites and Stings and Injuries due to Marine Animals	76		

Chapter Summary

General Considerations	74
Cutaneous Myiasis—Ectoparasitic	74
Deep Tissue Myiasis	75
Ophthalmic Myiasis	75
Intestinal Myiasis	75
Urinary Myiasis	75

General Considerations

Invasion of tissues or body cavities by the larvae (maggots) of dipterous flies is called myiasis. Myiasis may be of either primary or secondary type.

In primary myiasis the human infection occurs as part of the obligate life-cycle of the parasite and in secondary myiasis the human infection is accidental. Primary myiasis affects persons in good general health, whereas secondary myiasis supervenes on dead or necrotic tissues.

Classification: In general, the infection is of two types:

1. *Ectoparasitic, Auchmeromyia leuteola*,
2. Endoparasitic.
 - a. Cutaneous, e.g., caused by *Dermatobia hominis* and *Cordylobia anthropophaga*,
 - b. Tissues or cavities, e.g., caused by *Sarco-phaga*, *Wohlfartia*, *Fannia*, *Oestrus*, *Chrysomia*, and *Callitroga*.

The maggots are dull white or pink in colour, actively motile and have spines on their body. The body is tapered and segmented, the narrow anterior end bears the mouth parts, the thicker posterior end bears the opening of the spiracles which are dark coloured and useful in identifying the genera. Their length varies from 0.5 to 3 cm. The larvae feed voraciously on tissues or discharges and in 2 to 4 weeks develop and fall off to the ground to pupate.

Final identification of the species can be done by allowing the larvae to complete the life-cycle *in vitro* and examining the adult flies.

Cutaneous Myiasis—Ectoparasitic

***Auchmeromyia leuteola* (Congo maggot fly)** This fly lays eggs on soil and crevices in the floor. The larvae hatch out in 2 days. They can survive drying and starvation upto one month. Once hatched out, they attach themselves to the skin of the humans who sleep on the floor unprotected, suck blood for 20 minutes and drop off leaving maculopapular lesions. This process is repeated several times before the larva pupates in 2-12 weeks. Bites can be prevented by protective clothing or insect repellents like dimethylphthalate or N-N diethyl benzamide.

Localised Cutaneous Myiasis

***Dermatobia hominis* (Human bot fly or warble fly)** The adult fly lays eggs on hematophagous insects like mosquitoes, stomoxys and ticks or others such as housefly (*Musca*). When the latter alights on man, the larvae hatch out and wriggle on to the surface. They enter through the wound, produced by the insect or penetrate the unbroken skin and develop in the subcutaneous tissues.

The initial lesion is papular and pruritic. It becomes furuncle-like and painful later. The posterior end of the actively motile larva may be seen in the lesion through the opening. In 2-3 months the larvae mature and fall off to the ground. Lesions are seen on the exposed parts. The disease is worldwide in distribution.

***Cordylobia anthropophaga* (African tumbu fly)** The adults lay eggs on clothes spread out for drying or in dirty soil.

The larvae develop in 24-48 hours and penetrate the human skin either from the clothes or through the bare feet.

The lesion is initially papular and pruritic and becomes painful in a short time. Secondary infection may occur. Unlike the former, the life-cycle is shorter and is completed in 2-3 weeks.

Treatment The maggots may be extracted surgically. A drop of mineral oil placed on the lesions suffocates the

larvae which wriggle out and can be extricated. Penicillin in usual doses should be used to prevent secondary infection.

Migrating lesions resembling cutaneous larva migrans are produced by the larvae of genus *Gastrophilus* (*horse bot flies*) and *Hypoderma* (*cattle bot flies*), which develop from eggs laid on the hairs. Man is an accidental host and the larvae penetrate the skin, enter the subcutaneous tissues and wander producing eruptions similar to larva migrans of *Ancylostoma braziliense*, but more painful. They survive for a few weeks and die. Application of mineral oil over the lesions helps to visualize the underlying larvae. Tissues of the eye may be affected. In addition to surgical removal, symptomatic relief may be obtained by antihistamines.

Deep Tissue Myiasis

Larvae of the flies belonging to the families *Callitroga* (*Cochliomyia*), *Chrysomya*, *Sarcophaga*, *Wohlfartia*, *Fannia* and *Oestrus* invade tissues extensively when the eggs are laid on open wounds, damaged tissues or discharging surfaces, by the adult flies. The larvae of *Wohlfartia* can penetrate even unbroken skin.

The lesions are commonly seen in the nasal cavities, paranasal sinuses, middle ear and orbit. Cartilage and bone may also be destroyed by the screw-shaped larvae which may extend intracranially leading to fatal meningitis. The lesions are very painful and the larvae may be discharged from these sites.

Treatment is manual removal of larvae or extraction after spraying the area with chloroform. Repeated sessions may be necessary.

Secondary infection has to be treated with broad spectrum antibiotics like ampicillin.

Ophthalmic Myiasis

Flies of the genus *Chrysomya* and *Oestrus* may lay their eggs in the conjunctival sac. The larvae hatch out and produce lesions resembling acute conjunctivitis with severe irritation. Rarely corneal ulceration and loss of sight may occur.

Removal of the maggot after anaesthetising the eye and application of topical antibiotic drops will relieve the condition.

Intestinal Myiasis

The larvae or pupae of *Musca*, *Fannia*, *Sarcophaga* and *Tubifera* may be passed in stools or appear in vomitus. The eggs may be laid by the flies around the lips or anus while sleeping, especially if there are foul smelling discharges around these orifices.

The larvae hatch out from a few hours to two days and are swallowed to reach the upper gastrointestinal tract or they may crawl up into the rectum and large intestine. They develop in the stomach or in the intestines. Sometimes larvae may be swallowed along with infested foodstuffs. The larvae cause symptoms of gastritis or colitis which may persist from weeks to months. If reinfection does not occur, the condition is self-limiting.

Treatment consists of administration of purgatives and reassurance about the self-limiting nature of the illness.

Urinary Myiasis

Larvae of *Muscae*, *Fannia* or *Sarcophaga* may enter the bladder, when the eggs are laid around the external genitalia and produce symptoms of lower urinary tract infection with proteinuria, pyuria and hematuria. The larvae may pass in urine. Rarely urinary system may be involved by maggots eroding their way from the gastrointestinal tract.

Arthropod Bites and Stings and Injuries due to Marine Animals

K.V. Krishna Das

Chapter Summary

- Spider 76
- Scorpion 76
- Bees, Wasps and Hornets 77
- Centipedes 77
- Ants 77
- Lice 78
- Ticks, Tick Paralysis 78
- Chigoe Flea 79
- Injuries due to Marine Animals 79

Spider

Nearly 40000 species of spiders have been identified worldwide. A few are poisonous and aggressive. Reliable information can be obtained from local inhabitants. Several species of spiders bite man accidentally. Some species like *Latrodectas mactans* (black widow spider) attack man (Fig. 10.1). Females are more aggressive and venomous compared to males. The venom is generally neurotoxic, sometimes, also hemolytic. The bite is followed by intense local pain and the part becomes tender and spastic. Generalized muscular rigidity especially marked over the abdomen, pupillary constriction, salivation, excessive sweating and cardiovascular collapse

Fig. 10.1: Black widow spider

may follow. Death may occur in children and debilitated subjects. Spiders of the genus *Loxoscelles* seen in the tropical regions of several countries cause necrotic ulcers at the sites of bite.

Treatment consists of washing the area of bite with soap and water. Administration of 20 mL of calcium gluconate intravenously relieves muscle spasm. Muscle relaxants like mephenesin in a dose of 1 g orally and anticholinergics like atropine (0.5 mg given intravenously) give symptomatic relief. Supportive measures are indicated if shock supervenes.

Specific antivenene is available in S. American countries, but not in India.

Scorpion

Scorpions are nocturnal in habits and they come out at night to catch insects as their prey. These are killed by injecting the poison by the sting arising from the poison gland situated at the posterior end of the tail like abdomen. Nearly 1000 species of scorpions belonging to six families are known. Among these some species belonging to the family *buthidae*, especially the red scorpions are capable of inflicting toxic sting which could be fatal. In India the *Mesobuthus tamulus* is one among the dangerous scorpions. Scorpion venom contains short chain peptides that affect the mechanisms of sodium and potassium channels in excitable tissues. The toxins are classified into α and β toxins. By acting on sodium potassium channels they lead to intense persistent depolarization of autonomic nerves with massive release of neurotransmitters from adrenal medulla.

The neurotoxic effects leads to a cholinergic stimulation followed by adrenergic stimulation resulting in tachycardia, hypertension, cardiac failure and pulmonary edema in 1-2%. ECG abnormalities may develop which clear up on recovery. Cerebral and cerebellar infarcts may develop. Other major effects include hemolysis, disseminated intravascular coagulation, myocarditis, motor paralysis and respiratory depression. Left ventricular dysfunction, which is reversible over varying periods is a sequel. At times dilation of the ventricle may persist.

There is intense pain, edema and redness at the site of sting. This is followed by tachycardia, sweating, salivation, and vomiting. In severe cases paralysis of the tongue and abdominal muscles, convulsions, and respiratory depression supervene.

Myocarditis manifesting as tachy or brady arrhythmias and cardiac failure may occur not unusually. Rarely, hemorrhagic states due to disseminated intravascular coagulation (DIC) may develop. Pancreatitis is a rare complication.

Treatment For local treatment the affected part is immersed in ice cold water and washed. In filtration of 5 mL of 2% xylocaine around the sting gives relief to pain.

General treatment consists in the management of anaphylactic shock, ventilatory support and prevention of cardiac death. The use of prazosin, an alpha blocker has revolutionized the management of scorpion stings. Oral prazosin given in a dose of 250 µg at 3 hours intervals for children and 500 µg three hourly for adults is life saving. Scorpion antivenene is available and it may be given in doses of 10-20 mL IV. This neutralizes the circulating venom. Acute pulmonary edema responds to general resuscitative measures and sodium nitroprusside given IV. Another drug which is also reported to be effective is captopril given in doses of 12.5-25 mg thrice daily orally. Physical activity should be permitted only after adequate convalescence and normalization of the ECG.

2. Krishnan A et al ibid pp 22-6.

Bees, Wasps and Hornets

These insects abound in many parts of India and other tropical and temperate regions, especially during the flowering season. Multiple stings, especially over the face, are serious. During the sting, the stinger which is the modified ovipositor at the posterior end of the abdomen is inserted into the skin and the venom is discharged. In the case of bees, the stinger is left behind in the skin and injection of the venom continues for a few minutes even after the insect has left. The toxic components include phospholipase A2, histamine, bradykinin, acetylcholine, dopamine, serotonin, mast cell de-granulating peptide, hyaluronidase and mellitins.

The venoms of bees and wasps differ from each other even though the main allergenic components are common. The composition of the venom may vary seasonally. In the case of allergy to bees most of the antibodies are directed towards phospholipase A2.

In the case of wasp venom antigen 5 is the specific component towards which IgE is directed.

Initial symptoms consist of intense local pain, angioneurotic edema, respiratory obstruction, and

anaphylactic shock. Local tissue necrosis, intravascular hemolysis and renal failure may complicate a few cases. Delayed hypersensitivity reactions resembling serum sickness may occur after two or three weeks. Multiple stings, especially over the face are associated with considerable mortality. Wasp stings may cause bilateral ptosis and other upper cranial nerve palsies which respond to neostigmine, suggesting a myasthenia like reaction (RD Singh et al JI Asso Phys. India, 2003;51: 828-9).

Treatment In all cases, the local site should be inspected. The stinger should be removed by gentle scraping. Injection of adrenaline and corticosteroids and other supportive measures may be required to combat the anaphylactic reaction. Maintenance of the airway and ventilatory support are life-saving when the edema obstructs respiration. Specific antisera are available in some countries. Sensitized persons should avoid further exposure to these insects and wear protective clothing when so exposed. Auto-injecting pen syringes loaded with 0.15 or 0.3 mg of epinephrine are available for instant use- Desensitization by repeated injections of the venom can be done in persons likely to be exposed to the risk occupationally.

Centipedes

Syn: Chilopoda

Several species of centipedes are seen in warm climates. They vary in length from a few centimeters up to twenty centimeters, the larger ones can affect painful bites on man. The poison glands are situated at the anterior end and the poison is injected through the claws on the mandibular legs during the bite. Centipedes hide under clothes or bedding and bites are accidental. Bite mark may be visible as a pair of tiny red spots separated by a few millimeters. Symptoms consist of local pain lasting for 2-4 hours, edema, redness and enlargement of the draining lymph node. Headache, vertigo, vomiting and fever may follow. Centipede bites are usually not fatal.

Treatment Treatment consists of antihistamines, analgesics and reassurance. Infiltration of 2% xylocaine locally gives immediate relief of pain.

Ants

Certain species of fire ants belonging to the genus *Solenopsis* inflict bites on the skin and also introduce the poison through the stinger situated at the posterior end of the abdomen. Local irritation and allergic reactions follow.

Ants may colonize in the bed clothes of debilitated patients, newborn babies and comatose subjects and eat away superficial tissues producing shallow ulcers. When large numbers are involved tissue loss may be considerable. This can be avoided by exerting care in nursing

chronically bedridden patients and dusting 10% DDT powder under the cot and beds.

Lice

Lice, belonging to the family *Pediculidae* cause pediculosis in man. Their bodies are flattened and their mouth parts which are retractile are intended for piercing and sucking. The legs are provided with single claws which enable the insect to cling to hairs or clothes. The posterior end of the male is rounded and that of the female is notched. Lice are worldwide in distribution.

Head louse (*Pediculus humanus capitis*) is found on the head, the body louse (*Pediculus humanus corporis*) is found all over the body and clothes; the pubic louse (*Phthirus*) is seen over the pubic hair, eye lashes and sometimes all parts of the body as well. The eggs (nits) are glued to the hairs. The nymphs hatch out within 7-10 days. They reach adulthood after three moultings in two weeks and the fertilized females start laying eggs within a month. Each female lays a total of about 300 eggs. Life span is 4-6 weeks. Pediculosis leads to local irritation, pruritus, secondary infection and local lymphadenopathy of the posterior cervical group. Chronic infestation leads to pigmentation—Vagabond's disease.

Spread from person to person is by close contact, sharing of clothes or sleeping in the same room. Pubic louse may spread through sexual contact.

Lice leave the body when it cools down after death or when there is rise of temperature due to fever or physical exercise, and seek new hosts. By this process the body louse transmits typhus, trench fever and relapsing fever.

Treatment Benzyl benzoate 25% emulsion, applied to the scalp or other infested areas for a period of three hours, followed by a bath serves to kill the lice and the nits. Alternatively DDT 10% powder applied over the surface once a week for 3 weeks eliminates the infestation. Reinfestation from bedding and clothes should be avoided. Lice and nits on clothes can be killed by immersion in boiling water or use of a hot iron. All affected members should be treated simultaneously.

Topical insecticides such as permethrin, synergized pyrethrin and malathion are effective for preventing reinfestation. Resistance to the insecticide may develop. Ivermectin applied as a 0.8% weight to volume solution is highly effective if applied overnight.

The local custom of wet-combing of hair practiced in several communities is an effective and safe method of delousing.

Ticks

Medically important ticks belong to the families ixodidae (hard ticks) and argasidae (soft ticks). *Dermacenter*,

amblyomma, *rhhipicephalus*, *hemaphysalis* and *ixodes* are the hard ticks which are vectors of rickettsiae, borrelia, viruses and bacteria. Among the soft ticks *Ornithodoros* is the most important. It transmits *Borrelia recurrentis* and *Pasteurella tularensis*. Ticks crawl up and attach themselves to skin folds, insert their mouth parts into the skin and feed for 24-48 hours after which they fall off and undergo moulting. The site of bite may develop into an eschar which is an indolent necrotic ulcer.

- *Borrelia recurrentis* and *Coxiella burnetii* can be transmitted transovarially to the subsequent generations of ticks and hence an infected colony can act as reservoir of infection for prolonged periods. Ticks live for two years or more.

Tick Paralysis

This is a neurologic syndrome caused by a potent neurotoxin produced by female ticks which attach themselves to feed, particularly in the upper parts of the body, especially on the scalp, face or neck. *Dermacenter variabilis* and *D. andersoni* have been described from N. America. In Australia the main offender is *Ixodes holocyclus*. The ticks take 4-5 days to engorge fully and drop off. Mating with male may occur during this process and this leads to acceleration of the engorgement of the tick, fertilization of the ova and oviposition after falling off. The toxin of the tick is called ixovotoxin.

The neurotoxic venom causes impairment of nerve conduction, reduction of muscle action potential, inhibition of terminal nerve conduction and acetylcholine release at the presynaptic neuromuscular junction of muscle fibres. It may lead to total blockage of transmission at myoneural junctions.

Clinical Features

Children are more affected mainly on account of their lower body weight and greater susceptibility to tick infestation. Symptoms start with tingling sensations of extremities and weakness of limbs and trunk, ataxia of limbs and trunk and flaccid paralysis closely resembling Guillain-Barré syndrome. If the tick continues to feed this may progress to total flaccid paralysis demanding ventilatory support to maintain life. With the removal of the tick rapid resolution of symptoms occur and recovery may be complete within hours to days. Untreated, the condition can be fatal. Differential diagnosis includes Guillain-Barré syndrome, paralytic poliomyelitis, other forms of paralytic viral diseases, botulism, myasthenic reactions and others. Electrophysiology tests show reduced nerve conduction, reduction in muscle action potentials and neuromuscular block. The CSF is normal unlike as in Guillain-Barré syndrome and encephalomyelitis.

Fig. 10.2: 1. Hard tick 2. Soft tick

Diagnosis Strong clinical suspicion and careful search of the scalp and other parts of the body for attached ticks help to establish the diagnosis (Fig. 10.2). Its removal and supportive care during the period of paralysis are most rewarding. In Australia *Ixodes holocyclus* antitoxin is available for administration before the tick is removed.

Chigoe Flea

***Tunga penetrans*-Jigger** This is found in the feet or other exposed parts of body in people who walk bare-footed and with poor hygiene. The fertilized female burrows into the skin and produces painful itchy lesions. Secondary infection is common. Treatment consists of immersing the part in lysol baths, surgical removal of the fleas and antibiotics to combat secondary infection.

Injuries due to Marine Animals

Seabathers, fishermen or persons working under water may be stung by marine animals. Among these the most important are jellyfish, cone shells and stinging fish.

Jellyfish belonging to the class *Hydrozoa* (*Portuguese men of war*) and *Scyphozoa* are frequently found in coastal water in the sea, backwaters and riverine estuaries in all parts of India especially the eastern coast. They possess tentacles which may be several meters long and these bear nematocysts which contain poison and on contact with the human skin the contents are injected over a period of time. There is intense irritation followed by formation of wheals, vesicles and anaphylactic reaction. Sweating, abdominal pain and vasomotor collapse may occur. Rarely, the stings may be fatal due to cardiac and respiratory

failure. Treatment is to give intravenous calcium gluconate, adrenaline and glucocorticoids to combat the allergic reaction. If tentacles are left on the surface, the nematocysts must be inactivated by the application of dilute acetic acid (vinegar) for 30 seconds, concentrated sugar or salt solution before pulling out the broken tentacles. In some countries (Australia), specific antisera are available. The dose is 20000 IU given IV slowly.

Cone Shells (*Conidae*) are large marine snails found in the bed of lakes, coral reefs, and similar regions. The venom is neurotoxic and in severe cases death results from respiratory paralysis. Treatment is symptomatic. The spines on sea urchins may cause painful injuries.

Stinging Fishes Many species of fishes are capable of inflicting painful stings. Their dorsal fins contain spines connected to poison sacs. The spine may be broken and remain embedded in the victim. Intense local irritation occurs. In a few, neuromuscular symptoms may develop. Rarely respiratory paralysis may lead to death. Treatment is symptomatic and supportive. Immersion of the part in hot water may give relief of pain. In some countries specific antiserum is available.

Sting Rays These are common around the sea coasts and river mouths in tropical countries. Venom secreting tissue is situated in the grooves and sheaths of barbed horny spines seen on the dorsum of the tail. Stings are inflicted when these animals are trodden upon. Treatment is symptomatic.

Several animals inhabiting the sea effect dangerous and painful stings with the injection of poison.

These include the following:

Sting rays	Neurotoxic venom
Scorpion fish	Neurotoxic venom
Coelenterates including hydroids, jellyfish and anemones	Local effects and systemic toxicity
Sponges	Local pruritus
Sea urchins, Starfish	Myotoxicity
Bristle worms	Local pruritus
Molluscs and others	Curare like effect (paralysis)

Chapter Summary

Identification of Poisonous Snakes 80
The Venom 80
Clinical Features 81
Management 82
Prevention 84

Snake bite is a common emergency seen in almost all parts of India. Most of the bites occur in persons while engaged in agricultural operations or while walking in darkness. Snakes are found more frequently around dwelling houses, embankments, cultivated fields and in bushes. They tend to frequent places where they get their prey—rodents and frogs. Most of the bites take place in the rural areas though they do occur in towns also. About 15 to 20 thousand deaths occur in India due to snake bite annually. Most of the poisonous bites (80%) are due to *vipers* (*Vipera russelli* and *Echis carinatus*). Cobras (*Naja naja*) cause 10% and kraits (*Bungarus caeruleus*) 4%. Rarely, poisoning due to sea snakes is encountered (1%). Majority of bites are inflicted by non-poisonous snakes. The incidence of snake bites varies with the season in different regions.

Identification of Poisonous Snakes

- 1. They have large ventral scales covering the whole of the ventral aspect.
- 2. The mouth contains only one pair of poison fangs in the upper jaw, placed anteriorly (krait and cobra) or posteriorly (viper).
- 3. Presence of rows of small teeth is characteristic of non-poisonous snake.

Viper: The head is triangular with a narrow neck. The scales on the body and neck are small and of uniform size. *Vipera russelli* is larger, often grows to one meter in length and shows three rows of oval rings on the body, running along the whole length. *Echis carinatus* has overlapping saw-shaped scales covering its body and a broad

arrowmark on its head and two rows of wavy bands running longitudinally.

Pit vipers belonging to the family Crotalidae are less common in India. They show a depression between the nose and the eye, the loreal pit. Vipers have larger fangs which are tunnelled and the bite marks are more prominent. Often the snake hangs on to the limb and it has to be disentangled by violent movements.

Cobra: Cobra has an expandable neck and the head shows a single (monocellate) or double (binocellate) dark ring on the dorsum. The third supralabial shield touches the eye and nostril. When provoked, the head and neck are raised to form the hood. The fangs are small and anteriorly grooved.

Rarely, king cobras (*Naja hanna* or Hamdyard) may be seen in thick forests but bites by these deadly snakes are very uncommon. They grow to large size (often 3-4 meters) and unlike the cobra, they are unhooded.

Krait: Kraits show white bands on the body; those in the posterior part being more definite. The dorsal scales on the body are hexagonal. The head and the sides of the lower jaw are covered with large shields, the fourth shield on the lower jaw being the largest.

Sea snakes: Sea snakes are found in good numbers in the coastal waters of India. They show laterally compressed and flattened tails. The two common genera seen in the Western coast are *Enhydrina* and *Hydrophis* (Fig. 11.1).

Snakes bite when they are inadvertently trodden upon. Rarely, cobras may attack but they usually do so only during the mating season.

The Venom

Venom is modified saliva and 0.25 to 1 mL of it is injected into the victim when the snake bites. Enzymes such as phosphatidases, proteases, cholinesterases, hyaluronidases, ribonucleases, deoxyribonucleases, ophioxidase, lecithinase and erepsins are present in the venom. In addition, the venoms of cobra and krait also contain non-

Fig. 11.1: Identification of snakes

- A Small uniform head scale, narrow neck—viper.
- B Undersurface of mouth, the 4th inferolateral shield is largest—krait.
- C 3rd supralabial shield larger than the rest and touches the shields of the nostril and eye—cobra or coral snake.
- D Large head shields.
- E Deep pit midway between the nostril and the eye (Loreal pit)—pit viper.
- F Under surfaces of non-poisonous snakes—small belly & scales and moderately large transverse scales which do not reach the entire length.
- G Hexagonal row of spinal shields on the dorsum of krait.
- I Large ventral shields reaching the entire width of the body—poisonous or non-poisonous.

enzymatic components like basic polypeptides which are highly neurotoxic. These toxins produce neuromuscular block.

The viperine venoms contain hemorrhagic, necrotic, coagulant and hemolytic substances leading to extensive damage to several tissues. Lesions are due to intravascular coagulation, fibrinolysis, damage to the vascular endothelium and extensive necrosis. The venoms of sea snakes are neurotoxic and they also cause extensive necrosis of the muscles.

The speed of action of the venom depends upon the site of injection and the amount of venom injected. If the venom directly enters the bloodstream, the effect may be rapid and lead to sudden death. In most of the cases, the absorption of venom is slower and especially in viperine bites with extensive local reaction, considerable amount of venom may remain locally to be absorbed into circulation in due course.

The severity of envenomation depends upon the circumstances of the bite. Bites sustained during the early part of the night are generally more serious since the poison sacs of the snake are full at this time. Bites through clothes are less dangerous. Children and underweight persons suffer more than normal adults since the

concentration of the venom is relatively higher in them. Violent physical activity helps to disseminate the venom rapidly and this worsens the prognosis.

Clinical Features

Immediate response Severe fright and mental agitation leading to tachycardia, sweating, hypotension and even vascular collapse are prominent features soon after the bite. These nonspecific symptoms may be seen in all snake bites.

Local reactions Local reactions are more prominent in the case of viper bites and less so in others. Intense pain, swelling and violaceous discoloration develop within minutes and often serosanguinous fluid exudes from the fang marks. The edema and discoloration spread proximally and in a few hours vesicles and hemorrhagic blebs may appear. Rarely, gangrene may supervene (Fig. 11.2).

General effects These vary with the type of snake. Cobra and krait venom are predominantly neurotoxic, while those of vipers are histotoxic and hemorrhagic. Some degree of overlap does occur, especially during certain seasons of the year, cobra bites producing moderate or severe tissue necrosis and viperine bites leading to mild neuromuscular paralysis.

Cobra and krait bites Soon after the bite, the patient complains of a sinking feeling, drowsiness, blurring of vision, diplopia, dysphagia and dyspnea. Extraocular palsies and paralysis of palate, pharynx, tongue, and respiratory muscles supervene. The limbs show flaccid paralysis. Coma and death due to respiratory failure or shock may occur within 6-48 hours.

In some cases the clinical features may resemble acute myasthenic crisis. In the cases that survive, recovery starts in 12-24 hours and may be complete in 48-96 hours.

Fig. 11.2: Viper bite. Note gangrene of middle finger right

Viper bites: Within 3-4 hours of the bite, the hemorrhagic manifestations appear in the nature of extensive bruising, bleeding from the bitten part and injection sites, bleeding from the gums, epistaxis, blotchy purpura, hemoptysis, hematuria, hematemesis and melena. Bleeding may exsanguinate the patient and produce shock.

The blood is uncoagulable when taken in a test tube and estimation of coagulation time provides a fairly reliable side room test for the severity of envenomation and requirement of antivenin. Cardiac manifestations include tachycardia, myocarditis and cardiac failure. Electrocardiogram may show abnormal T waves and disturbances of conduction. Pulmonary edema and hemorrhage may develop.

Rarely, optic neuritis may develop leading to partial or complete blindness in 2-7 days. Delayed onset of optic atrophy has also been recorded. Blindness may also result from intraocular bleeding.

Renal changes Proteinuria and hematuria may develop within a few hours after the bite. In the majority of cases these subside with treatment. Acute renal failure may develop in 50-60% of cases with severe envenomation. This manifests in 3-7 days of the bite. The most frequent and dreaded complication is anuric renal failure developing as a result of direct nephrotoxicity of the venom, hypotension, disseminated intravascular coagulation, hemoglobinuria and reactions to the antivenom administered therapeutically. Lesions include acute tubular necrosis, hemorrhagic interstitial nephritis, and even glomerulonephritis. Shock aggravates the renal damage. In 10% anuria may supervene and persist demanding peritoneal or hemodialysis. In survivors renal sequelae are rare but salt losing nephritis, renal parenchymal calcification and membranous glomerulonephritis have been reported.

Death in viperine bite is due to shock, hemorrhages, secondary infection, renal failure or cardiac failure.

Long-term sequelae like panhypopituitarism may manifest 3-5 years after severe viperine envenomation. Pituitary apoplexy has been noted. Myxedema may develop rarely.

Krait venom is the most lethal on weight for weight basis. Manifestations are similar to that of a cobra bite but the local reaction at the site of bite may be minimal.

Since kraits are prone to come into dwelling houses and hide under clothes or other material, bites acquired during sleep and paralysis manifesting on waking up are more likely to be due to krait bites. Careful search of the premises may reveal the offender.

Sea snake bites are identified by the victims as sharp pricks. The local reaction may be insignificant. Signs of envenomation occur within one hour and initial symptoms consist of pain and stiffness of the muscles of the neck,

back and proximal parts of the limbs but rapidly becoming generalised. Trismus, ptosis, external ophthalmoplegia and paralysis leading to respiratory failure may follow. Proteinuria and myoglobinuria are seen 3-6 hours after the onset of symptoms. Death is due to respiratory paralysis or renal failure. If the victim survives, muscle weakness may persist for months.

The overall mortality of the poisonous bites is 10-15%.

Death in snake bites is due to: (1) paralysis of respiratory muscles, (2) upper airway obstruction, (3) cardiac arrest, (4) hypotension and shock, (5) severe bleeding including intracranial bleed, (6) renal failure and (7) septicemia.

Interval between the Bite and Time of Death

	Range	Mean
Cobra	30 minutes-60 hours	8½ hours
Krait	3-68 hours	18 hours
Russels' viper	2 hours - 9 days	2 days
Echis carinatus	1-41 days	5 days
Sea snakes	12-24 hours	variable

Management

The most important step is to start first aid, reassure the victim and to decide upon the need for specific antivenin. *Distinction between poisonous and non-poisonous bites* Information from the local inhabitants is very helpful in identifying the species.

Poisonous	Non-poisonous
1. Only two fang marks	Multiple teeth marks
2. Local reaction present	No local reaction
3. Evidence of systemic envenomation present	Only fright reaction

Proper first aid is vitally important to reduce envenomation and this plays a major role in subsequent treatment. The bitten part should be immobilized using an improvised splint, washed well with soap and water and a tight tourniquet applied nearest to the site of bite where there is only a single bone. This tourniquet should occlude the lymphatics and veins but not the arteries. Chilling the limb in ice reduces the rate of absorption of venom. Immediate hospitalization is required.

General treatment consists of reassurance, sedation with diazepam, treatment of shock, antibiotics to cover the infection, and immunization against tetanus and gas gangrene. Corticosteroids may be necessary to combat shock. Metronidazole in a dose of 500 mg intravenously every 8 hours is very useful in treating anaerobic sepsis which invariably accompanies the snake bite.

Specific Treatment

Specific treatment is to administer anti-snake venom (ASV) which should be given only if signs of envenomation are definite or if the snake is identified to be definitely poisonous. The ASV available in India is made by Haffkine Biopharmaceutical Corporation Ltd, Bombay, and the Central Drug Research Institute, Kasauli. It is polyvalent. 1 mL of reconstituted ASV can neutralize 0.6 mg each of cobra, krait, Russell viper, and saw scaled viper venoms. It is prepared from sera of horses hyperimmunized with the venom and is available as the lyophilized product with the diluent.

Once reconstituted, the ASV has to be used immediately since it rapidly loses its potency. Being made from horse serum, it has to be tested for anaphylaxis by the intradermal and intravenous methods before administration and the product instructions should be carefully followed.

The total dose of ASV depends on the severity of envenomation.

Dose of ASV

Mild envenomation	3-5 vials
Moderate envenomation	5-10 vials
Severe envenomation	10-20 vials
Very severe envenomation	20-40 vials

ASV is given intravenously as a drip or slow push doses.

Children and underweight persons require the same dose of ASV as for the normal adults.

In cases allergic to horse serum, ASV may have to be withheld. In such cases desensitization may be done by injecting small quantities of ASV under cover of corticosteroids, before administering the full dose.

Local treatment The tourniquet should be released after systemic administration of antivenom. Wound toilet and protective dressings must be done. Incisions, suction, drainage and local instillation of ASV which used to be in vogue earlier are not undertaken. With adequate dosage of systemic ASV such aggressive measures can be avoided.

Guidelines for repetition of ASV Clotting and clot retraction can also be employed to assess the adequacy of ASV in viperine bites. Antivenom administration is adequate if the clotting time is within 20 minutes, the clot retraction is complete within 6 hours and the serum is straw coloured. If clotting time is prolonged beyond 20 minutes a further 10 vials may be needed. If clotting time is below 20 minutes but clot retraction is poor after 6 hours, a further 5 vials of ASV are needed. If clotting and retraction are normal, but the serum is red, two vials have to be given further.

For neurotoxic bites, since there is no laboratory parameter to monitor treatment, higher doses are often

Fig. 11.3: Cobra bite with myasthenic reaction

used. ASV should be given if signs of envenomation are present even if the patient is seen 1-2 days after the bite. Trials employing regimen containing higher and moderate doses of ASV have shown that the latter is quite adequate if laboratory monitoring is possible and the clinical condition is stable. Cases which have received smaller doses of ASV have quicker recovery and shorter hospitalization and therefore overdose of ASV should be avoided. The cost of 1 vial of ASV ranges around Rs. 300.00.

Treatment of complications Since cobra and krait bites may lead to acute myasthenic reaction with respiratory paralysis, prompt administration of neostigmine can be life-saving (Fig. 11.3). Intravenous doses of 2.5 mg repeated at suitable intervals brings about prompt relief. Respiratory failure has to be managed with artificial ventilation, if injection of neostigmine does not work. Renal failure has to be anticipated in all cases of viperine bites. Urine volume has to be regularly monitored. Early institution of hemodialysis and careful management of renal failure in an institution with facilities for renal support have helped to save many patients, who would otherwise have died. Extensive local sloughing may demand skin grafting.

Steroid Therapy

In a few cases methyl prednisolone given in a dose of 1 g IV daily for 2-3 days may be life saving. The indications include:

- (1) hypotension persisting after fluid and electrolyte correction before the administration of antivenin
- (2) peri-orbital puffiness,
- (3) chemosis of conjunctiva,
- (4) acute respiratory distress and
- (5) edema due to capillary leak.

Ref: Vimala, Kasi Visweswaran, Georgy K Nainan. In Snake bite: Consensus Statement as the management of common diseases in Kerala (ed) Poulose KP, Sajith S Kumar 2006; 268-9.

Prevention

Snakes should not be indiscriminately destroyed since they play a major role keeping the rodent population under check.

Snake bites can be avoided by:

1. Carrying a torch while walking in the snake infested areas,

2. Wearing shoes and other protective clothing, and
3. Using a stick which, if tapped on the ground, scares away most of the snakes.

Potent antivenin in sufficient quantity should be readily available in all the hospitals situated in snake-infested areas.

- Water Depletion Heat Exhaustion 89
- Salt Depletion Heat Exhaustion 89
- Heat Cramps 90
- Skin Lesions Caused by Exposure to Sun and Hot Environment 90

GENERAL CONSIDERATIONS

Man has a remarkable ability to withstand physical stresses and strains and adapt to varying environment. When changes in climate are abrupt, adaptation may not be possible in some individuals and this leads to adverse effects. Ill effects of heat are seen in tropical conditions either among the natives or the new entrants. Heat is dissipated from the human body by conduction, convection and radiation, through breathing and by evaporation of the sweat, which is the most effective way. Radiation accounts for 65% of body heat loss under normal conditions. But at high temperatures evaporation becomes the major mechanism for dissipation of heat. Heat disorders result from the breakdown of heat regulatory mechanisms. The clinical picture may be acute or chronic.

On a very hot day the total loss of water in the form of sweat may reach 5-6 litres with a salt loss of 10-12 g. When acclimatization occurs there is increase in extra-cellular fluid volume, which is accommodated by expanded vascular bed. This results in reduction of the pulse rate, and increase in the cardiac output. The sweat glands start producing more sweat even at lower temperatures. Excretion of salt is reduced by lowering the levels of salt in the sweat (2 g/litre) and urine, mainly due to activation of renin-angiotensin system and increased production of aldosterone. Acclimatization to hot environment by proper training occurs in 10-14 days.

Acclimatized individuals are capable of performing well in hot climates, provided the intake of water and salt are adequate (5-6 litres and 15-20 g/day respectively).

There is evidence that the global temperature is going up steadily due to various factors such as increase in population, burning of fossil fuels, denudation of forest cover, irrigation schemes and the effect of heat-trapping gases which produce a greenhouse effect. The Intergovernmental Panel on Climate Change (IPCC) has predicted that the global temperature may go up by 2.5 °C by 2100 AD. In addition to the direct effects of warming it may also increase the incidence of natural disasters and vector transmitted diseases. It is estimated that the sea level will rise by an additional 19 inches by 2100, flooding coastal areas. Heat waves will be more frequent and more intense. Droughts and wildfires will occur more often. Disease-carrying mosquitoes will expand their range. More than one million species could be committed to extinction by 2050 if global warming pollution is not curtailed.

Despite wide variations in ambient temperatures, humans and other mammals can maintain a constant body temperature by balancing heat gain with heat loss. When heat gain overwhelms the body's mechanisms of heat loss, the body temperature rises, and a major heat illness ensues. Excessive heat denatures proteins, destabilizes phospholipids and lipoproteins, and liquefies membrane lipids, leading to cardiovascular collapse, multiorgan failure, and, ultimately, death. Management of heat related disorders is closely linked with that of fluids and electrolytes.

Heatstroke

Syn: Heat Hyperpyrexia

Definition, etiology and pathogenesis. Heatstroke follows exposure to heat and is characterized by hyperpyrexia owing to deranged heat regulatory mechanism. Heatstroke is defined clinically as a core body temperature that rises above 40°C and that is accompanied by hot, dry skin and central nervous system abnormalities such as delirium, convulsions, or coma. Heatstroke results from exposure

to a high environmental temperature (classic, or non-exertional heatstroke) or from strenuous exercise (exertional heatstroke). Neuropsychiatric disturbances are prominent. Heatstroke generally occurs at temperatures ranging from 40 to 45° C, but may also occur at wet bulb temperatures as low as 30-35° C, especially if the humidity is high. The external temperature at which heatstroke occurs varies between individuals and therefore is not a reliable parameter for diagnosis. Precipitating factors include lack of acclimatization, unaccustomed and sustained heavy work at high temperatures, alcoholism, infections, dehydration, use of drugs like atropine, antihistamines, phenothiazines, antidepressants and diuretics, and obesity.

The systemic and cellular responses to heat stress include thermoregulation, an acute-phase response whereby various cytokines and acute phase proteins are liberated, and the production of heat-shock proteins. Increased levels of heat-shock proteins in a cell induce a transient state of tolerance to heat stress, allowing the cell to survive. Thermoregulatory failure, exaggeration of the acute phase response, and alteration in the expression of heat-shock proteins may contribute to development of heatstroke.

Clinical features: The onset is sudden or even abrupt with a rapid rise of body temperature to 41°C or more with acute neurological features such as confusion, restlessness, delirium, agitation, convulsions and coma. In a few patients there may be prodromata, including headache, giddiness, thirst, irrational behaviour and restlessness, and the onset is gradual.

The cardinal diagnostic features are hyperpyrexia, neuropsychiatric disturbances, and a hot and dry skin (hot dry man). The temperature (oral or rectal) varies from 41.5 to 44°C. It is preferable to take the rectal temperature in these cases. The patient has tachycardia and tachypnea. 25% of patients have hypotension. Electrocardiogram shows T wave changes suggestive of myocardial involvement.

Complications The most serious complication of heatstroke is multi-organ dysfunction. This includes encephalopathy, rhabdomyolysis, acute renal failure, acute respiratory distress syndrome, myocardial injury, hepatocellular injury leading to jaundice, intestinal ischemia or infarction, pancreatic injury, and hemorrhagic complications, especially due to disseminated intravascular coagulation. Untreated, the condition is fatal owing to circulatory, hepatic or renal failure.

Diagnosis: Diagnosis should be suspected in the presence of the three cardinal features, viz. hyperpyrexia, neurologic disturbances, and a hot and dry skin in a subject exposed to high ambient temperature. It is important to rule out falciparum malaria. Malaria may

coexist with heatstroke but in cerebral malaria the peripheral blood will show signs of malaria hyperinfection. Other conditions like septicemia, typhus, pyogenic meningitis, encephalitis, pontine hemorrhage and closed head injuries have to be excluded.

Laboratory features of heatstroke include neutrophil leucocytosis, thrombocytopenia, elevation of blood urea bilirubin, uric acid, and reduction of plasma bicarbonate, potassium, sodium, calcium and phosphorus. None of these are diagnostically specific. Therefore, diagnosis has to be clinical.

Treatment: Heatstroke is a medical emergency. Treatment aims at the reduction of the rectal temperature to 39°C within one hour, restoration of circulating blood volume and support of various organ system functions.

The patient is covered with wet sheets or towels and sprayed with cold water while air is blown or fanned over him to promote evaporative cooling. The patient should preferably be in the lateral recumbent position or hands and knees position to expose as much of skin as possible to the air. As an alternative the patient may be immersed in cold water. Immersion in ice water is not preferred because of the possibility of shivering and hypotension. The limbs are gently massaged to promote circulation. When the rectal temperature falls to 39°C the patient is transferred to a cool room and watched for further rise of temperature. Recurrence is quite common and temperature regulation may remain unstable for weeks.

Rapid cooling to rectal temperatures below 38-39°C may precipitate convulsions, vomiting and hypotension. A mechanical body cooling unit is available in which cold water at 20°C is sprayed over the patient, while a blast of hot air at 50°C is blown from above. This prevents vasoconstriction and also augments evaporation.

Prompt and effective cooling restores neurological functions in the majority of patients. Recovery of central nervous system function is a favorable prognostic sign. Chlorpromazine (25-50 mg) administered intravenously is a useful adjunct during cooling. Antipyretics like acetaminophen and aspirin have no role and are contraindicated also.

If there is suspicion of malaria, antimalarials are given parenterally. Shock and cardiac failure have to be treated appropriately. The patient should also be observed and treated for renal failure due to rhabdomyolysis, disseminated intravascular coagulation and hepatic failure. Maintenance of hydration and electrolyte balance are important to prevent renal failure.

Sequelae include headache, insomnia, giddiness, cerebellar dysfunction and even coma. Most of these clear up in the course of weeks or months.

Prognosis: If left untreated, 50 -70% of subjects die of heatstroke. Early treatment reduces the mortality to

Disorder due to Physical Agents

15-20%. Shock also carries a bad prognosis. Presence of other systemic diseases and extremes of age worsen the prognosis.

Prevention: Heatstroke is a preventable disease. To prevent heatstroke, people should acclimatize themselves to heat, schedule outdoor activities during cooler times of the day, reduce level of physical activity, drink additional water and consume extra amounts of salt – (12 to 15 g/day).

Important points

1. Heatstroke, which is preventable, occurs at temperatures ranging from 40-45°C
2. Heat stroke could be exertional or non-exertional
3. Neuropsychiatric manifestations are prominent
4. Multiorgan dysfunction is the usual cause of death
5. Shock, extremes of age and systemic diseases are bad prognostic features

Anhidrotic Heat Exhaustion

Syn: Tropical Anhidrotic Asthenia, Thermogenic Anhidrosis

This is characterized by depression of sweating, exhaustion, and vesicular skin lesions on the trunk (Miliaria profunda).

Etiology: The condition is probably caused by the blockage of the sweat ducts by swelling of the cells of the stratum corneum and keratotic plugs, with consequent absence of sweating. This leads to retention of fluid and vesicle formation. The syndrome is frequently associated with prickly heat.

CLINICAL FEATURES

The illness can occur in newcomers or even in normal acclimatized persons, on prolonged exposure to heat. Feeling of extreme warmth during the hot part of the day, asthenia even at rest and impairment of working capability are initial symptoms. These symptoms are aggravated by even mild exertion. Tachycardia, tachypnea, and mild pyrexia (38-40.5°C) occur. Anhidrosis may extend all over the body or may be localized. This may persist for several weeks. There may be polyuria, the urine contains diminished amounts of chlorides.

Skin lesions superficially resemble prickly heat, but in miliaria profunda there is no erythema around the lesions and these are seen most commonly in the proximal parts of the limbs and on the trunk.

Diagnosis: Clinical diagnosis is based upon the symptoms. Simple heat exhaustion and malingering are to be ruled out.

Treatment: The patient should be transferred to cool surroundings. Recovery is generally rapid. Resumption of work in hot environment may lead to relapse.

Important points

1. Anhidrotic heat exhaustion is caused by blockage of sweat ducts
2. Frequently associated with prickly heat
3. Asthenia even at rest and impairment of work capacity are early features
4. Diagnosis is based on symptoms

Heat Syncope

Syn: Heat Collapse

Heat syncope may occur in a hot environment in the absence of demonstrable water and salt depletion. Heat syncope may occur in a wide range of temperatures, not necessarily the highest. The condition may affect newcomers or the natives in the locality doing excessive physical exertion.

Syncope results from cutaneous vasodilatation and resultant systemic and cerebral hypotension, pooling of blood in the blood vessels of the muscles and skin, especially of the lower limbs, during or after physical activity.

CLINICAL FEATURES

Syncope or collapse occurs either during or immediately after heat exposure on prolonged standing or sudden change of posture. Giddiness, vertigo, and nausea are common. The patient is pale with shallow breathing and frequent yawning. The blood pressure is low and the pulse is slowed as in vasovagal syncope. The symptoms may pass off in a few minutes after lying down. Rapid recovery occurs if the patient is transferred to cool environment.

Diagnosis

Syncope with postural changes during or immediately after heat exposure, without demonstrable water or salt depletion and the rapid recovery of the patient are diagnostic.

Treatment

The patient should be transported to a cool room and put to bed. Adequate fluids in the form of simple beverages should be given and urine output maintained at 1.5 liters per day. The patient should be encouraged to take adequate amounts of salt (15-20g/day) to avoid recurrence.

Important points

1. Heat syncope occurs in the absence of demonstrable water and salt depletion
2. Syncope is caused by secondary to cutaneous vasodilatation
3. Rapid recovery results when patient is transferred to cool environment
4. Intake of adequate quantity of water and salt are to be ensured for recovery

Water Depletion Heat Exhaustion

This type of dehydration is caused from prolonged strenuous activity in a hot environment with inadequate intake of water and other fluids. This is usually preceded by a period of prolonged sweating which leads to considerable loss of water. Children are more susceptible to this disorder than adults.

Etiology and pathogenesis. The major factor is water deprivation, which may be due to insufficient provision of water at the place of work, or voluntary avoidance of fluids in between meals. Negative water balance develops in persons doing heavy manual work in hot environment due to excessive sweating. From 6 to 8 litres of sweat may be lost in a day. Loss of water leads to reduction in the volume and increase in the osmolarity of the extracellular fluid. Intracellular water moves into the extracellular compartment. Salt depletion does not occur if salt intake is adequate, otherwise hyponatremia also develops. Heat exhaustion is characterized by dehydration, sodium depletion or isotonic fluid loss with associated cardiovascular changes.

CLINICAL FEATURES

Severe thirst is experienced in the early stages. The patient sweats even when the extremities are cold. Other early symptoms are nonspecific such as dryness of the mouth, irritability, restlessness, and weakness. Hyperventilation secondary to heat exhaustion can lead to respiratory alkalosis. In the fully established case dysphagia, hoarseness of voice, tachycardia, hypotension, oliguria, and anuria follow. Untreated, mental changes such as delirium and coma supervene and the condition may end fatally.

Diagnosis: The circumstances under which this syndrome occurs viz. the high environmental temperature and the clinical picture, especially with intense thirst, are diagnostic in a conscious patient. Difficulties arise in comatose patients who are also febrile. Distinction from salt deficiency may be difficult but the high sodium content of urine and plasma help to distinguish pure water depletion state.

Treatment: Patient should be kept at rest in a cool room. In mild cases oral fluids and flavored drinks are adequate. In severe cases the oral intake should be 5-8 liters on the first day with 15-20g sodium chloride. In an unconscious patient 5% dextrose solution is given intravenously in the first 24 hours with close monitoring of urine output. The levels of serum sodium, urinary sodium and chloride should be estimated and deficiencies should be corrected. Increasing urine output, rise of blood pressure and return of weight to normal are indications of clinical recovery.

Salt Depletion Heat Exhaustion

This condition is characterized by asthenic symptoms, because of salt depletion caused by prolonged sweating without sufficient intake. The symptoms are fatigue, nausea, vomiting, giddiness, insomnia, and cramps, but these patients do not complain of thirst.

Etiopathogenesis Unacclimatised subjects engaged in hard work in a hot environment are affected. There is considerable variation in susceptibility. Salt depletion has been proved to play a major role in the pathogenesis. There is a fall in osmolarity of extracellular fluid leading to movement of water intracellularly and consequent reduction in extracellular fluid volume. Plasma sodium and chloride levels fall.

CLINICAL FEATURES

A wide spectrum of symptoms may occur. In many patients there is a prodromal phase with vague symptoms like anorexia, nausea, giddiness and headache. Even at this stage the patient sweats profusely and the urine output is reduced. Diagnosis at this stage may not be very clear in the absence of cramps. The severe illness is characterized by asthenia and painful cramps. As the condition progresses, tachycardia, hypotension, dehydration, oliguria, and even shock ensue. Postural syncope is common. Coma and pulmonary edema precede death.

Laboratory findings Plasma sodium and chloride levels are proportionately reduced. Volume and salt content of urine are low. Severe dehydration leads to pre-renal azotemia.

Diagnosis The salt depletion heat exhaustion has to be differentiated from the water depletion type by the absence of thirst, the presence of muscle cramps, and oliguria with low levels of sodium and chloride in urine.

Treatment In mild cases oral replacement with 4-5 liters of normal saline in 24 hours may be adequate. 10-20 g of salt can be added to food and drinks as supplement. Severe cases require intravenous fluids. Two liters of isotonic saline are given in the first four hours rapidly with monitoring of urine volume and urinary chloride. Intravenous 3% saline may be necessary if sodium depletion is severe. Recovery is rapid. Consumption of extra salt in food and drinks helps to prevent recurrence.

Important points

1. In salt depletion heat exhaustion asthenic symptoms occur due to salt depletion
2. Usually there is a prodromal phase with vague symptoms
3. Asthenia and painful cramps and absence of thirst are characteristic features
4. With severe sodium depletion IV 3% saline infusion may be required

Heat Cramps

This occurs in persons who sweat excessively in hot environment without having normal or supplementary salt intake. This is a milder form of salt deficiency heat exhaustion. Severe cramps develop in the voluntary muscles. These are painful and may last from a few seconds to several minutes. The cramps are precipitated by heavy work, are very painful and commonly involve the extremities. Muscle cramps recur at intervals. Laboratory evaluation may show low serum sodium, hemoconcentration, and elevated urea and creatinine. Oral Supplementation of 10-15 g of salt relieves the cramps in mild cases. In more severe cases, administration of 600 mL normal saline gives dramatic relief. The patient has to take rest for 1-3 days with continued dietary salt supplementation before returning to work.

Skin Lesions Caused by Exposure to Sun and Hot Environment

Direct exposure to sun leads to sunburn and solar keratosis. Prickly heat develops in persons exposed to hot environment even without direct exposure to the sun.

Sunburn: It is caused by direct exposure to ultraviolet light. Fair-skinned persons, especially newcomers are more commonly affected. Symptoms start with erythema and pruritus and proceed to acute painful edema, vesiculation and bullae formation. Prolonged and repeated exposure results in increased pigmentation and improved

tolerance. Local application of calamine lotion containing 0.5% crystal violet or any antihistaminic cream gives relief. Para-amino benzoic acid, which absorbs ultraviolet light, gives some protection and this can be applied as a cream (5%) or lotion. Prevention consists of avoidance of direct exposure and the use of protective clothing and umbrella.

Solar keratosis Repeated exposure to direct sunlight causes patchy hyperkeratosis. The neck, back, dorsum of the hands and forehead are affected maximally. Albinos suffer more. These lesions may predispose carcinoma, especially melanoma.

Miliaria rubra (Prickly Heat) These are papular lesions seen in persons exposed to hot environment, especially if humidity is high. This condition results from blockage of sweat glands by the prickly cell layer of the epidermis, escape of sweat in to the epidermis and further inflammatory changes. Areas covered by clothing are more severely affected. Papular lesions develop which may become vesicular or pustular with surrounding erythema. These may be associated with pruritus and a prickly sensation. Secondary infection may develop later.

Treatment Local application of calamine lotion gives soothing relief. Excessive washing of the skin with strong soap should be avoided. Use of bland soaps and regular use of gingeli oil (sesame oil) over the skin applied for one hour weekly prevents this lesion in the native population. In established cases, stay in a cold environment and use of loose clothing brings about relief in 2-3 weeks.

13

Injuries due to Cold

T.K. Suma, K.V. Krishna Das

Chapter Summary

Freezing Cold Injury 90
Nonfreezing Cold Injury 91
Hypothermia 91

muscular work occurs when there is abrupt demand to increase heat production. The core temperature will drop if there is failure to maintain thermal balance.

Freezing Cold Injury

Syn: Frost Bite

This is seen in persons exposed to temperature below freezing point such as mountaineers, explorers, war

Humans adapt to cold by peripheral vasoconstriction, which reduces heat loss, and increase in the metabolic rate, which produces more heat. Shivering, which involves

Fig. 13.1: Blisters of fingers due to frostbite

casualties, or victims of natural disasters. There is freezing of extravascular fluid with formation of ice crystals in tissues leading to damage of vascular endothelium, microvascular thrombosis, ischemia and superficial necrosis. In mild cases where only the skin and subcutaneous tissues are involved numbness, prickling and itching are the features. Paraesthesia and stiffness occur with involvement of deeper tissues. The skin loses its elasticity and becomes immobile. Blisters, edema, necrosis and gangrene may set in (Fig. 13.1).

Management Rewarming: Superficial frostbite can be treated by firm pressure with a firm hand, placing fingers in the axilla. General warming of the body to elevate core temperature should be undertaken before local warming of the affected limb. After restoration of the core temperature, the affected limb should be warmed in a moving water bath preheated to 40–42° C. During thawing re-establishment of circulation may result in intense pain. Analgesics and antibiotics are given if indicated. Protection of the affected part by avoiding friction or pressure is important. Tetanus prophylaxis has to be considered as there is increased susceptibility. Antiplatelet agents, haemodilution, peripheral vasodilators and hyperbaric oxygen are other therapies used with varying results. Early sympathetic blockade may reduce symptoms, but use of sympathectomy is controversial. The condition can be prevented by covering the body with proper clothing, protection of the affected part, avoidance of local pressure, frequent changes of position and avoidance of smoking.

Important points

1. Frost bite occurs when exposed to temperature below freezing point
2. Damage to vascular endothelium caused by the ice crystals is the main pathology
3. In mild cases only the skin and subcutaneous tissue are involved

4. Severe cases produce parasthesia, weakness, and gangrene
5. General warming the body followed by local warming of affected limb is important

Nonfreezing Cold Injury

Syn: Trench foot, immersion foot

Exposure to cold damp environment above freezing point for long periods leads to tissue ischemia. This is seen in warfare, persons marooned in floods, cases of shipwreck and other natural calamities. Initially, the limb is cold, numb and pale (pre-hyperemic phase). During the hyperemic phase they become hot with intense pain and burning. The post-hyperemic phase is the vasospastic period where the skin becomes pale or cyanotic. Movements may not be possible. Arterial pulses may be undetectable. The limbs are especially susceptible to trauma and infection leading on to gangrene and maceration. In many cases, permanent sequelae like sensorimotor defects may result. Secondary complications are lymphangitis, cellulitis and thrombophlebitis.

Management The body is gradually warmed by exposure to air at room temperature, keeping the limb elevated and taking care to avoid overheating of the part. Analgesics and antibiotics should be given as indicated. Chilblains result from minor forms of cold injury. This manifestation is reversible if the environment is altered.

Important points

1. Trench foot occurs on exposure to damp environment above freezing point
2. Three phases- prehyperemic, hyperemic and post-hyperemic
3. Permanent sequelae like sensorimotor defects may occur
4. Gradual warming of the part without overheating reverses the lesion

Hypothermia

When the core temperature falls below 35 °C (95 °F), the condition is called hypothermia. Hypothermia may be induced for therapeutic purpose or may be accidental. The later is serious and it affects persons at the extremes of age with disturbed thermoregulatory mechanisms, or may be caused by disease, starvation or injury. It can occur in fit subjects when subjected to extreme cold without protection.

Accidental Hypothermia

This condition develops during cold-water immersion, shipwreck, mountaineering, etc. Hypothermia may be rapid or slow depending upon the rate of cooling. When cooling is slow, compensatory mechanisms set in.

Disorder due to Physical Agents

3

Starvation, alcoholism and drugs like phenothiazines aggravate the ill effects of cold environment. Diseases like hypothyroidism, hypopituitarism, hypoadrenalism and cirrhosis of the liver predispose to hypothermia. Physiological functions such as oxygen consumption, myocardial repolarisation, peripheral nerve conduction, gastrointestinal motility and respiration will be slowed down due to systemic hypothermia.

CLINICAL FEATURES

The appearance of a patient with accidental hypothermia is characteristic. The skin is pale, cold and cyanotic. Initial manifestations include lethargy, drowsiness, irritability, confusion and impaired coordination. As the core temperature falls below 35°C, there is progressive slowing down of cerebral functions resulting in mental stupor and subsequently leading to coma.

Shivering may occur if the temperature is above 30 °C but below this level the muscles become spastic and resemble rigor mortis. Respiration is slow and shallow. Tissues suffer from hypoxia since the oxygen dissociation curve of hemoglobin shifts to the left at low temperatures. Cardiovascular signs include bradycardia, hypotension, and cardiac arrhythmias like atrial fibrillation and ventricular fibrillation.

Cardiac arrest is likely to occur when the core temperature drops to 25°C. Electrocardiographic changes such as prolongation of PR and QT intervals and J waves (positive deflection at the end of QRS complex) may occur. Biochemical abnormalities include hypoglycemia, metabolic acidosis, hyperkalemia and mild azotemia. Thyroid function may be depressed.

Complications The core temperature usually continues to drop further for 10-20 minutes even after removing the patient from the cold environment. This phenomenon is called the 'after drop'. Respiratory infections are common in cases of hypothermia.

Differential diagnosis This includes myxedema coma which closely resembles hypothermia, poisoning, starvation, hypoglycemia, and neurological disorders.

Treatment Accidental hypothermia has to be managed as a medical emergency to save life, if possible in an

intensive care room. As in all comatose patients attention should be given to the maintenance of patent airway, proper ventilation, blood volume, and levels of electrolytes.

External re-warming is effective in the mildly hypothermic patient. External re-warming is done in a moving water bath heated to 40-42°C. When the core temperature has reached 34-35°C, the patient is placed on a warm bed and insulated against further heat loss. Antibiotics are required in many patients. In severe cases it is advisable to increase the core temperature by hemodialysis or repeated peritoneal dialysis using 2 L of warm potassium free dialysate warmed to 37°C, wherever facilities are available.

Prognosis The prognosis depends upon the duration and severity of hypothermia and the underlying disorder. Aged patients are at a higher risk. In general, majority of deaths occur within 30 minutes of rescuing the victim. Death is caused by cardiac arrest or ventricular fibrillation. In a few patients with apparent absence of vital signs on admission, these appear when the body is warmed. *Hence, all cases should be resuscitated irrespective of the initial findings and they should not be pronounced dead until they have been observed for at least 30 minutes, after warming to 36°C or above.* In persons who are susceptible to chronic hypothermia, preventive measures like domestic heating and visits by social workers should be arranged. In all cases of hypothermia, underlying medical conditions such as hypothyroidism, hypopituitarism and poisonings should be excluded by early investigation, since specific management for these conditions is absolutely essential to save life.

Important points

1. Accidental hypothermia is more common and more serious in extremes of age
2. Slowing of cerebral function occurs at body temperatures below 35°C leading to stupor and coma
3. Cardiovascular changes include bradycardia, hypotension and atrial or ventricular fibrillation
4. "After drop" is a complication during management
5. Hypothermia is a medical emergency and death is caused by cardiac arrest or ventricular fibrillation

14

Disorders due to Alterations in Barometric Pressure

3

T.K. Suma, K.V. Krishna Das

Chapter Summary

Exposure to Increased Barometric Pressure 93

Effects of Sudden Reduction in Barometric Pressure 93

Caisson Disease 94

EFFECTS OF SUDDEN REDUCTION IN BAROMETRIC PRESSURE**Syn:** Dysbarism

Those who live in high altitudes, passengers in unpressurized aircrafts, divers and workers in pressure chambers who are decompressed without proper supervision are susceptible to the ill-effects of sudden reduction in ambient pressures. Slow and graded decompression allows the gases contained in body cavities and dissolved in the blood and tissue fluids to be liberated gradually without producing untoward effects. Normally eustachian tube functions to equalize middle ear and ambient environment pressures. In persons suffering from upper respiratory infection, sinusitis, or Eustachian blockage, symptoms like ear pain, vertigo, giddiness, or deafness may occur. Expansion of gas in the alimentary tract results in abdominal distention and dental pain which results from increase in the volume of gases within dental cavities. Aseptic necrosis of bone may occur in some cases.

As a result of rapid decompression more serious consequences occur due to formation of bubbles from liberation of nitrogen dissolved in the blood and tissues fluids. Acute decompression sickness follows rapid reduction of environmental pressure sufficient to cause the formation of bubbles from dissolved gases in the tissues. The bubbles act as emboli. This disease is seen in divers and those working under water in harbours, ports, naval installations, offshore oil drilling, and mining industry. In patients with airway obstruction, expansion of air in the lungs leads to pulmonary rupture with resultant pneumothorax or surgical and mediastinal emphysema.

Factors, which influence clinical manifestations are obesity and physical activity during the compression phase and individual susceptibility. Obese subjects suffer more. In addition to the mechanical effects due to the liberated gases, secondary phenomena also develop. These are fat embolism, sludging of erythrocytes in the micro-circulation, platelet activation and disseminated intravascular coagulation. The gas bubbles themselves may be transient, but the effects they induce are

93

The standard atmospheric pressure of 760 mm Hg exerted at mean sea level may fluctuate by 15-20 mm Hg under normal weather conditions. Lowering of barometric pressure is generally associated with lowered oxygen content of inspired air. If the oxygen supply is maintained adequately, humans can tolerate lowering of atmospheric pressure for prolonged periods. The volume of gases held in closed body cavities changes inversely with the external pressure.

EXPOSURE TO INCREASED BAROMETRIC PRESSURE**Syn:** Barotrauma

This may occur in deep-sea divers, tunnel workers and patients under hyperbaric therapy chambers. The volume of gases held in the middle ear, paranasal sinuses, lungs, intestines, dental cavities etc., diminishes under the high pressure and transudation occurs into these cavities. Severe rise of pressure leads to distortion and damage to tissues. In the middle ear it may lead to transudation and in severe cases even rupture of the tympanic membrane - *otitic barotrauma*. Changes in the volume of air in the paranasal sinuses leads to headache, nasal discharge, or epistaxis.

Compressed air, used for breathing at depths by sea divers, is generally safe but the increased partial pressure of nitrogen can cause nitrogen narcosis. This is characterized by euphoria, error of judgment and intellectual impairment. Oxygen toxicity may occur if pure oxygen is administered at a pressure of 2.8 bar (equivalent to a depth of 18 m water), especially when the individual is engaged in vigorous activity. Confusion, convulsions and damage to the lungs may result from oxygen toxicity.

prolonged. Increased permeability leads to fluid loss into tissues, hypovolemic shock, hemoconcentration and hyperviscosity states.

The classical form of decompression sickness occurs in Caisson disease. Caisson is pressurized equipment used to take divers under water for work. Safety rules have been laid down for surfacing such workers from depths. Non-compliance with the rules results in development of decompression sickness.

Important points

1. Increase in volume of gases in body cavities produces symptoms when there is sudden reduction in barometric pressure
2. Nitrogen bubbles liberated during decompression result in serious problems like embolism.
3. Pulmonary rupture, pneumothorax and mediastinal emphysema are other complications
4. Fat embolism, disseminated intravascular coagulation, hypovolemic shock and hemoconcentration are secondary phenomena of decompression sickness

Caisson Disease

Syn: Bends, Acute Decompression Sickness, Compressed Air Illness

Caisson is a large water tight chamber open at the bottom in which workers can work under water for long periods. A high air pressure is maintained within the caisson to keep water out. Persons who work in deep under-water surroundings have to follow strict safety precautions to avoid ill effects of rapid changes in barometric pressure. This disorder occurs in divers who have been brought to the surface rapidly without conforming to the safety precautions. Under high barometric pressure more of air dissolves in blood and tissue fluids. Oxygen may be used up but nitrogen is not. When the barometric pressure is lowered the nitrogen comes out of the solution as bubbles which lead to pathological consequences. Some workmen are particularly susceptible. Nitrogen being more lipid soluble, more bubbles are formed in the nervous tissue and hence neurological symptoms predominate. The spinal cord is most commonly affected, the brainstem and cerebral hemispheres are affected to a lesser extent. Autopsy shows hemorrhages in the white matter and micro infarcts. Other tissues involved include the joints, skin and lungs.

CLINICAL FEATURES

Symptoms start within three hours of surfacing, but rarely they may be delayed by several hours. Mild cases show pains and cutaneous lesions. In the severe types neurological and pulmonary lesions are prominent. An apparently mild case may rapidly become severe and

hence the initial presentation may be misleading. Early cutaneous manifestations include pruritus, erythematous skin lesions and cyanotic patches, and these should alert the physician of the impending disease. The commonest presenting symptom is joint pain (bends) felt over the knees, shoulder, hips, and elbows.

More serious features are pulmonary decompression sickness (chokes) presenting with retrosternal pain, cough and dyspnea and neurologic manifestations. Tachypnea, hypotension and shock may follow the onset of chest pain and the patient may die in coma. The neurologic symptoms include paraesthesiae, girdle pains, varying degrees of motor and sensory deficits, headache, blurring of vision, diplopia, pupillary abnormalities, dysarthria and vestibular dysfunction characterized by vertigo, nystagmus, nausea and vomiting (staggers).

Diagnosis The condition is likely to be missed by the unwary physician. History, the circumstance of the case and the physical manifestations should suggest the possibility of decompression sickness. Delay in onset of symptoms should not go against the diagnosis if other features are suggestive.

Course and prognosis The course is unpredictable since mild cases may rapidly become serious and die. Prognosis depends upon the promptness and adequacy of recompression and graded decompression. This measure should be instituted without delay even in hopeless cases. Many a time the recovery is remarkable. Neurological deficit tend to persist if treatment is delayed. Early recompression can prevent the development of neurological lesions. In suggestive cases valuable time should not be wasted by undertaking detailed clinical examination before recompression is instituted.

Treatment Specific treatment is to institute immediate recompression in a pressure chamber, as an emergency measure. Respiratory depressants like morphine should be avoided. The pressure equivalent and the duration of recompression have to be decided by personnel trained in recompression techniques. Usually, a pressure of 2.8 atmospheres (283.7 kPa) is beneficial. *Hyperbaric oxygen* helps to improve oxygenation of ischemic tissues.

In patients with neurological deficits, shock or cerebral edema, corticosteroids are beneficial. Low molecular weight dextran (dextran 40) helps to reduce vascular sludging. Infusion of appropriate fluids helps to restore blood volume, improve the circulatory state, and mobilize trapped bubbles.

After suitable recompression, the patient should be carefully decompressed, allowing sufficient periods at each stage to prevent recurrence of bubble formation. Susceptible persons should refrain from diving till recovery is complete.

Important points

1. In Caisson disease nervous system involvement is more predominant-spinal cord being commonly affected, than the brainstem or cerebral hemispheres

2. Joint pain (bends) involving knee, elbow, hip and shoulder are common
3. Pulmonary symptoms (chokes) are retrosternal pain, cough, dyspnea and tachypnea
4. Immediate recompression in a pressure chamber is the treatment

15

Diseases due to High Altitude

T.K. Suma, K.V. Krishna Das

Chapter Summary

Introduction 95

Acute Mountain Sickness 95

High Altitude Pulmonary Edema 96

High Altitude Cerebral Edema 97

Chronic Mountain Sickness 97

Introduction

Twenty-five percent of the earth's land mass is mountainous, at heights above 2500 m above sea level. 10% of the world's population lives in mountains. More than 80% of them are poor without basic medical facilities. Iodine deficiency is common. Natural calamities such as land slides, avalanches, floods, thunder and lightning and earthquakes are more common in these regions since mountains are sites of continental plate collision in the natural evolution of the planet. Many people from other regions of the world visit the mountainous regions for occupation, sport or adventure. *The term high altitude illness refers to the total clinical picture occurring in unacclimatised entrants into high altitude regions shortly after their entry.*

In India, in the Himalayas alone more than 2 lakh persons undertake trekking annually. Many of the Indian troops are deployed at high altitudes. Constant vigil and unexpected combats have to be performed by our troops to protect our northern borders, were very adverse conditions such as altitude above 3000 m, temperature below 5°C, atmospheric pressures far below normal and

inadequacy of communication are built-in handicaps. Peoples inhabiting heights above 2000 m are smaller in size, have a higher hemoglobin level in health and are adapted to the environment. Features such as koilonychia have been detected in them, even in the absence of iron deficiency anemia. Incidence of tobacco smoking and alcoholism is high among the mountain tribes. Mountaineering and trekking by holiday makers are popular sports in India.

The term "high-altitude illness" describes the cerebral and pulmonary syndromes developing in unacclimatized persons shortly after ascent to high altitude. These include acute mountain sickness, high altitude cerebral edema and high altitude pulmonary edema.

Acute Mountain Sickness (AMS)**Syn: Soroche**

Sudden exposure to heights above 2,400 m may lead to hyperventilation, increased heart rate, palpitation, and headache resulting from lowered oxygen tension and this is known as acute mountain sickness (AMS). The symptoms typically develop within 6 to 10 hours after ascent. In most individuals symptoms subside within 24-48 hours. Cold weather and intense physical activity predispose to this condition. The exact process of acute mountain sickness is not known. Hypoxia elicits neurohumoral and hemodynamic responses in brain and lungs and these result in over perfusion of microvascular beds, elevated hydrostatic capillary pressure, capillary leakage and edema. Newer evidence suggests that all people develop swelling of the brain on ascent to high

altitudes. Those with a greater ratio of cerebrospinal fluid to brain volume are better able to compensate for swelling through displacement of cerebrospinal fluid. These people may not develop acute mountain sickness. So acute mountain sickness might be related to a person's ability to compensate for the swelling of the brain.

3

CLINICAL FEATURES

Three clinical patterns are seen

1. The **pulmonary form** is characterized by cough, dyspnea, chest pain, and basal rales. Cheyne-Stokes respiration may be observed. During the apneic phases the patient may be cyanosed. There is peripheral vasoconstriction. Appearance of basal rales may precede the onset of high altitude pulmonary edema.
2. The **cerebral form** presents with headache, giddiness, irritability, forgetfulness, insomnia, drowsiness and convulsions. Vertigo, tinnitus, visual and auditory disturbances can also occur. Papilledema may be observed in severe cases. Headache increases with increase in cerebral edema.
3. The **hypoxic form** is vague in its clinical picture. Symptoms include muscle cramps, anorexia, gastrointestinal disturbances and epistaxis.

In the majority of cases the onset is within 6-24 hours after arrival. Symptoms subside spontaneously, but recur everyday for 3-4 days till acclimatization occurs. A few cases may develop acute pulmonary edema. Altitude proteinuria is a common finding, which tends to disappear with oxygen therapy or on returning to the lower altitudes.

Treatment Definitive treatment is immediate descent to lower altitude. Rest and administration of oxygen 1-2L/min often relieves acute symptoms. If immediate descent is not possible portable hyperbaric chambers may be useful. Other recommended therapies are acetazolamide 125-250 mg every 12 hours and dexamethasone injections 8 mg initially followed by 4 mg every 6 hours.

Prevention Slow ascent and avoidance of physical exertion for 72 hours help to prevent AMS. Acetazolamide in a dose of 250 mg four times a day is beneficial if started a day prior to the travel and continued for 2-3 days. Dexamethasone 4 mg every 12 hours beginning the day of ascent, continued for three days at high altitude and then tapering off over 5 days is another alternative.

Important points

1. Acute mountain sickness occurs on rapid ascent to above 2000 m
2. Symptoms usually start within 6 to 10 hours after ascent and subside within 48 hours
3. Hypoxia and its effects result in edema in brain and lungs
4. Oxygen inhalation, acetazolamide and dexamethasone recommended for treatment
5. Slow ascent and avoidance of physical exertion help to prevent AMS.

High Altitude Pulmonary Edema

This is a more serious complication compared to AMS. Young subjects in apparently good health are more affected. It may manifest in newcomers and also in subjects acclimatized to high altitudes, if they ascend the heights rapidly after long periods of stay at lower altitude. Altitudes above 2500 m can be harmful, but most of the cases occur at heights of 3050 to 4550 m. Heavy meal, physical exertion and too rapid an ascent precipitate the condition. Symptoms start within 6 to 48 hours of reaching the station.

Pathophysiology Though pulmonary hypertension is invariably found as a consequence of hypoxia, only a small proportion of subjects develop acute pulmonary edema. High-altitude pulmonary edema is a non-cardiogenic pulmonary edema associated with pulmonary hypertension and elevated capillary pressure. The pulmonary hypertension is secondary to the exaggerated pulmonary vasoconstriction induced by hypoxia. Sympathetic over activity, endothelial dysfunction, and hypoxemia are the proposed mechanisms. An immunogenetic basis also has been suggested because of higher incidence of HLA-DR6 and HLA-DQ4 antigens in susceptible individuals.

CLINICAL FEATURES

Many cases follow acute mountain sickness, but in some, pulmonary edema develops abruptly. Early symptoms are cough, tachypnea, dyspnea, and chest pain. These are soon followed by hemoptysis, cyanosis, frothy expectoration, and intense chest discomfort. Oliguria may develop.

The course is variable. In some, the pulmonary edema worsens while in others it may become sub acute and persist for a few days. In severe cases right-sided heart failure may follow and this may precede death. Radiographic abnormalities include prominence of the pulmonary arteries, irregular patchy infiltration of one lung or bilateral nodular densities (Fig. 15.1). Electrocardiogram reveals acute right ventricular strain due to pulmonary hypertension.

Diagnosis High altitude pulmonary edema should be anticipated in healthy subjects who develop vague cerebral and respiratory symptoms on reaching high altitudes. Early recognition and treatment are necessary to avoid rapid deterioration or cardiac failure. Malingering has to be differentiated from this condition.

Treatment Immediate treatment under field conditions is rest and administration of 100% oxygen at a rate of 4-6L/min for 15-30 min. Recompression using a portable hyperbaric bag will reduce symptoms if immediate descent

Fig. 15.1: X-ray chest: High altitude pulmonary edema
Note the bat-wing like opacities arising from the hilum

Important points

1. High altitude pulmonary edema is a serious complication occurring at heights of > 3000 m
2. Pulmonary hypertension and elevated capillary pressure secondary to hypoxia form the basic pathology
3. Radiographic abnormalities vary from patchy opacities in one lung to bilateral nodular opacities
4. Immediate descent and hospitalization are required in severe cases
5. Education of prospective mountaineers helps in prevention

High Altitude Cerebral Edema

This disorder is less common than pulmonary edema. Cerebral edema may follow acute mountain sickness several hours after reaching the high altitude. Vaso-dilatation, impaired cerebral autoregulation and elevated capillary pressure are the pathogenic mechanisms. Cerebral edema occurs due to cell swelling caused by increase in intracellular osmolality. Alteration of blood brain barrier secondary to hypoxia also contributes to the symptoms. The mediators are endothelium derived vasodilator growth factor, bradykinin and nitric oxide. Early clinical features consist of lethargy, insomnia, dreamy state, and irritability. Cheyne-Stokes respiration may develop. Severe cases develop intense headache, confusion and coma before ending fatally.

Treatment The patient should be administered pure oxygen (2-4L/min) and evacuated to a lower camp. Dexamethasone given intravenously or intramuscularly in a dose of 4-8 mg every 6 hours gives relief.

Chronic Mountain Sickness

Syn: Monge's disease, Chronic soroche, high altitude disease

Some persons living at high altitudes lose their acclimatization and develop symptoms. Most of such reports have come from South America. Males are affected more than females. The mechanism is not fully understood. Features include somnolence, hypoxemia, cyanosis, clubbing of fingers, polycythemia, mental depression and evidence of right ventricular failure. ACE inhibitors such as enalapril in doses of 5 mg daily have been shown to reduce polycythemia. Palliative measures are only of temporary benefit. Therefore it is advisable to remove affected individuals to low altitudes. The whole picture reverts to normal on reaching low altitudes.

is not possible. If oxygen is not available the patient should be evacuated to a lower camp, hospitalized and administered oxygen. Frusemide 40 mg should be given intravenously. Persistence of pulmonary edema is an indication for repeating frusemide. Nifedipine 10 mg initially followed by 20 mg repeated every 12 hours gives symptomatic relief. Physiological venesection by applying tourniquets proximally to the limbs helps to reduce pulmonary edema. Precipitating factors such as respiratory infection have to be looked for and treated appropriately.

Cases, which do not respond to the resuscitatory measures, should be evacuated to lower altitude urgently to prevent death.

Prevention Proper training and conditioning for 1-2 weeks should be undertaken before reaching high altitudes. Ascent should be gradual to permit acclimatization. On reaching high altitudes all unacclimatized persons should avoid physical exertion for 48-72 hours. Salmeterol inhalation 125 mg every 12 hours beginning 24 hours before the ascent is recommended to reduce incidence of high altitude pulmonary edema. Nifedipine 20 mg administered as a slow release preparation 8 h is also effective in preventing high altitude pulmonary edema.

Those planning to ascent 3000 m should carry supply of oxygen and equipment sufficient for several days.

16

Drowning

3

T.K. Suma, K.V. Krishna Das

Chapter Summary

General Considerations 98

Pathology and Clinical Features 98

Management 98

GENERAL CONSIDERATIONS

Definition: Drowning is the pathological state leading to death resulting from the aspiration of water into the respiratory tract or due to asphyxia immersion. More than 2 lakh persons die annually of drowning, 25% in sea and 75% in inland waters. Two types of drowning have been recognized - *dry drowning* and *wet drowning*. In dry drowning death is due to laryngeal spasm, which proves fatal in 20% of the subjects. This also prevents the entry of water into the lungs.

In wet drowning water enters the lungs. The consequences differ between fresh water and sea water drowning. In fresh water drowning, water is quickly absorbed from the lungs, leading to hemodilution and hemolysis with release of potassium from the red blood cells. In addition to hypoxia and ventilatory failure, hyperkalemia precipitates ventricular arrhythmias, which may prove fatal.

In salt water drowning the fluid in the lung is hyperosmotic. It absorbs more fluid into the alveoli causing pulmonary edema and respiratory failure. Hypernatremia follows later when the salt is absorbed into the circulation. In addition to the metabolic and local effects, impurities and contaminants give rise to local infection.

Secondary Drowning or *near-drowning* occurs a few hours or few days after the initial resuscitation due to the secondary changes in the lungs such as pulmonary edema, pneumonia, pneumothorax, electrolyte disturbances and metabolic or respiratory acidosis. This accounts for 25% of deaths.

Immersion syndrome. In this, sudden death occurs due to cardiac arrest caused by vagal stimulation brought about by sudden immersion into cold water.

PATHOLOGY AND CLINICAL FEATURES

Lungs: Pulmonary edema develops. Fresh water interferes with surfactant leading to formation of hyaline membrane, atelectasis and hypoxemia. Aspiration of foreign particles worsens the atelectasis. Bacterial infection leads to pneumonia or lung abscess.

Heart: Arrhythmias such as ventricular fibrillation and cardiac arrest may occur. Electrocardiogram may show nonspecific changes due to asphyxia.

Kidneys: Acute tubular necrosis may develop in near-drowning in fresh water due to hemolysis and prolonged hypotension.

Central nervous system: Asphyxia leads to loss of consciousness, cerebral edema and convulsions. Sequelae of anoxic encephalopathy such as transient hemiparesis, quadriparesis, choreoathetosis, aphasia and faciobrachial weakness may develop.

MANAGEMENT

First aid: (1) clear the airway of water and foreign bodies by putting the patient head low and by suction, (2) institute mouth-to-mouth breathing as early as possible, (3) closed chest cardiac massage should be instituted if heart sounds are absent, and (4) all cases must be hospitalized to prevent death from secondary drowning.

Hospital treatment: This aims at (1) maintenance of adequate oxygenation, (2) correction of metabolic and electrolyte imbalance and (3) prevention of secondary effects. Adequate oxygenation is achieved by the use of controlled ventilation with 100% oxygen, later to be reduced to 40%. If these measures fail to respond intubation and application of positive and expiratory pressure (PEEP) respiration should be resorted to. The PEEP increases the functional residual capacity, thereby minimizing intrapulmonary shunts and ventilation perfusion abnormalities, and promotes better oxygenation. If bronchospasm is present, an aerosol of salbutamol 200 mcg should be administered. Acidosis is to be corrected

with sodium bicarbonate given intravenously in a dose of 0.7 to 1 mmol/kg bw. Proper correction of electrolyte imbalance and acidosis should be monitored with laboratory estimations.

Constant observation and appropriate management of pulmonary edema, pneumonia and pneumothorax serves to prevent secondary drowning. Prophylactic antibiotics have to be used to prevent respiratory infections. Skiagram of the chest is necessary in all cases to detect complications. Atelectasis has to be managed with bronchoscopic aspiration. In severe cases of pulmonary edema, dexamethasone given in a dose of 0.5-1 mg/kg bw in 24 hours IM or IV has been successful. If signs of intracranial hypertension develop, it is treated with hyperventilation and IV infusion of 200 mL of 20% mannitol.

Prognosis

This depends on the extent and duration of hypoxia and the first aid. Patients presenting with coma and cardiac irregularities have higher mortality and morbidity.

Immersion in cold water causes death earlier due to rapid cooling, but survivors show less tendency to develop neurological sequelae. Residual complications of near drowning include convulsive disorders, intellectual impairment, cardiac neurosis and pulmonary atelectasis leading to bronchiectasis.

Prevention: Education of the public on the hazards in water and first aid measures to save drowning victims should be available in places of water sports, holiday resorts and beaches. Trained lifeguards should be available at public swimming places.

Important points

- 1. In dry drowning laryngeal spasm is the cause of death
- 2. In fresh water wet drowning hemodilution, hemolysis, ventilatory failure and ventricular arrhythmia may occur
- 3. Pulmonary edema and respiratory failure are the features in salt water drowning
- 4. Maintenance of adequate oxygenation, correction of metabolic and electrolyte imbalances and prevention of secondary effects are the mainstay of management

17

Injuries due to Ionizing Radiations

T.K. Suma, K.V. Krishna Das

Chapter Summary

- General Considerations 99
- Acute Radiation Syndrome 100
- Damage to Embryo by Irradiation in Fetal Life 101
- Local Radiation Injury 101

General Considerations

Ionizing radiations are either electromagnetic or particulate in nature. They are derived from natural or artificial radioactive isotopes, nuclear reactors, diagnostic and therapeutic equipment (e.g. X-rays, CT scan) and the complex shower of particles from the outer space known as cosmic rays. The radiations include alpha, beta, and gamma particles and electromagnetic waves.

Radiation injury is seen in survivors of nuclear war, after radiotherapy, persons engaged in industries involving radioactive materials, radiologists and radiotherapists. In some parts of the world radioactive sand accounts for low dose continuous radiation, e.g., the mineral beaches of Kerala. Radiation is harmful at all doses, the danger increasing with the rate and dose of exposure (Table 17.1). The age group 10-19 years is most susceptible. The maximal permissible radiation exposure for occupationally exposed workers is 0.1 rem per week for the whole body. Critical targets are the cellular nuclei.

The damage caused to the biological systems is of two types:

- 1. Direct absorption of radiation energy results in the formation of H⁺ ion, OH⁻ ion and hydrogen peroxide which all interfere with enzyme systems.

TABLE 17.1

The clinical response to different doses of whole body irradiation

Dose Centigray (cGy)	Clinical effects	Mortality
0-100	Men may develop temporary azoospermia	Nil
100-200	Nausea and vomiting starts in 3-6 hours and may persists for a whole day or so. In some cases, this starts after a latent period of even two weeks	Nil
200-600	Nausea and vomiting lasts for 1-2 days, there may be a latent period of 1-4 weeks, symptoms may recur for up to 8 weeks, and severe leukopenia, purpura, hemorrhage, infections and loss of hair may develop	Up to 90% in 2-12 weeks from hemorrhage or infection
600-1000	Nausea and vomiting start within 30 minutes and last for 2 days. There is a latent phase of 5-10 days followed by severe leukopenia, purpura, hemorrhage, infections and death	90-100% in 6 weeks from hemorrhage or infection
1000-3000	Nausea and vomiting start within 30 minutes and last for 1 day. The latent phase is for 7 days or less. This is followed by gastro-intestinal syndrome with diarrhea, fever and disturbed electrolyte balance. These last for 2-14 days	100% within 14 days from toxemia and circulatory collapse
More than 3000 respiratory	Nausea and vomiting start almost immediately followed by convulsions, tremor, ataxia and lethargy	100% in 48 hours from failure or brain edema

Note: X-ray and gamma rays used to be measured in rads. Exposure to 1 roentgen results in an absorption of about 1 rad equivalent to 100 ergs/g. At present the unit of measurement used is the Gray. 1 rad = 1 Centigray (cGy)

2. Direct injury to chromosomes lead to chromosomal breaks and abnormal cross links in the DNA or between the DNA and cellular proteins.

Dividing cells are more susceptible to radiation injury. The effects may be: (1) delay in mitosis, (2) reduction in the number of dividing cells, and (3) chromosomal changes.

The effects of radiation vary according to the degree and nature of exposure. Massive radiation exposure causes immediate effects, while small repeated exposures induce response that may not be perceived even for years. When the dose is large and exposure is extensive over the body, the acute radiation syndrome results. Excessive dosage delivered locally gives rise to localized damage, e.g., radiation dermatitis, radiation nephritis etc.

Pathological changes Radiation leads to arrest of mitotic activity, which progresses to cell damage and death. Tissues, which have a high rate of cell division such as bone marrow, intestinal epithelium and germinal cells of gonads, suffer most. Secondary complications include infection, hemorrhage and fibrosis. Loss of epithelium, neutropenia and depression of immune response favor bacterial invasion and septicemia. Infective lesions are most evident in the oropharynx and intestines. The brain and spinal cord are more sensitive to radiation than peripheral nerves.

ACUTE RADIATION SYNDROME

Acute exposure of the whole body to 300 cGy is fatal. Lethal doses produce maximal effects on the bone marrow and the intestinal epithelium. With high doses, intestinal

lesions predominate over marrow toxicity. With still higher doses neurological features such as disorientation, convulsions and shock predominate. Except in the fulminant neurological type of injury, the classical form occurs in four phases:

Phase 1 This phase occurs within minutes of exposure and is characterized by nausea, vomiting and diarrhea. Reduction in lymphocytes may occur in 24-30 hours due to direct destruction of these cells.

Phase 2 There is a latent period of about a week after which the third stage develops.

Phase 3 During this critical phase there is marrow failure leading to neutropenia and thrombocytopenia, which result in secondary infection and hemorrhage. Fever, vomiting, diarrhea, oropharyngeal ulceration, and purpura may be seen.

Phase 4 The survivors enter the fourth (recovery) phase in which the symptoms subside.

Temporary sterility may develop and persist for up to one year. Risk of developing malignancies such as chronic myeloid leukemia, cancers of the breast, thyroid, lungs and digestive organs is considerably increased in such persons.

Treatment It is supportive and aims at:

1. Correcting toxemia and infections,
2. Correcting fluid and electrolyte imbalances and
3. Treating hemorrhagic manifestations, profound anemia and neutropenia.

These patients are preferably managed in an aseptic environment. Adequate antibiotic therapy and transfusion

of neutrophils and platelets are life saving. Hemopoietic factors such as *filgrastim* and *sargamostim* help in the recovery of blood cells. Blood stem cell transplantation and bone marrow transplantation may be may be needed later.

Important points

1. The extent of damage due to radiation depends on the dose, rate and type of radiation and organ exposed
2. Tissues with high rate of cell division such as the bone marrow, gastrointestinal epithelium and gonads are affected mostly
3. Acute exposure of >300cGy may be fatal

DAMAGE TO EMBRYO BY IRRADIATION IN FETAL LIFE

Irradiation during stage of implantation results in fetal death. During the stage of organogenesis, fetal

malformation or abortion may result. After three months, by which time, the main organs would have formed, gross deformities are not produced, but stunting of growth, reduction of life span, sterility and tendency to develop leukemias and cancers have been noted. Radiation dose as low as 5 cGY can injure the growing fetus. The irradiation given out by modern X-ray machines for skiagram of the chest is only 1/100 cGY.

LOCAL RADIATION INJURY

Erythema develops over the area of exposure within days or weeks after acute exposure and this may progress to epidermolysis. Late complications are atrophy of the skin, subcutaneous fibrosis, telangiectasia, and later hyperkeratosis. These hyperkeratotic lesions may develop malignancy later.

18

Electrical Injuries and Lightning

T.K. Suma, K.V. Krishna Das

Chapter Summary

Electrical Injuries 101
Lightning 102

ELECTRICAL INJURIES

The risk of electrical injuries is often overlooked due to over familiarity. In most cases accidents occur from faulty domestic electrical apparatus, rarely it may be from high tension lines or other installations. Electrical characteristics of the exposed part, conductivity of tissues, extent of grounding and the duration of the contact determine the amount and the path taken by the current, which is important in relation to the severity of the injury. Electrical accidents are common where electrical installations are more such as surgical theaters, intensive care rooms and others.

The type and severity of injury depends upon the strength of the current, its type, duration of exposure and

the path taken by the current. Individuals vary in susceptibility to the effects of electricity. Injuries associated with electricity may be due to either direct electrical shock, or burns resulting from electrothermal effects and flames. Alternating current (AC) is more damaging than direct current (DC). A current of 100 mA flowing from hand to feet can induce ventricular fibrillation. Following the passage of the current, the myocardium is vulnerable and highly excitable. Fatal ventricular arrhythmias may occur.

Clinical features: Burns develop at the sites of entry and exit of the current. When the current is high, instantaneous ignition of clothing or nearby objects add to the injury. Electrical current may produce three distinct types of burns. Flash (arcing) burns, flame (clothing) burns and the direct effect of the current (Joule burn). Burns get secondarily infected in 2-3 days.

The nervous system is highly sensitive to electrical injury. Spinal cord may develop lesions leading to paraplegia and urinary retention. Convulsions, cerebral

edema, and cerebral thrombosis may develop. Current passing through the skeletal muscle can cause muscle necrosis and contractions severe enough to result in bone fracture. Peripheral nerve involvement can cause acute or delayed peripheral neuropathy. Cardiac symptoms include tachycardia, which may be persistent, shock, cardiac arrhythmias including ventricular fibrillation and cardiac failure. Pneumonia, pleural effusion and disorders of ventilation, and hypoxia are the common respiratory findings. Secondary hemorrhage from blood vessels and acute upper gastrointestinal bleeding may develop in a few days. Acute renal failure is a common sequel. Current passing through the abdomen may be complicated by damage to the viscera. Cataracts may form as late sequelae. If current passes through the heart or brainstem death is immediate.

Treatment: First aid includes immediate disconnection of the live contact and cardiorespiratory resuscitation. Due to muscle spasm, the limb holds on to the live wire. This prolongs the injury and this is the main cause of death. Urinalysis, Serum Creatine Kinase (CK) and CK-MB and an electrocardiogram should be done immediately. Administration of intravenous saline or Ringer lactate solution helps to combat shock. Dexamethasone 8 mg and 20% mannitol 250 mL given IV help to reduce cerebral edema. Furosemide 40-80 mg IV is given to overcome pulmonary edema and prevent renal shutdown. Sodium bicarbonate is given to prevent acidosis as an early measure. The prognosis is monitored by estimating the hematocrit, urine volume and arterial pH serially. Suspicion of visceral damage calls for imaging studies and surgical management.

Prevention Proper insulation is necessary while handling electrical equipment. Low plug sockets should be protected from the reach of children. While rescuing an electrocuted person the rescuer should take enough care in first insulating himself properly. Many deaths have occurred among rescuers who have failed to observe proper precautions.

LIGHTNING

Injuries due to lightning are encountered occasionally in the tropics. Lightning induces a high electrostatic charge on the victim. Identically charged particles repel each other, giving rise to disruptive forces, which lead to damage of organs. Organ damage may occur even without external injury. The high current produces violent muscular contractions and severe burns, and ignites inflammable objects on the body.

Clinical features The patient is usually restless, disoriented and may be comatose. Retrograde amnesia is common. Later on he may show psychiatric and hysterical manifestations. Severe vasoconstriction produces manifestations like cold limbs and transient ischemic palsies. Arterial spasm may result in loss of pulse in the affected limb. Increased vascular permeability results in massive edema of the affected part.

Cardiovascular manifestations include tachycardia, extrasystoles and electrocardiographic abnormalities such as elevation of ST segment and inversion of T waves. Sudden death may occur on account of respiratory center paralysis or cardiac arrest (asystole). Intracranial hemorrhage may develop.

Treatment If the vital signs are absent, immediate resuscitatory measures should be started. Even in apparently hopeless cases, gratifying results are not uncommon. Management of survivors consists mainly of supportive measures and treatment of the complications. Vasodilators and low molecular weight dextran help to prevent gangrene. Tetanus prophylaxis must be given if tissue injury has occurred.

Important points

1. Lightning usually involves high voltage
2. Organ damage occurs even without external injury
3. Multisystem involvement is common
4. Death is usually due to cardiac asystole rather than ventricular fibrillation

19

Dangers of Nuclear Explosion

3

T.K. Suma, K.V. Krishna Das

The present day warfare makes use of nuclear explosion to increase destructive power. Many nations on the globe are having sophisticated nuclear weapons, the explosive powers of which exceed the power of several thousand tons of trinitrotoluene (TNT). Nuclear explosions may result from deliberate actions of warring nations or accidents in high power nuclear reactors. It is estimated that among the nuclear powers like the United States of America and Russia, the destructive power that can be generated by nuclear armament may be far in excess of that required to annihilate life totally from the surface of the globe. Many physicians all over the world consider a nuclear war as the worst and the last disaster that can happen to mankind and all other living organisms.

A nuclear explosion results when the fission of Uranium or plutonium proceeds in a rapid and relatively uncontrolled manner. The tremendous release of energy can produce severe explosive shock and temperatures exceeding one million degrees Celsius. The explosion is associated with several destructive phenomena.

The blast wave (also Known as shock wave or pressure wave) is transmitted to the surrounding medium with a highly destructive force. The blast arising from an ordinary nuclear bomb will destroy most of the commercial buildings, apartments and houses, within a radius of 1 km.

Thermal injury The high temperature produced by the explosion converts the materials of the explosive into a ball of very hot gases. This ball expands rapidly engulfing and incorporating the air it meets, becoming larger in the process and this progresses centrifugally. This causes severe burns, maximal at the centre and reducing towards the periphery. At Hiroshima, during the explosion of the atom bomb in the Second World War almost all persons within a radius of 1.6 km were burnt to varying degrees. Another consequence of thermal injury is flash blindness, which is transient blindness (which may become permanent) that results from too powerful a flash.

Ionizing radiation Nuclear explosion emits large amounts of ionizing radiations which themselves are highly injurious to life and health. In addition, they can make other objects also radioactive, so that these objects act as

sources of long-term radioactivity in that area, with consequent health hazards. Large areas may be made unfit for human existence for several decades. Long-term ill effects include higher incidence of several cancers, genetic mutations and congenital malformations. Since the radioactive fall out spills over a much wider area from the target of attack, these phenomena also involve neighboring countries. Radioactive materials may go up into the atmosphere to form radioactive clouds, move to other regions and cause '**radioactive rain**'. The radioactive particles may remain in the troposphere (layer of atmosphere extending up to 11 km from the earth) and stratosphere (layer above troposphere) for up to thirty days or more.

The very high temperatures produced by the explosion will ignite all inflammable materials and lead to large urban fires and forest fires. Liberation of soot and smoke into the atmosphere block the sunlight reaching the earth's surface and lead to a precipitous fall in temperature to well below minus 20 °C which may persist for several months. This phenomenon is referred to as "**nuclear winter**".

Other consequences of a nuclear explosion are common to all mass scale accidents, but on a much higher scale. These include total disruption of communication, breakdown of all rescue and medical facilities, disruption of essential services such as protected water and electricity, and occurrence of severe environmental pollution. These, in their turn start off problems such as starvation, widespread epidemic and famine.

Medical men from several countries have joined to form an international organization - **The International physician for the prevention of nuclear war (IPPNW)**- with a view to educate governments and the public on the possible ill effects of a nuclear war and to use the moral and social position of the doctors on the public and government to adopt nuclear disarmament.

India is a participant in this movement. It is the duty of every doctor to uphold and promote these aims. The National Association of Indian Doctors for the Prevention of Nuclear War (NAIDPNW) which was later changed to

Indian Doctors For Peace and Development (IDPD), has its office at 139-E, Kitchlu Nagar, Ludhiana- 141001 (Punjab)India

Important points

1. Release of energy during nuclear explosion produces severe shock and high temperature

2. Thermal injury causes severe burns and flash blindness
3. Ionizing radiation from nuclear explosion results in long-term effects like development of cancers, genetic and congenital abnormalities
4. Nuclear winter is a complication of nuclear explosion
5. It is the duty of all doctors to prevent nuclear warfare at all costs

3

20

Adverse Effects due to Noise and Vibrations

T.K. Suma, K.V. Krishna Das

Chapter Summary

Noise 104

Vibration 105

Noise

Noise is unwanted sound and it produces adverse effects on man. With the progress in industry and transport, noise pollution is increasing in all countries. Continuous loud noises lead to impairment of hearing, irritability and accelerate fatigue. Noise disturbs sleep.

Noises occur in various forms. They may be pure tones (siren), narrow bands of frequencies (hiss of escaping stream), broad bands of frequencies (radio), impulses (explosive release of gas in gun fire) or impacts (hammer striking a steel plate). The stimulus may be continuous or intermittent and the intensity also varies. The unit of sound is the decibel. Decibel is 1/10 of a bel. Bel is the unit of sound pressure intensity and is measured as the logarithmic ratio of the particular sound to that of a reference sound, which has an intensity of 0.002 dynes/sq.cm at 1000 cycles per second.

Exposure to noise levels greater than 85 and 95 decibels for months to years can lead to cochlear damage. In the early stages, there is loss of hearing at or near frequencies of 3000 to 4000 cycles per second. Later the damage extends to both higher and lower frequencies. Higher tones are affected early, later extending to lower tones as well. The subject may not be aware of the hearing

loss until it is severe. Speech reception is not altered seriously until the loss of hearing is greater than 30 decibels in the speech frequencies (500,1000, 2000 cycles per second). Children are more susceptible for noise-induced hearing impairment than adults.

Noise induced loss of hearing has two phases. In the initial phase there is a rise in threshold of sound, which is temporary and in the latter phase this defect becomes permanent. Further a temporary threshold shift can be superimposed on permanent defect of hearing.

Persons vary in their sensitivity to the effects of noise. The factors, which influence the final outcome are:

1. Overall sound pressure levels of the noise,
2. Frequency bands of which the noise is composed,
3. Daily distribution and total duration of noise exposure, and
4. Susceptibility of the ear exposed to the noise.

The most striking finding in noise-induced loss of hearing is injury of degeneration of the sensory cells, mainly the outer hair cells of the organ of Corti. After exposure to noise the cilia in the inner and outer hair cells of the cochlea become fused and bent. After more prolonged exposure, there is degeneration of the outer and inner hair cells related to transmission of high-frequency sounds.

In old age there is a general tendency to develop hearing loss, (*presbycusis*) = due to degeneration of the striae vascularis of the cochlea. Presbycusis starts with loss of high frequency sound. Exposure to heavy background noise, smoking and high lipid diet accelerates this hearing loss.

EFFECTS OF IMPULSE NOISE ON MIDDLE EAR AND EAR-DRUM

Impulse noise can be defined as an acoustic event associated with sudden changes in pressure. The pressure wave initially travels faster than the speed of sound. Very high intensity impulse noises from explosions are known to damage the eardrum, middle ear and inner ear structures. The body reacts to impulse noise by increasing blood pressure, heart rate and respiration. Muscles become tense and there will be increased secretion of catecholamines. These changes can occur even during sleep and continuous exposures during the night may affect person's general health producing irritability and fatigue. Studies have shown that children studying in schools near airport subjected to chronic aircraft noise exposure have impaired reading comprehension, intellectual performance and long-term memory.

Mortality in relation to noise pollution Probably death due to cerebrovascular accidents, cardiovascular disease and cirrhosis of liver increases with increasing noise pollution. There is also increasing incidence of stroke, hypertension and peptic ulcer. It may affect fetal development.

Prevention of noise-induced loss of hearing involves regular audiometric screening of workers exposed to industrial noise and reducing the noise levels to the minimum and protection of exposed personnel. The recommended noise level at night is a maximum of 35 dB. For hospital wards an ambient level of 40 dB has been recommended.

Important points

1. Exposure to noise levels more than 85 to 90 dB can lead to cochlear damage
2. Children are more susceptible for noise-induced hearing impairment than adults
3. Noise induced hearing impairment may be permanent
4. Impulse noise damages the eardrum, middle ear and inner ear structures

VIBRATION

Vibratory tools and machines of various types including pneumatic hammer and drills are in common use at present. Frequencies of 250 Hz with an amplitude of 1 mm are most likely to cause damage. The group of symptoms and signs produced by exposure to vibration is known as **Hand-Arm Vibration Syndrome** or HAVS. This depends on a) the amount of vibration the tool produces, b) the length of time the tool is used each day, c) the total number of hours or days or month the tool has been used, d) the way in which tool has been held. HAVS results in vascular damage, neurological and musculoskeletal dysfunctions. Due to vascular damage episodic blanching of one or more fingers occurs, which will be well demarcated and is known as the *white finger*. This is usually triggered by cold. The latency period for development of *white finger* may vary from 6 months to 20 years. Neurological symptoms are tingling and numbness, reduced strength of grip and impaired dexterity.

Musculoskeletal damage caused by vibration includes:

1. Decalcification or cyst formation of carpal bones,
2. Injuries to the soft tissues of hand,
3. Arthritis of wrist, elbow and shoulder, and
4. Spasm of the arteries and *Raynaud's phenomenon* - "The White hand" or "dead hand"

Bone cysts rarely produce pathological fractures. Injuries to the soft tissues often involve the palmar aponeurosis and may produce adventitious bursae, which fill the palm. Arthritic symptoms are attributable to active damage of joint surfaces, caused by the large pneumatic tools. Once established, the damage persists. Very recently, Hand-Arm Vibration Syndrome has been reported following prolonged use of vibrating computer games especially in children.

21

Motion Sickness, Problems due to Air Travel and Road Accidents

T.K. Suma, K.V. Krishna Das

Chapter Summary

Motion Sickness 106
Medical Problems of Air Travel 106
Road Accidents 108

MOTION SICKNESS

The term motion sickness refers to the clinical picture resulting from movement of an individual on land, sea or air when journeys are undertaken. Repetitive irregular movement as in a swing, a lift or even dancing, may bring on such symptoms.

It is mainly a disorder of gastric and intestinal functions brought on in susceptible subjects while traveling. Irregular and unaccustomed stimulation of the labyrinth causes nausea and vomiting and also disorders of function in the viscera innervated by the vagus or parasympathetic system. During sea voyage the roll and pitch of the ship causes excessive stimulation of the labyrinth. In the case of car and aeroplane travel, labyrinth is subjected not only to the effects of rotation of the body through planes to which it is not accustomed, but also to rapid acceleration, deceleration and altitude changes. Angular acceleration of train and the linear-angular acceleration of turbulent flights are important causes of motion sickness. Visual stimuli from moving objects and proprioceptive stimuli from muscles and joints contribute to the final outcome. Fear and anxiety make the condition worse. Early infancy is immune from this affection, since the orienting mechanism has not attained full physiological activity and old age is relatively immune, probably because of the lessened sensitivity of the nervous system. The signs and symptoms of motion sickness occur when sensory information about the body's position in or movement through space is contradictory to prior experience. Susceptibility and tolerance to motion sickness vary widely among individuals. Motion sickness is more common in women, especially during pregnancy or menstruation, in children aged 2-12 years, and in persons who have migraine headaches.

Clinical features The initial symptoms include loss of usual sense of well being, abdominal and visceral discomfort, salivation, nausea and yawning. The patient becomes pale and respiration becomes irregular. These symptoms are followed by retching, vomiting and desire to defecate. The vomiting may be mild and transient in some, while in others this may be violent, distressing and recurrent. Headache, giddiness, continued pallor, apathy, lassitude, weakness, dehydration and prostration follow. The skin may become cold and clammy, tongue coated, both breath and urine may contain acetone bodies, pulse and respiration become rapid and the blood pressure drops.

Diagnosis is easy when the symptoms are related to travel, but other causes of abdominal disorders must not be overlooked.

Course and prognosis The symptoms usually subside when the travel or the movement causing the condition comes to an end, but in some cases dizziness, headache and gastric symptoms persist for a long time. In cases of long voyages by seas, the symptoms may subside in a few days but may sometimes persist.

Prophylaxis and treatment Reclining posture, avoidance of visual stimuli and reduction in head movements to the minimum help to minimize the condition. Mental distraction may help to allay the symptoms.

Antihistamines given in small doses 30–60 minutes before starting the travel prevent motion sickness, e.g., diphenhydramine 25-50 mg oral. phenothiazines such as trifluoperazine 10 mg or hyoscine (0.3 mg) are good alternatives. To treat motion sickness higher doses of the same drugs have to be given. The choice of drug should be based on the underlying conditions if any.

MEDICAL PROBLEMS OF AIR TRAVEL

The long hauls and undue delay *en route* are matters of great concern to the severely ill patients. Psychological stress caused by frequent dislocation of connecting flights and fear of skyjacking adds to the problem. Travel by

modern aircrafts is safe and comfortable on account of the appropriate adjustment of cabin pressure, cabin atmosphere, air conditioning and oxygen supply. Many modern aircrafts fly at altitudes of 7,000-13,000 meters.

Problems due to reduction in barometric pressure and partial pressure of oxygen The commercial transport aircrafts are pressurized, but cabin pressure is subject to fluctuations. At 2,600 meters the ambient pressure is about 560 mm Hg, the partial pressure of inspired oxygen is 118 mm Hg, and that of alveolar oxygen 65 mm Hg. In patients with ischemic and hypertensive heart diseases this degree of hypoxia can cause angina or cardiac failure. Cerebral ischemia may manifest in atherosclerotic individuals. Sick cell crises may be precipitated in susceptible patients. There are many airports situated at altitudes more than 1800 meters above sea level and relative hypoxia at these levels can cause problems of high altitude in such individuals. Decreased barometric pressure results in expansion of gas trapped in body cavities. Blocking of sinuses and Eustachian tubes lead to severe facial or middle ear pain. Dental pain may develop due to expansion of air trapped in badly filled cavities. In pneumothorax and pneumoperitoneum the entrapped air expands and can cause rise in tension. The gas in the stomach and intestines (about 1 to 1.5 liters) can expand as much as 25%. This may cause a feeling of fullness and discomfort, acute abdominal colic, lower central chest pain and collapse resembling myocardial infarction. The risk of gastrointestinal hemorrhage is increased. Unsupported hernias strangulate more readily.

Problems in apparently healthy travelers Long flights result in rapid changes in climate and time zones. Rapid geographical transitions around the world disturb the natural biological rhythms of the individual. Motion sickness, sleeplessness, tension, headache, pain in the neck, shoulders and back, nausea, dyspepsia, urinary frequency and constipation are not unusual accompaniments of the flying stress. More serious symptoms such as cardiac arrhythmias, manic excitement, hallucination and paranoid delusions may develop in a few. As a result of long flying sessions and rapid changes of climate and time zones, symptoms like physical exhaustion, spurious sensation of mental alertness and mild euphoria may persist for one or two days after reaching the destination. Some passengers find it difficult to adapt quickly to the new climatic environment and they may develop sleep disturbance, intellectual under-functioning and psychosomatic symptoms. Reduction in fatty food and alcohol intake during flights help to reduce the symptoms to a great extent. Immobility during long flights may predispose to deep vein thrombosis.

Problems in chronically ill patients Facilities in commercial aircraft make it possible to airlift even acutely

ill and seriously injured persons, although isolation facilities may not always be available. Oxygen delivered by nasal masks is available in all modern aircraft for emergency use.

Cardiovascular diseases In view of the lower partial pressure of oxygen, it is advisable to avoid flying for six weeks following acute myocardial infarction.

Treated cardiac failure, occasional angina, old infarction, hypertension and chronic valvular diseases do not carry any added risk. During "check-in", patients with implanted pacemakers should avoid electronic and magnetic devices used for screening the passengers. Many major airports are equipped with emergency resuscitation equipment and trained volunteers who can attend to sudden cardiac events.

Cerebrovascular accidents and epilepsy Flying is contraindicated for six weeks following strokes. Flying at more than 3000 meters altitude may precipitate epileptic attacks if proper medication is not given.

Pulmonary diseases Persons with pulmonary decompensation at rest or on mild exertion should undertake air travel only when there are facilities for therapeutic oxygen. Patients with acute asthmatic episodes not relieved by self-medication, and status asthmaticus should avoid air travel till such attacks are well controlled. Rupture of emphysematous bullae producing tension pneumothorax is a possible risk on board of the aircraft.

Hematological diseases It would seem wise to restrict air travel if the hemoglobin level is less than 9 g/dL. Patients with sickle cell disease should undertake air travel only if the ambient oxygen tension can be maintained at 150 mm Hg. Splenic infarction and serious sickle cell crises can be precipitated if the oxygen tension is low.

Pregnancy Pregnancy beyond the 35th week may pose the risk of labour during flight.

Deep Vein Thrombosis

Many long distance travellers who sit crammed up in aircraft for flights exceeding eight hours may develop deep vein thrombosis (DVT) in the lower limbs particularly so in obese and elderly persons. Presence of thrombophilia adds to the risk. In addition to the mechanical obstruction to venous drainage and inactivity during the flight, there is evidence that continuous flights exceeding 8 hours may activate the coagulation cascade in predisposed individuals.

Fighter aircrafts Modern fighter aircrafts exceed human physiological limits to withstand head to foot acceleration forces (positive G2 forces). This may lead to sudden syncope with prolonged periods of incapacitation, especially in vagotonic individuals. Psychomotor

Disorder due to Physical Agents

performance may be impaired. All these adverse effects can be avoided by proper conditioning of the individuals during training.

All commercial airlines provide information on the facilities available with them for transportation of invalid passengers. All airports have facilities for attending to emergencies that may develop during air travel.

3

Important points

1. Hypoxia may aggravate angina or cardiac failure in a hypertensive or patients with coronary artery disease
2. Atherosclerotic individuals may develop cerebral ischemia
3. Expansion of gases in body cavities produces various symptoms
4. Healthy individuals may be prone to motion sickness, cardiac arrhythmias and manic excitement
5. Chronically ill patients should take sufficient precautions before undertaking air travel
6. Deep venous thrombosis may occur in susceptible individuals during long flights

ROAD ACCIDENTS

General Considerations

In modern times mortality and morbidity caused by road accidents is on the rise. This is common in all countries of the world where fast traffic on the road is increasing.

In India 30 persons out of 100000 die annually due to road traffic accidents. The accidents may involve the vehicles or the pedestrians using the road. The major types of accidents are collision between vehicles, loss of control of the vehicle and collision with hard objects or overturning. The other type of accidents involves knocking down pedestrians or occupants of lighter vehicles such as two wheelers and light motor vehicles. In general the major damage and passenger injury occurs to the lighter vehicle.

The major factors contributing to road accidents can be classified as given below:

A. Causes attributable to the vehicles

1. *Speed of the vehicle*- The rate and severity of the accident increases with increasing speed of either vehicle. With the introduction of modern highways speed-related injuries have become much more common
2. *Mechanical defects in the vehicle*, which lead to failure of the controls.
3. *Exceeding the safety limits* prescribed for the vehicle in terms of speed, loading and maintenance.

B. Causes attributable to the driver

1. *Fatigue and sleep*- long driving exceeding 6 hours of continuous driving leads to driver fatigue, delay in the reflexes and tendency to sleep.

2. *Drunkenness*: Consumption of alcohol and less commonly other narcotic drugs impairs the efficiency of the driver
3. *Inattention, non-compliance with signals and rash driving*
4. *Inexperience of the driver*

Most of the major collision accidents occur on highways, especially in the early hours of the morning when driver fatigue and somnolence are maximal. Rarely accidents may occur due to organic disease in the driver such as epilepsy, cardiovascular disease, strokes and others.

Injuries to Pedestrians

Walking on highways and fast traffic roads is associated with injury to the pedestrians.

Elderly people, obese individuals, persons with movement disorders, alcoholics and children are involved more.

INJURIES CAUSED BY ROAD ACCIDENTS

Vehicular Accidents

Trauma to the driver and passengers due to the impact and damage and deformation to the vehicle are usually serious. This leads to injuries which may be instantaneously fatal. In motor car accidents, the luggage kept unsecured in the passenger compartment fly out and cause further missile- like injuries to the passengers. Trauma to vital parts such as head, chest cage, spine, bones, abdomen and major blood vessels, intracranial injuries, intracranial bleeding, tension pneumothorax, rupture of major blood vessels like aorta, injuries to the heart, rupture of solid organs and hollow viscera in the abdomen and pelvis and exsanguinating bleeding (both external and internal) are the causes of death at the site of accident or within a few hours. Pedestrian injuries cause death due to damage to vital structures, especially intracranial bleeding, chest injuries, intra abdominal injuries and exsanguination.

MANAGEMENT AT THE SITE OF ACCIDENT

Effective first aid helps to save life and reduce morbidity and delayed mortality. Mainly this consists of maintenance of the airway and attention to ventilation, tourniquets to arrest external hemorrhage, immobilization of parts of the body such as the neck and spine to avoid further damage to the vital neural structures, covering open chest injuries which interfere with ventilation and rapid transport to the nearest hospital with adequate facilities. *It is the duty of all medical men to give first aid in such a situation.* It is to be remembered that an obvious injury may distract the attention of the doctor from other invisible injuries such

as internal bleeding or rupture of viscera which can cause death.

When major accidents involving buses occur, a large number of persons will be simultaneously affected and this may cause a heavy strain on the medical facilities. In this situation, a senior medical officer has to inspect the victims and using the principles of 'triage', arrange for appropriate management. In such an emergency all medical personnel have to participate in the emergency management.

All road traffic accidents invite legal procedures which have to be complied with.

General guidelines to reduce road traffic accidents and their consequences

1. Education of the public on the safe use of roads and motor vehicles
2. Strict compliance with road traffic rules
3. Avoidance of alcohol and drugs before driving
4. Avoid driver fatigue and somnolence

5. Avoid the presence of unsecured luggage in the passenger compartment
6. Use the seat belts as prescribed.
7. Enforcement of traffic regulations by the appropriate authorities.

Note: In all developed countries, well coordinated emergency management teams attached to major hospitals are available, ready to render assistance at the site of accident, during transport to hospital, and later. This team consists of trained ambulance personnel, anesthetists, trauma care surgeons, other physicians and specialists, trained nursing team and paramedics.

Points to remember

1. Road accidents are increasing to reach epidemic proportions
2. Main causes are over speed and driver fatigue
3. Proper first and specialized care help to save life and reduce morbidity
4. Road accidents are preventable to a great extent

4

Toxicology

22. Acute Poisoning: General Considerations	112	24. Food Poisoning	125

Acute Poisoning: General Considerations

T.K. Suma, K.V. Krishna Das

4

Chapter Summary

General Considerations 112
 Clinical Presentation 112
 General Management 112
 Specific Measures 113
 Forced Diuresis 114
 Dialysis and Hemoperfusion 115

GENERAL CONSIDERATIONS

Acute poisoning accounts for 2-3% of admissions into major general hospitals in India. Poisoning may be suicidal, accidental or homicidal. The high incidence of poisoning is attributed to the widespread use and free availability of insecticides, pesticides and other harmful chemicals for use in agriculture and industry. Depending upon the cost and local availability, varied substances are used. In the order of frequency, the toxic agents include organophosphorus compounds, barbiturates, benzodiazepines, vegetable poisons, phenothiazines, corrosive acids, and several others. The precipitating factors, which drive persons to commit suicide, are depressive illness, financial problems, domestic conflicts, and frustration in studies and jobs or incurable illness. Among epileptics and alcoholics the incidence of suicidal poisoning is high. Accidental poisoning is common in children. Persons engaged in the use of toxic chemicals in agriculture and in industry are liable to suffer if proper safety precautions are not adhered to.

CLINICAL PRESENTATION

Though poisoning by many chemicals lead to characteristic clinical features, in the majority of cases symptoms are non-specific and may be mistaken for other acute illnesses. The common presentations are coma, acute psychosis, convulsions, gastroenteritis, circulatory collapse, or pulmonary edema.

112 Corrosive poisons produce noticeable lesions at the points of maximum contact such as the mouth, esophagus

and stomach. Other poisons affect specific organs maximally, e.g. liver damage in paracetamol poisoning, renal damage in copper sulphate poisoning, and cardiac dysfunction in *Cerebera odollam* poisoning. Poisons consumed on an empty stomach are absorbed more rapidly than if taken on full stomach. Also, if taken along with alcohol, many poisons are quickly absorbed and their damaging effects are cumulative.

Diagnosis Diagnosis is rendered easy if proper history or evidence of the material is obtained, but in many cases such help is not available. A high index of suspicion on the part of the physician is absolutely necessary for arriving at an early diagnosis in such cases.

Abrupt occurrence of acute illness in a person who is in good health should suggest acute poisoning as a possibility. Smell of alcohol or kerosene, severe respiratory depression, circulatory collapse, convulsions, constricted pupils, cardiac arrhythmias, dystonic postures, and muscle fasciculations add support to this diagnosis.

The outcome depends upon factors like:

1. The amount of poison and its mode of administration,
2. Presence of food in the stomach at the time of ingestion,
3. Delay in starting treatment,
4. Age,
5. General health and concurrent illness, and
6. Availability of specific antidotes.

Patients who are comatose due to acute poisoning face the twin dangers of the toxic-effects of the chemical and the grave consequences of an obstructed airway.

GENERAL MANAGEMENT

Acute poisoning is a medical emergency and is best treated in a well-equipped hospital with teams specially trained to handle such cases. Since in many cases the nature of the poison will not be evident at first, the aim of treatment is to keep the patient alive with support of vital functions, eliminate as much of the poison as possible from the body and prevent further absorption of poison. Specific antidotes are given as soon as the nature of the poison is

known. Selective antidotes are available only for 2% of such poisons.

Emergency Management Most important is to clear the airway and ensure adequate ventilation by positioning, suction, or by insertion of nasal or oropharyngeal airway. The respiration should be clinically assessed and if there is ventilatory impairment necessary support with supplemental oxygenation and mechanical ventilation should be instituted. Intermittent positive pressure respiration has to be started with endotracheal intubation, if conservative measures fail. The patient should be turned from side to side at four-hourly intervals to prevent aspiration and hypostatic pneumonia. Frequent bronchial suction helps to prevent atelectasis and aspiration pneumonia.

Shock is managed on the usual lines. Maintenance of fluid and electrolyte balance is of utmost importance in all cases.

Decontamination of skin Pesticides and other chemicals which are present on the cloths and skin get absorbed through the skin and worsen the condition. Similarly corrosive agents rapidly injure the skin and eyes. In these situations washing the affected area with large quantities of water and soap prevents further systemic absorption of the toxin. Normal saline is preferred for irrigation of the eyes.

General Measures

An intake output chart should be maintained and a urine output of at least 1500 mL should be ensured. Replacement of electrolytes and correction of acidosis should be done with proper laboratory monitoring. Maintenance of nutrition is equally important. Diet containing 2000 calories should be given orally if the patient is conscious. In unconscious patients food has to be given through a nasogastric tube. Parenteral nutrition has to be started in severely affected patients.

Repeated examination of blood and urine for the level of the toxic agent helps to monitor the progress with treatment.

Specific Measures

a. **Ingested poisons** In many cases of ingested poisons, considerable amounts remain in the gastrointestinal tract up to four hours; hence it is absolutely necessary to take appropriate measures for their removal. Induction of vomiting is safe in conscious patients. Vomiting is induced by tickling the pharynx or administration of gastric irritants such as concentrated common salt solution 200-400 mL. In the case of corrosive poisons and highly irritant substances like kerosene, emesis and gastric intubation are

contraindicated. Gastric lavage by using a stomach tube is an effective method to empty gastric contents rapidly and this can be done even in unwilling patients. This is the method of choice in all conscious patients who have consumed noncorrosive poisons. However, it is risky in comatose patients due to the danger of aspiration into the respiratory tract and in such cases aspiration through Ryle's tube is preferable. Gastric contents should be preserved in a sealed bottle for chemical examination and further medicolegal procedures. Use of activated charcoal, which adsorbs many toxins reduces gastric and intestinal absorption further. Dose is 50-200 g in 200 mL water initially and 50 g 6 hourly till recovery. The surface area of activated charcoal is increased several folds, compared to the parent substance and this large surface area adsorbs several substances non-specifically.

Purgatives such as magsulph. 15-30 g or sorbitol 1 g/kg bw (maximum of 150 g) orally followed by bowel wash 2 hours later help to eliminate the poison from the intestine.

b. **Removal of absorbed poisons** Forced diuresis enhances the renal excretion of many poisons. Hemodialysis helps to eliminate many water soluble substances.

Forced Diuresis

The kidneys can be made to eliminate poisonous drugs at a rate consistent with the urine output. Contraindications include congestive cardiac failure, renal failure, rhabdomyolysis and cerebral edema.

In an unconscious patient a Foley's catheter should be introduced to facilitate uninterrupted flow of urine and for proper monitoring of output.

Dialysis and Hemoperfusion

Dialysis Since most of the cases recover with forced diuresis, hemodialysis is indicated only in a few. Indications for hemodialysis are: (a) high blood levels of the drug, (b) renal failure, and (c) non-responsiveness to forced diuresis and (d) poisoning associated with deep coma, hypotension and fluid and electrolyte disturbances. In the absence of facilities for hemodialysis, peritoneal dialysis should be undertaken. Hemodialysis is 6-10 times more efficient than peritoneal dialysis.

Hemoperfusion is the process of passing the patient's blood through cartridges packed with activated charcoal, which adsorbs drugs and toxins such as barbiturates, carbamazepine, glutethimide, meprobamate, methaqualone and several others. Cartridges ready for use are available commercially at around Rs. 4000 per piece.

Multiple dose activated charcoal Doses of activated charcoal 1-2g/kg bw repeated every 2-4 hours hasten

TABLE 22.1

Specific antidotes to poisons commonly consumed

Organophosphates	Atropine	Loading dose 2 mg IV every 2–5 minutes until pupils dilate and salivation is reduced. Maintenance based on pupil size for hours to days.
	Pralidoxime	Loading dose 1-2 g IV repeat after 3 hrs.
Opiates (Opium, morphine, meperidine, propoxyphene, pentazocine, diphenoxylate)	Naloxone (Nalorphine hydrochloride)	Loading dose 0.4-2 mg IV repeat in 2-5 min, as is required
Methanol, ethylene glycol	Ethanol	Loading dose 0.6-0.7 g/kg. Maintenance: sufficient ethanol to keep serum alcohol level at 100 mg/dL (approx. 125 mg/kg/hr) and methanol concentration falls below 10 mg/dL
Cyanide	Amyl nitrate, sodium nitrite, sodium thiosulphate to be given sequentially	1. Start with amyl nitrate inhalation 1 amp. every 2-3 min 2. then give sodium nitrite 10 ml of 3% solution IV over 5 mts. 3. then give 50 ml of 25% sodium thiosulphate over 10 mts.
Acetaminophen	N. acetylcysteine	140 mg/kg oral, thereafter 70 mg/kg oral every 4 h for 17 doses (72 hours)
Iron salts	Desferrioxamine	If the patient is hypotensive 10 mg/kg/hr IV for 4 hours, then 5 mg/kg/hr IV until serum iron level is less than 100 mcg/dL. If patient is normotensive, 40 mg/kg IV every 4-12 hrs. Total daily dose should not exceed 6 g.

elimination of drugs by adsorption of drugs excreted into the gut lumen (gut dialysis).

Antidotes Antidotes are available for 2% of the poisonous substances. These may be chemical antidotes, which neutralize the action of the poison, or biological antidotes, which prevent their pharmacological response. They should be employed only after ascertaining the nature of the poison. In most cases, the antidote is indicated by the manufacturers on the packing of the toxic chemical (Table 22.1).

Many of the patients with suicidal poisoning attempt to repeat these episodes because of their psychiatric problems. Hence, it is necessary to instruct their relatives and also arrange for proper psychiatric treatment after the initial episode is treated.

Important points

1. Poisoning accounts for 2-3% of admissions into major general hospitals in India
2. Selective antidotes are available only for 2% of the poisons
3. Management goals include support of vital signs, enhancement of elimination of the poison, prevention of further absorption of the poison and administration of specific antidote
4. Forced diuresis, hemodialysis, hemoperfusion and peritoneal dialysis are methods by which absorbed poisons could be removed

APPENDIX

Methods to Eliminate Poisons

- Forced diuresis
- Peritoneal dialysis
- Hemodialysis
- Hemoperfusion

FORCED DIURESIS

This is employed when the toxin is removable by the kidney and the metabolites are toxic to the system. A substantial proportion of the poison is excreted in the urine unchanged. The poison should be distributed mainly in the extracellular fluid and only minimally bound or not bound at all to proteins.

Rationale Elimination of the toxic substance is enhanced by manipulation of the urine pH so as to render the toxin in the ionized form. Forced diuresis should be considered, and may be indicated, in poisoning due to the following substances.

Alkaline diuresis

- Phenobarbitone or barbitone
- Salicylates
- Phenoxyacetate herbicides

Acid diuresis

- Phencyclidine
- Amphetamine
- Fenfluramine

Potential complications

- 1. Fluid overload
 - 2. Pulmonary edema
 - 3. Cerebral edema
 - 4. Electrolyte and acid-base disturbances.
- Diuresis is induced by giving 5% glucose continuously IV as drip and frusemide IV in dose of 20 mg 6th hourly depending on the response.

Proper estimation of electrolytes and acid-base states should be undertaken during and after the procedure.

Forced acid diuresis The urine pH is adjusted to 5.5-6.5 by giving: 10 g arginine or lysine hydrochloride intravenously over 30 minutes followed by ammonium chloride 4 g 2 hourly, by mouth.

Forced alkaline diuresis The urine pH is adjusted to 7.5-8.5 by giving boluses of 50 mmol (approx 50 mL) of 7.5% sodium bicarbonate solution. Often 200-300 mmol is required in the first 1-2 hours. Since a large sodium load is being given with the bicarbonate cardiac failure may be precipitated in susceptible individuals.

DIALYSIS AND HEMOPERFUSION

In hemodialysis, materials, which are dialyzable including toxic materials, are dialyzed across a semipermeable membrane, using appropriate solutions, which will permit the removal of the toxic substance. Dialysis machines are available in several hospitals offering secondary care. Hemoperfusion is the removal of the toxic material by perfusion of blood through a cartridge containing material, which will adsorb the particular substance.

Requisites for Instituting Dialysis Procedures

- 1. The drug or toxic substance should diffuse easily through the peritoneum or dialysis membrane or be readily adsorbed to activated charcoal or uncharged resin.
- 2. A significant proportion of the poison should be present in plasma water or be capable of rapid equilibration with it.
- 3. The pharmacological effect of the substance should be directly related to the blood concentration.
- 4. Antidote is not easily available.

Depending on the situation any one of the procedures can be adopted. Compared to peritoneal dialysis, the other procedures are thrice more efficient.

Indications for Dialysis and Hemoperfusion

- 1. Severe clinical intoxication as shown by grade IV coma, hypotension, hypothermia and hypoventilation caused by hypnotic drugs.

Types of elimination procedure ideal for specific toxic agents	
Salicylates	1,2,3
Phenobarbitone	1,2-3
Barbitone	1-2-3
Methanol/ethanol	1-2-3
Lithium	1-2
Isopropanol	1-2
Short and Medium acting barbiturates	3-
Glutethimide	3-
Meprobamate	3-
Methaqualone	3-
Disopyramide	3-
Theophylline	3-
Key:	
1. Peritoneal dialysis 2. Hemodialysis 3. Hemoperfusion	

- 2. Progressive clinical deterioration, despite adequate supportive management.
- 3. High plasma concentration of the toxic agents.

Drugs that can be effectively dialysed includes barbiturates, phenytoin, primidone, paraldehyde, chloral hydrate, amphetamine, alcohols, methanol, ethylene glycol, salicylates, paracetamol, several antibiotics, isoniazid, quinine, quinidine, metallic salts including lithium, bromide, iodide and potassium, ergotamine, carbon tetrachloride toxic principles of mushrooms and others.

Contraindications

- 1. The toxic substance is a rapid acting metabolic poison.
- 2. The effect of the substance is irreversible, e.g. organophosphorus compounds.
- 3. The drug is relatively non-toxic, e.g. benzodiazepines.
- 4. The drug has a very large volume of distribution.
- 5. Cardiogenic shock.
- 6. Coagulopathy.

Potential Complications

- 1. Thrombocytopenia (about 30% reduction)
- 2. Leucopenia (about 10% reduction)
- 3. Loss of clotting factors.
- 4. Lowering of calcium, glucose
- 5. Bleeding tendency due to heparinization
- 6. Patient may disconnect shunt lines
- 7. Air embolism
- 8. Infection

The choice of elimination technique should depend upon the plasma level of the substance.

Elimination Procedures to be Adopted if the Plasma Level of the Toxic Substance is High

Salicylates			
500 mg/L + metabolic acidosis, or 750 mg/L	Alkaline diuresis	Methanol, ethylene or glycol 0.5g/dL	Peritoneal dialysis hemodialysis.
750 mg/L + renal failure, or 900 mg/L	*Hemodialysis or	Dialysis	is indicated if more than 30 g has been ingested or
All barbiturates except Phenobarbitone and Barbitone 50 mg/L	*Hemoperfusion Hemoperfusion		there is metabolic acidosis, mental, visual or fundusco-pic abnormalities. Many antifreeze solutions now contain methanol as well as ethylene glycol.
Ethchlorvynol 150 mg/L	-do-		Hemodialysis, significant hypotension is an important clinical indication for hemodialysis.
Glutethemide 50 mg/L	-do-		Peritoneal dialysis or hemodialysis. Forced diuresis is ineffective and an infusion of sodium chloride is dangerous as well
Meprobamate 100 mg/L	-do-	Isopropanol 0.4 g/dL	
Methaqualone 40 mg/L	-do-		
Trichloroethanol derivatives 50 mg/L	-do-		
Phenobarbitone and barbitone 75-100 mg/L	Alkaline diuresis Hemodialysis, hemoperfusion	Lithium 5 mmol/L (3470 g/L)	
150 mg/L	Hemoperfusion. Correction of hypokalemia is most important and this may obviate the need for hemoperfusion		
Theophylline 60 mg/L			

NB *Hemodialysis and hemoperfusion are two to three times more efficient than forced diuresis.

Narcotics-Morphine and Opioids 123
Paracetamol 123
Petroleum Products–Kerosene 124
Organochlorine Insecticides 124
Ethylene Dibromide Poisoning (EDB) 125
Phosphide Poisoning 125

Organophosphorus Compounds

These are the most widely used toxic agents for suicidal poisoning. Accidental poisoning occurs in workmen engaged in spraying operations. Contamination of food materials during storage or transportation has led to dramatic outbreaks of food poisoning in Kerala and many other parts of India. A dose of 40-100 mg proves fatal.

The commonly available products are methyl parathion (Folidol, Paramar, Metacid, Paramet), malathion (Malathion, Cythion) and phalone (Zolone, Sumithion, Faithion, Timidan, Ektakin).

Organophosphorus compounds irreversibly phosphorylate acetyl cholinesterase (AChE) leading to the accumulation of acetyl choline at the cholinergic nerve endings such as autonomic ganglia, parasympathetic nerve endings and motor end plates.

CLINICAL FEATURES

Symptoms start within 15-30 minutes after ingestion of the toxin. Consumption on an empty stomach and along with alcohol favours rapid absorption.

Gastrointestinal or neurological symptoms may predominate. Nausea, vomiting, diarrhea, involuntary defecation, blurring of vision, miosis, excessive sweating, lacrimation, salivation, and pulmonary edema constitute the muscarinic effects. Effects on central nervous system include drowsiness, coma, convulsions, and respiratory depression. Stimulation of pre-ganglionic fibres leads to sympathetic overaction and later paralysis, muscle twitching, fasciculation, weakness, and flaccid paralysis (nicotinic effects) (Table 23.1).

Diagnosis

In almost all cases, history, circumstances and the smell of the poison help to confirm the diagnosis. The chemical

compound can be identified by examination of gastric contents and blood.

Diagnosis is clinical, supported by evidence of consumption of the poison. Estimation of serum levels of pseudocholinesterase is helpful. Normal level of pseudocholine esterase in serum is 1750-3500 μ U/mL. Serum levels of the enzyme correlate inversely with the severity.

Reduction of serum pseudocholinesterase values below 50% of base line suggests poisoning.
Levels of 20-50% = mild poisoning.
10-20% — moderate severity
<10% — severe
Levels <200 IU are associated with ventilatory failure.

TREATMENT

The general measures for oral poisons should be instituted without delay.

Atropine

Atropine is the pharmacological antidote, and it is the sheet anchor of treatment since it antagonizes the peripheral effects of acetylcholine. It is freely available in all hospitals and cheap. This drug prevents pulmonary edema and excessive secretions. The dose requirement varies widely. In general, large doses have to be used. The ideal way to administer the drug is through an intravenous 5% glucose drip. A dose of 2 mg is given initially and 1 mg or more is repeated every 10 minutes (or even at shorter intervals) till the pupils are dilated to normal size and pulmonary edema and bronchorrhea is cleared. In many cases heroic doses, often several hundred ampoules of atropine may be required within a few hours to tide over the crises. The patient has to be observed very closely to prevent deterioration and death.

Maintenance dose is continued to keep the pupils in mid-dilation. It is usually possible to withdraw atropine after 24-48 hours but in some cases it may have to be continued for up to 5 days. Release of the toxin from lipid tissues after an interval of 2-3 days may result in return of symptoms and death after a period of apparent recovery. Hence, all patients have to be closely watched for at least 7 days after onset of the symptoms. In such cases, repetition of massive doses of atropine and supportive measures are to be undertaken.

Pralidoxime Hydrochloride

Pralidoxime hydrochloride is the specific antidote. It is given IV in a dose of 1-2 g initially and repeated 2-3 hrs later. It is available as 500 mg in 20 mL vials. Pralidoxime hydrochloride reactivates cholinesterase enzyme at the neuromuscular junctions by removing the phosphate group bound to the cholinesterase. It also binds to free

TABLE 23.1 Effects of AChE inhibition on cholinergic nervous system functions		
Muscarinic effects	Nicotinic effects	CNS effects
Excessive salivation	Muscle cramping	Restlessness
Lacrimation	Weakness	Headache
Urination	Respiratory failure	Emotional lability
Diarrhea		Drowsiness
G I distress		Tremor
Emesis		Slurred speech
Miosis		Confusion
Bronchitis		Delirium
Bronchospasm		General weakness
Bradycardia		Ataxia
Sweating		Seizures

organophosphate. The toxic effects of pralidoxime include tachycardia, cardiac arrhythmias, tachypnea, hypertension and relaxation of sphincters. The commercial preparation is 2 pyridine aldoxime ("aldopam"). Pralidoxime methane sulphate (Unichem laboratories) is also available in India. In addition to pralidoxime, atropine has to be continued for symptomatic therapy in the required doses till the enzyme levels reach normal.

A high dose regimen of pralidoxime consisting of a continuous infusion of 1g/h for 48 hours after a 2 g loading dose reduces morbidity and mortality in moderately severe cases of acute organophosphorus pesticide toxicity. This reduces the need for atropine, as well as duration of ventilatory support. The cost is around Rs. 20000/ for the first 48 hours of management.

Ref: Kirti S Pawar et al. Continuous pralidoxime infusion versus repeated bolus injection to treat organophosphorus pesticide poisoning: randomized controlled trial. The Lancet 2006. 368; 2136-2141.

Complications

Fatal bronchopneumonia may develop during convalescence. The neurological complications may take the form of **intermediate syndrome** occurring within 1-4 days of poisoning, characterized by bulbar, nuchal and proximal muscle weakness including respiratory paralysis or a distal sensorimotor polyneuropathy occurring 2-3 weeks later. The onset of intermediate syndrome usually coincides with the time of atropine withdrawal. Therefore oximes and atropine should be withdrawn carefully and gradually.

Prevention and first aid Accidental poisoning can be prevented by taking adequate precautions detailed on the commercial packing. Persons spraying insecticides should wear protective clothing and masks, and wash their bodies with soap and water thoroughly after the work, and before taking food or drink. Immediate first aid after accidental poisoning includes induction of emesis and removal of contaminated clothing and washing the body thoroughly with soap and water. The subject should be transported to a hospital without delay.

Organocarbamates

Organocarbamates (OC) are structurally similar to organophosphorus compounds and they inhibit acetyl choline esterase. The commonly available preparations are adicarb (TERMIK), aprocarb, bendiocarbonate, carbofuran (FURADAN), carbosulphan (MARSHALL), N-methyl carbamate (Carbamyl), propoxur (BAYGON) and others.

Duration of action of OC is shorter than that of organophosphorus compounds and therefore, generally the duration of symptoms in mild cases is shorter. This may not be true in severe cases.

Treatment: Atropine is quite effective as in the case of organophosphorus poisoning.

Glycopyrrolate which is a quaternary ammonium compound is an effective antidote. It is available as 1 mL ampoules containing 2 mg of the drug. The dose is 0.05 mg/kg IV or IM, to be repeated to achieve symptom relief. It does not reach the CNS and therefore the CNS side effects of atropine such as delirium and involuntary movements are avoided.

Important points

1. Organophosphorus compounds irreversibly phosphorylate acetyl cholinesterase enzyme
2. The symptoms include muscarinic and nicotinic features
3. Atropine is the pharmacological antidote to be given till features of atropinisation appear
4. Pralidoxime hydrochloride reactivates cholinesterase enzyme by removing phosphate group
5. Intermediate syndrome is a complication occurring 1-4 days after poisoning

Methanol

Poisoning with methanol may occur sporadically when industrial (methylated) spirit is consumed in the place of ethanol or epidemically when the supply of liquor is adulterated with methyl alcohol. Several outbreaks have occurred in closed communities from time to time. Minimum lethal dose is 30 g. Methanol is metabolized in the system to formaldehyde and formic acid by alcohol dehydrogenase enzyme. In addition, derangement of hepatic metabolism results in the accumulation of lactate. Severe metabolic acidosis results after a latent period of 8-12 hours. Optic neuritis develops as a specific toxic reaction.

CLINICAL FEATURES

Within hours of consuming methylated alcohol, patients develop restlessness, irritability, confusion, epigastric pain, vomiting and rapid loss of vision followed by metabolic acidosis. Visual loss is concentric. Ophthalmoscopy shows pale edematous discs. Coma may develop, which may become deep. Mortality in a large series is about 20%.

Treatment Aims of treatment are (1) correction of acidosis, (2) inhibition of methanol oxidation, and (3) removal of circulating methanol and its toxic products.

Acidosis is corrected by sodium bicarbonate given intravenously in adequate amounts. Hemodialysis helps to remove circulating methanol. Hemodialysis should be started without delay if the blood level of methanol exceeds 0.5g/L or the total quantity ingested exceeds 30 mL. Peritoneal dialysis is only one-eighth as effective as hemodialysis in removing methanol and, therefore, this should not be relied upon.

Ethanol should be given if methanol level in blood exceeds 20mg/dL. Blood ethanol concentration above 100 mg/dL inhibits the metabolism of methanol to formaldehyde and formic acid by competing for the enzyme alcohol dehydrogenase.

It is worth trying in any instance if the patient arrives early. The equivalent of 30-50 mL of ethanol is given orally at 2-4 hours interval for a few days. Once the optic nerve is affected, ethanol does not reverse the damage.

Folic acid or folinic acid in amounts of 10-15 mg intramuscular repeatedly is effective in reducing methanol toxicity in experimental animals.

Important points

1. Lethal dose of methanol is 30 g
2. Severe metabolic acidosis occurs within 12 hours and optic neuritis is a specific toxic reaction
3. Treatment aims at correction of acidosis, inhibition of oxidation of methanol by giving ethanol, and removal of the toxic products
4. Hemodialysis should be started if blood level of methanol is more than 0.5 g/L.

Barbiturates

Till recently barbiturates were the most common drugs used for suicide. Accidental poisoning is seen in epileptics, psychiatric patients and children who get regular prescription for these drugs.

The most widely used barbiturate is phenobarbitone and it is used as an anticonvulsant. Absorption and metabolism of phenobarbitone are slow. About 10% of the drug is excreted in urine unchanged. The lethal dose for adult is about 5 gm. Simultaneous administration of alcohol aggravates its effects.

CLINICAL FEATURES

Central nervous, respiratory and cardiovascular systems are affected the most. Drowsiness, slowing of respiration, and hypotension follow. Pupils are small and react to light. In severe poisoning when medullary centers are depressed, the pupils are dilated and fixed, which indicates a poor prognosis. Tendon reflexes are sluggish or absent. Necrosis of sweat glands and bullous lesions over the skin develop in a few as a hypersensitive reaction. These lesions heal slowly.

Diagnosis can be confirmed by detection of barbiturates in the gastric contents and estimation of barbiturate in blood.

Treatment In addition to general measures, forced alkaline diuresis and dialysis are helpful. Bemegride (megimide) considered to be a specific antidote but subsequent research has disproved this assumption. Repeated doses of activated charcoal and hemoperfusion are the modalities described. Since pneumonia is a fatal

complication, these patients should be observed for a week till recovery is complete.

Important points

1. The lethal dose of phenobarbitone, the most commonly used barbiturate, is 5 g
2. Central nervous system and cardiovascular systems are most affected by overdosage
3. Respiratory depression indicates poor prognosis
4. Forced alkaline diuresis and hemodialysis are the treatment options

Alcohol Intoxication

Alcohol is available in several forms commercially. The common forms are toddy (5%), beer (5%), wine (10%), arrack (40-60%), and gin, whisky and brandy (45-60%). Illicitly distilled liquor may contain several chemical impurities. One standard drink contains 12 g alcohol. It is made up by 180 mL wine, 360 mL beer or 45 mL 90% proof spirit.

Absorption of alcohol from the stomach and small intestine is rapid and detectable blood levels occur within five minutes of ingestion, reaching the highest levels in 30-90 minutes. The peak level is maintained for two hours. Fat in the food impedes absorption. Alcohol is widely distributed in tissues. It appears in the CSF, urine, and alveolar air. Alcohol is metabolized primarily in the liver. It supplies energy like carbohydrates, though it has no nutritive value.

Consumption of alcohol is not a criminal offence till it leads to alcoholic intoxication and antisocial behavior. Both the physical and psychiatric disturbances caused by alcohol fall under the purview of the physician.

Alcohol produces acute and chronic gastritis, acute intoxication ranging from excitement to coma, various nutritional and nervous disorders, and hepatic damage. Long-term use of large amounts of alcohol results in parenchymal damage to several organ systems like the liver, heart and brain.

Acute gastritis This occurs in people who consume spirits in large amounts. It is characterized by severe vomiting, abdominal pain and headache. The vomiting responds to any phenothiazine such as triflupromazine HCl. 10 mg IM (Siquil, marketed by Sarabhi). Oral antacids and intravenous fluids are required in cases which show persistent vomiting.

The cerebral effects of alcohol start within minutes of ingestion. The amount of alcohol and the extent of habituation of the patient determine the clinical picture. Slurring of speech and loss of refined mental and physical capacities occur when the blood level is 0.5 g/liter. At 3 g/liter ataxia, double vision, tremor, incoherent speech and serious loss of mental capacity are evident. Blood levels above 5 g/liter are fatal. Death occurs in coma and is caused by respiratory failure.

Diagnosis Alcoholic intoxication should be suspected from the smell of alcohol, clinical picture and the circumstances. Estimation of the levels of alcohol in urine, blood, or expired air help in confirming the diagnosis. Samples of 10 mL of urine and 2 mL of blood should be collected and sent in sealed bottles for chemical examination.

All other organic causes of coma, hysterical conversion reaction, psychiatric disorders, and malingering should be excluded.

4

Treatment Supportive treatment as in the case of coma is instituted without delay. The diuretic effect of ethanol may lead to dehydration. Intravenous administration of dextrose solution (500 mL of 20% solution followed by 1 liter of 5% solution) along with massive doses of vitamin B complex factors and vitamin C are beneficial. Early treatment improves the prognosis. Common complications include aspiration pneumonia and lung abscess. Psychiatric assessment and counselling with rehabilitation are required to avoid recurrence.

Important points

1. Symptoms of acute intoxication range from excitement to coma
2. Lethal blood level of alcohol is 5 g/L
3. Diagnosis is by clinical picture and estimation of levels in blood or urine
4. Correction of dehydration, intravenous dextrose and B vitamins are the treatment modalities

ALCOHOL WITHDRAWAL SYNDROME

This occurs typically within 5-24 hours after withdrawal of alcohol, in alcohol dependent subjects. The signs and symptoms are largely due to autonomic overactivity. Three groups of symptoms may occur.

1. Signs of autonomic overactivity occurring within a few hours of the last drink, and becoming maximal in 24-48 hours. These consist of tremulousness, sweating, nausea, vomiting, anxiety and agitation.
2. Signs of neuronal excitation such as generalized seizures occurring within 12-48 hours of abstinence.
3. *Delirium tremens*, characterized by tremor, auditory and visual hallucinations, confusion, disorientation, clouding of consciousness, hypokalemia, hypomagnesemia and prolonged autonomic hyperactivity leading to tachycardia, hypertension and tachypnea. Death may occur at this stage due to cardiovascular and respiratory collapse in less than 5% of cases. In many cases the symptoms are self-limiting within one week.
4. **Management** consists of supervised detoxifying regimes, sedation on demand, counselling, reassurance, and social support. Large doses of diazepam, 10-20 mg given at 2-hour intervals or chlordia-

zepoxide 25 to 50mg every 4-6 hours may be needed to sedate the patient. Once sedated, the drug is stopped. Repeated dosage may be required in a few. Seizures are also controlled by diazepam given in doses of 5-10 mg oral or 2-5 mg IV slowly or as a slow IV infusion, the total dose not to exceed 1-2 mg/kg bw in 24 hours. In those with hepatic damage, sedatives such as oxazepam 30 mg or lorazepam 20 to 30 mcg/kg IV should be given. They do not cause further damage to the liver. More serious complications such as Wernicke's encephalopathy, dehydration and electrolyte imbalance may develop. Prophylactic thiamine is given in a dose of 20 mg IM or IV b.d.

Management of alcohol withdrawal syndrome and de-addiction are specialized procedures requiring the combined effects of the physicians, psychiatric and social workers.

Important points

1. Alcohol withdrawal symptoms develop typically within 5-24 hours after withdrawal
2. Predominant symptom is autonomic hyperactivity
3. Delirium tremens is a serious complication wherein cardiovascular and respiratory collapse may occur
4. Management includes benzodiazepines and other supportive measures

Cerebera Odollam

Cerebera odollam belonging to the family Apocynaceae is a small tree found all over India, is a frequent cause of poisoning especially in Kerala. Many cardiac glycosides have been isolated from the plants belonging to this family, e.g., stophanthin, ouabain, oleandrine, cereberin and thevetine. The active principles seen in *Cerebera odollam* are *cerberin*, *cerberoside* and *odollin*, which are seen in highest amounts in the kernels of the seeds. The seeds taste very bitter. The contents of a single fruit can be fatal if ingested.

Cerberin, like digitalis, reduces the heart rate by inhibiting sinoatrial and atrioventricular conduction, mainly by a vagotonic action, which can be partially reversed by atropine. In higher doses cerberin has a direct depressant action on the myocardium, which cannot be reversed by administering atropine. The majority of poisoning cases are suicidal.

Morbid anatomy Autopsy studies are not very rewarding. Except for subepicardial and subendocardial hemorrhages, the gross anatomy appears normal. The conducting tissue of the heart is histologically normal.

Clinical features Within an hour of taking the poison, retching, nausea, vomiting and abdominal pain occur. Later, the patient becomes weak and drowsy and may lapse into coma. Bradycardia, only partially responsive to atropine, is the most obvious finding.

4

Fig. 23.1: ECG changes cerbera odollam poisoning

1. **Early stage:** Sinus bradycardia, responding to atropinisation
2. **Mild case:** Sinus bradycardia persisting for one week after recovery, Responding normally to exercise
3. **Moderately severe cases:** Note (a) tachycardia (b) ST depression in leads I, II, III aVF and V1-V6 (c) ST elevation in lead aVR (d) Biphasic T waves leads II, aVF and V1-V6
4. **First degree A-V block,** (top) responding to atropinisation (bottom)
5. **Severe toxicity:** Idioventricular rhythm. Often this is fatal

Ref: Kunhali et al Ind. Heart J. 1970;22.4:373-377.

Narendranathm et al. Ind. Heart J. 1975;27.4:283-286.

The ECG may show various types of bradyarrhythmias like sinus bradycardia, A-V dissociation, and junctional rhythms. Different grades of A-V block and S-A block have been described. Ventricular extrasystoles may occur rarely. The changes in the ST segment, the T wave and the QT interval are similar to those produced by digitalis. 60% of the patients show hyperkalemia

Treatment Management consists of the elimination of unabsorbed poison by stomach wash, purgatives, bowel wash and correction of bradyarrhythmias by intravenous atropine (0.5mg). In severe cases, the drug has to be repeated even at 15 minutes intervals, or it has to be administered as a continuous drip. Hyperkalemia should be treated by appropriate measures (Insulin glucose regimen). When bradycardia is not corrected by atropine, the patient may require cardiac pacing. The presence of hypotension, alteration of consciousness, bradyarrhythmias not responding to treatment, hyperkalemia, and significant electrocardiographic changes indicate severe poisoning and the outlook in such cases is poor with an overall mortality of 20-25%. Management in a cardiac intensive care facility is certainly likely to improve results,

although the experience is still limited. Once established, the cardiac phenomena persist for one to three weeks since the toxin is only very slowly eliminated. Hence prolonged observation is required.

Important points

1. Active principles of Cerebra odollam are cereberin, cereberoside and odollin
2. Cereberin has vagotonic action and direct depressant effect on the myocardium
3. Various types of bradyarrhythmias and hyperkalemia can occur
4. Treatment is with atropine, management of hyperkalemia and temporary cardiac pacing when required.

Cleisthanus Collinus Leaf

This is emerging as a common suicidal poison in Tamil Nadu. It is ingested in several forms. Main toxic effect is on the heart. Progressive bradycardia, sudden cardiac arrest and progressive respiratory failure follow. Hypokalemia occurs in over 70%. Prolongation of the corrected Q-T interval in the ECG above 0.45 second is associated with poor outcome. General measures, atropine

and temporary cardiac pacing have been employed in treatment.

Corrosive Acids

Acids like hydrochloric acid, sulphuric acid, and nitric acid are widely used in the laboratory. Cases of accidental and suicidal poisoning are not rare. Corrosive acids produce similar clinical picture, which is due to their direct chemical action on tissues.

4

Clinical features Sites of intimate contact like the lips, throat, palate, and posterior pharyngeal wall show scalding. They bleed easily and slough away leaving raw areas. Clinical features of acidosis occur if large amounts are ingested. Metabolic acidosis occurs as a result of cellular injury and from systemic absorption of acids. Complications like perforation of the esophagus and stomach, severe hematemesis, acute renal failure and severe shock are fatal. Esophageal stricture is a common sequel.

Treatment Emesis and gastric lavage are contraindicated. The acid in the stomach can be diluted by large volumes of water or milk. Pain is relieved by local anesthetics like xylocaine viscous and analgesics. Oral feeds should be avoided for a day or two after which swallowing of fluids like milk should be encouraged. Infection has to be prevented by the administration of ampicillin 1 g IV 6th hourly. If esophageal perforation is excluded, corticosteroids may be given parenterally in doses equivalent to hydrocortisone 25 mg 6 hourly for 3-5 days. This may prevent the formation of esophageal stricture.

Metabolic acidosis develops in most of the cases. This has to be corrected by the administration of IV normal saline and sodium bicarbonate, depending upon the requirement.

Treatment of shock, perforation, peritonitis and acute renal failure should be undertaken when they occur. Early institution of oral feeds helps to reduce the occurrence of esophageal stricture. If stricture occurs, the treatment is surgical.

ACETIC ACID

Acetic acid is used for coagulating rubber latex and, therefore, it is freely available to workers in rubber plantations. Poisoning is usually suicidal, rarely accidental. The fatal dose varies from 15-60 mL.

Clinical features Intense scalding and burning of the lips, mouth, pharynx, and throat occur over areas of direct contact. Dysphagia and burning pain along the esophagus and stomach follow. There is excessive salivation. The patient shows anxiety and is acidotic. Hemoglobinemia and hemoglobinuria develop within hours. Bronchitis,

bronchopneumonia, and aspiration pneumonia follow. Shock, severe acidosis, pneumonia, mediastinitis, perforation of the stomach or esophagus and renal failure result in death.

Treatment Diazepam in a dose of 5-10 mg is given intravenously to sedate the patient. Gastric intubation is contraindicated. Demulcents like egg albumin or milk may be given if the patient can swallow. Oral intake of fluids should be encouraged early, since this helps to prevent stricture. Glucose saline drip is started early to provide nutrition, fluids, and electrolytes. Acidosis is corrected by suitable doses of sodium bicarbonate. Frusemide 20 mg given intramuscularly may be beneficial to prevent the development of renal failure. Mortality ranges from 20 to 30%. Esophageal stricture may occur which will require surgical treatment.

FORMIC ACID

Formic acid and its salts are used in textile, leather and rubber industries. It is also a component in some descaling agents, disinfectants and preservatives. Suicidal attempts and accidental ingestion of formic acid are common in many rubber cultivating areas of Kerala and Tamil Nadu because of its free availability. Protoplasmic coagulation, precipitation or dissolution of proteins, and exudation of fluid occur at the sites of intimate contact.

Since in most cases of accidental ingestion, the person tries to spit out the acid, burns occur in and around the mouth. However, if acid is consumed with suicidal intent, the attempt to swallow evokes reflex cough because of its irritant vapors. Acid enters not only the esophagus but also the respiratory tract. This results in ulceration, bleeding, sloughing and perforation of the esophagus and stomach, tracheitis, bronchitis, pulmonary edema, and pneumonia. Systemic effects of the acids are acidosis, intravascular hemolysis, hemoglobinuria, and shock. Renal failure is common.

Hemoglobinuria and oliguria should portend the onset of renal failure, which demands early and repeated hemodialysis. Recent reports from Kozhikode medical college show that even superficial burns exceeding 20% of body surface caused by formic acid may lead to acute tubular necrosis and renal failure.

First aid treatment is to dilute the acid with water or neutralize with milk. Gastric intubation is contraindicated, antacids are given if the patient can swallow. Parenteral fluids are given to hydrate the patient and acidosis is combated by the intravenous administration of sodium bicarbonate. Frequent feeding with milk, egg albumin and other demulcents helps to reduce the incidence of stricture. Antibiotics, analgesics and respiratory physiotherapy are indicated in all cases. Late occurrence of esophageal stricture has to be treated surgically.

Important points

1. Corrosive acids produce burns or scalding in the lips, throat and posterior pharyngeal wall due to chemical reaction
2. Ulceration and perforation of esophagus and stomach, pulmonary edema and pneumonia are the usual manifestation of corrosive acids
3. Systemic effects include acidosis, intravascular hemolysis, hemoglobinuria and renal failure
4. Esophageal stricture is a common sequel

Alkalies

Strong alkalies are used in industry. Household cleaning materials contain alkaline substances. Ammonium hydroxide, potassium hydroxide, sodium hydroxide, potassium carbonate, sodium carbonate, and sodium and potassium phosphates account for the vast majority of alkali poisoning. Strong alkalies lead to scalding and ulceration of tissue. On ingestion, patients experience severe pain in the mouth, throat, chest and abdomen. Tongue, oral mucosa and pharynx show areas of erythema and necrosis. Metabolic alkalosis develops as a systemic effect. Sodium and potassium phosphates may cause severe reduction in serum calcium leading to tetany.

Treatment This consists of diluting the alkali by the administration of water or milk and maintenance of fluid and electrolyte balance. Local pain can be allayed partly by the use of xylocaine viscous. Tetany is managed by the administration of calcium gluconate intravenously. Prevention of secondary infection by the use of antibiotics and corticosteroids to prevent stricture of the esophagus have to be considered in selected cases. Endoscopy done within 24 hrs of admission helps to assess the severity of lesions in the esophagus and stomach and institute surgical treatment when appropriate.

Narcotics-Morphine and Opioids

Poisoning by Morphine and its allied narcotic analgesics leads to initial excitement followed by a depression of the nervous system. The patient is stuporose or comatose with pin-point pupils, slow and shallow respiration, cyanosis and hypotension.

Treatment In addition to supportive measures and gastric aspiration, ventilatory assistance is required in comatose patients. Specific antidote is nalorphine hydrobromide (Lethidrone) given intravenously 0.4-2 mg every 2-5 minutes till the respiration and blood pressure become normal. In general, the total dose is limited to 40 mg in any case.

Toxic effects of nalorphine include respiratory depression, hypotension, drowsiness and hypothermia.

Paracetamol**Syn:Acetaminophen**

Paracetamol is the most widely used analgesic at present. Due to its free availability, paracetamol poisoning is becoming more frequent. Doses exceeding 8 g can produce toxicity. Acute hepatocellular and less frequently renal tubular necrosis may follow ingestion of a single dose exceeding 10 g. A highly reactive metabolite of paracetamol N acetyl benzoquinonimine (NAPQI), which is normally inactivated by hepatic glutathione is responsible for the hepatic failure. With overdosage of acetaminophen, hepatic glutathione is rapidly depleted and NAPQI binds to cellular proteins causing necrosis of cells. Hepatic levels of glutathione are increased by N Acetylcysteine and methionine thereby protecting the liver from injury. Alcoholism, malnutrition and concurrent use of drugs which induce microsomal oxidase enzyme (P450) like anticonvulsants predispose to hepatic damage.

Clinical features Early symptoms are nausea, vomiting and sweating. The most dangerous complication is hepatic damage.

This becomes manifest 1-2 days after onset with jaundice, bleeding tendency, and hepatomegaly. A few cases progress to fulminant hepatic necrosis resulting in hepatic coma and this is associated with high mortality. Other serious but rare complications are acute tubular necrosis, pancreatitis, carditis, hypoglycemia, metabolic acidosis and hypersensitivity reactions.

Liver function tests become abnormal and the maximum damage is reached within 72-96 hours. SGPT levels go very high (even up to 10000 iu/L). Prothrombin time is prolonged. INR above 6.5 portend the possibility of fatal liver failure. Blood lactate levels are raised due to over production and diminished excretion. Values above 3.5 mmol/L in arterial blood persisting after fluid replacement should alert the physician about the risk of hepatic failure and the need for hepatic replacement.

(Note: Normal lactic acid level in plasma is 5-20 mg/dL—i.e. 0.5-2.0 MEq/L)

Treatment Correction of fluid and electrolyte imbalance should be started immediately. Gastric lavage should be performed to remove unabsorbed drug. Activated charcoal may help to adsorb the residual drug. In severe cases where the blood level of paracetamol is above 300 mg/liter at 4 hours, hemoperfusion is the best method for rapid elimination of the drug. Forced alkaline diuresis is ineffective.

Specific management is to give the antidote N-acetyl cysteine (NAC). In patients who have reached the hospital within four hours of ingestion, gastric lavage and activated charcoal may help to prevent systemic effects. Serum levels of paracetamol should be estimated after 4 hours

in order to assess the risk. Paracetamol levels above 100 mg/dL indicate high mortality and therefore demand the administration of NAC. It is given as IV infusion as follows:

Dose	NAC mg/kg	Volume of 5% glucose	Duration of drip
1.	150	200	15 minutes
2.	50	500	4 hours
3.	50	500	8 hours
4.	50	500	8 hours

An oral preparation of N-acetyl cysteine is also available. The dose is 140 mg/kg orally initially followed by 70 mg/kg 4 hourly for 72 hours. This should not be relied upon in an emergency.

Liver failure should be treated on the lines of fulminant hepatic failure. Paracetamol poisoning is one of the frequent causes of fulminant hepatic failure in western countries.

Important points

1. The toxic dose of acetaminophen is 8g
2. The highly toxic intermediate metabolite N acetyl benzoquinonimine produces hepatic cell injury
3. Fulminant hepatic necrosis is the cause of mortality
4. Specific treatment is N- acetylcystiene 150 mg/kg body weight

PETROLEUM PRODUCTS - KEROSENE

Accidental poisoning with kerosene is common in India because of its free availability in the household. Children suffer more. Cases of poisoning with other petroleum products like petrol, diesel oil, and paint thinners are encountered less commonly. Petroleum products are used as solvents in the manufacture and application of polishes, paints, and pesticides. Some persons develop the habit of sniffing paints and polish for the nervous effects produced by the solvents. They contain various amounts of aliphatic and aromatic hydrocarbons, which are mainly depressants of the central nervous systems. They cause damage to the cells on direct contact on account of their ability to dissolve cellular lipids. The low surface tension facilitates their spread along mucosal surfaces and the lungs even when only small amounts are ingested or inhaled.

Poisoning usually results from ingestion but can also result from inhalation. The clinical features depend on the quantity and route of poisoning.

Clinical Features

Symptoms pertaining to the central nervous system include headache, nausea, tinnitus, drowsiness, convulsions, and coma. Severe vomiting occurs when the

oral route is adopted. Kerosene reaching the trachea spreads widely throughout the respiratory tract resulting in the most common and potentially dangerous complications of pneumonia and pulmonary edema. Death may result due to respiratory embarrassment, ventricular fibrillation, or severe pneumonia.

Treatment All suspected cases of kerosene poisoning should be hospitalized for 24 hours to watch for aspiration pneumonia. Simple gastric lavage is better avoided. If it is deemed essential, a cuffed endotracheal tube should be introduced prior to gastric lavage to protect the respiratory tract.

Chemical pneumonia is treated with oxygen inhalation, corticosteroids and ventilatory assistance when indicated. Antibiotics should be employed to prevent secondary infection.

ORGANOCHLORINE INSECTICIDES

These common chemicals, which are used as insecticides in houses, gardens and in agriculture, have different chemical structures.

1. Chlorinated diphenyls, e.g., DDT, TDE, DFDT, and DMC
2. Chlorinated polycyclic compounds, e.g., Chlordane, Aldrin and Endrin.
3. Hexachlorobenzene compounds, e.g., Lindane.

These are insoluble in water, but freely soluble in organic solvents and lipids. Their solutions in petroleum, kerosene, or other organic solvents are used for spraying. Poisoning may be accidental or suicidal. Acute toxicity results from ingestion or inhalation of these substances. Variable amounts of these chemicals may be absorbed through the skin and can result in toxicity. They stimulate the central nervous system. When used in the form of solutions, the action of the solvent modifies the total effect. The fatal doses of these compounds are:

DDT	20 g
Lindane	3 g
Chlordane	1 g
Aldrin and Endrin	Less than 1g

Clinical features Early manifestations are nausea, vomiting, irritant cough, headache, and bodyaches. These are followed by nervous irritability, mental sluggishness, muscle twitching, tremors, incoordination, convulsions, paralysis and coma. Acute pulmonary edema and shock may occur if the exposure is heavy. Liver dysfunction is a prominent feature in Endrin poisoning.

Treatment The general measures are instituted without delay. Administration of activated charcoal and saline purgatives help to reduce absorption of the chemical. Convulsions have to be controlled with injection of

10 mg of diazepam. Calcium gluconate 1 g given intravenously has been found to reduce the convulsive tendency. Ventilatory assistance is required if respiratory failure sets in.

Widespread use of organochlorine compounds in agriculture has led to their slow absorption through food, milk and water and these chemicals accumulate in human and animal tissues. Chronic toxicity is a potential hazard.

Ethylene Dibromide Poisoning (EDB)

EDB is used as an insecticide against soil nematodes, insects and termites and also as a fumigant to protect stored products. It is a colourless volatile liquid with an ethereal odour, available as liquid, capsules or granules. Suicidal poisoning has been reported from Madhya Pradesh. Symptoms include vomiting, circulatory failure, pulmonary congestion, liver damage leading to hepatic

encephalopathy, and renal failure. Mortality may go up to 50%. Treatment is symptomatic.

Phosphide Poisoning

Both zinc phosphide and aluminium phosphide are freely available rodenticides. When ingested, they liberate phosphine gas on coming into contact with moisture. This toxic phosphine is lethal to cells by reacting with the enzyme cytochrome oxidase. Zinc phosphide produces early vomiting and diarrhea within 20 minutes when ingested and severe cough, breathlessness and pulmonary edema when inhaled. Metabolic acidosis, hypocalcemic tetany and hypokalemia follow. Organs affected include the heart (toxic myocarditis), pleura (effusion) and lung (RDS). Fatal shock may ensue. Magnesium sulphate infused IV at a rate of 3 g in the first 3 hours and then 6 g in the next 24 hours is being evaluated in treatment. The results are equivocal.

Food Poisoning

T.K. Suma, K.V. Krishna Das

Chapter Summary

General Considerations 125
Toxin Type of Food Poisoning 126
Infection Type of Food Poisoning 127
Chronic Food Poisoning 127
Mushroom Poisoning 127
Fish Poisoning 128
Acute Cassava Toxicity 128
Onyalai 129
Hepatic Veno-occlusive Disease 129
Aflatoxicosis 129
Epidemic Dropsy 129
Lathyrism 130
Ergotism 130
Lead Poisoning 130

General Considerations

Sometimes, articles of food cause toxic reactions. This toxicity, in general, is caused by the following factors:

1. The food may be naturally toxic, e.g., poisonous mushrooms, toxic fish, etc.
2. Toxicity may be imposed upon the food material by the polluted environment, e.g., contamination of fish by mercury from industrial effluents, infection of oysters by Salmonella due to fecal contamination.
3. Contamination of food during collection, transportation, storage, cooking, or serving by:
 - a. Chemicals (accidental or by addition of adulterants),
 - b. Microbial agents - bacteria, viruses, protozoa, and
 - c. Preformed toxins contaminating the food articles.
4. Allergy to the food materials.

Episodes of food poisoning are characterized by several distinctive features, which help to diagnose them and study their epidemiology.

1. They occur in small outbreaks in several persons who have shared a common item of food.
2. The symptomatology is similar in all cases, but severity varies depending on the quantity of the food ingested, age of the individual and weight. Children suffer more than the adults.
3. The incriminated food material may show abnormalities such as putrefaction, distaste and altered consistency. Tinned food packed in vacuum shows bloating of the tins.

For preventing spread of the outbreak and to help in investigating the cause, the primary physician has to follow a set procedure. At the first suspicion of food poisoning, the incriminated food should be isolated and even small quantities should not be consumed further. Those who are apparently well and who would have consumed the food should be advised to induce vomiting by tickling the throat after drinking a glass of water and as much of the food as is possible should be removed, by repeated vomiting. This single measure reduces the risk considerably.

1. The appropriate health authorities should be notified.
2. Proper clinical records should be maintained.
3. Remnants of food should be preserved for chemical and microbiological tests.
4. Vomitus, urine and feces should be collected sealed, and sent for chemical analysis.
5. If death occurs, medicolegal autopsy is indicated and the stomach, intestines, liver and other organs have to be sent for chemical examination.

The general principles of treatment are similar to those for chemical poisoning.

Toxin Type of Food Poisoning

Preformed toxins present in food are responsible for this condition e.g., organisms like *Staphylococcus aureus*, *Bacillus cereus*, *Clostridium botulinum*, *Cl. perfringens*, and *Salmonellae* are the common agents responsible for such outbreaks. The most dangerous among them are the soil *Clostridium species* which are gram + *Cl. perfringens* causes food poisoning and necrotizing hemorrhagic enteritis. *Cl. Botulinum* is capable of producing toxin mediated food poisoning termed botulism, wound infection and intestinal infection. In all cases the absorption of toxin is the crucial pathogenic event. Staphylococcal contamination usually results from pustules in the udder of the cow or from the skin or nose of food handlers. *Bacillus cereus* is usually seen in contaminated fried rice.

STAPHYLOCOCCAL FOOD POISONING

It is caused by the enterotoxin of *Staph. aureus*. The common articles of food include stored cooked meat, milk and cheese. The onset is acute with vomiting, diarrhea and crampy abdominal pain developing 1-6 hours after ingestion of the food. Shock may supervene, but recovery in 24-48 hours is the rule. Treatment is symptomatic.

BOTULISM

This results from the ingestion of the toxin of *Cl. Botulinum*. The organism grows under anaerobic conditions in contaminated meat foods like sausages, fish, etc. The organism is present in the soil and it spreads through the spores, which can resist boiling for considerable periods. The toxin, which can be separated into fractions A, B and E acts on the nervous system and it inhibits release of acetylcholine at the neuromuscular junction and blocks neuromuscular transmission in cholinergic nerve fibers. The toxin rapidly fixes to the nerves and once endocytosis occurs, its effects cannot be reversed. The toxin consists of seven serologically distinct, but structurally similar components A, B, C, D, E, F and G of which only types A, B, E and F cause illness in humans. The paralysis persists for 2-3 months or even more. Botulism may occur in one of three forms, food borne botulism, infant botulism and wound botulism. In addition to its role as a cause of food poisoning, *Cl. botulinum* can contaminate wounds and also grow in the intestinal tract and elaborate toxins.

Symptoms start in 12-36 hours after ingestion with diplopia, blurring of vision and paralysis of cranial nerves. Other features are dry mouth, dysphagia and dysphonia. Progressive muscular involvement results in respiratory paralysis. Death is caused by respiratory failure or pneumonia (10-20%). Neurological sequelae in the form of motor paralysis may persist for several months in a few.

Diagnosis Other conditions leading to neuromuscular paralysis such as Guillain-Barré syndrome, myasthenic crises, cobra or krait bites, and vascular accidents of the brainstem have to be differentiated. Myasthenic crises responds to Tensilon whereas in botulism this is not so.

Treatment Adequate ventilatory support and general supportive measures should be instituted. Guanidine hydrochloride in a dose of 15-50 mg/kg/day has been used but without proven effect. A trivalent preparation containing anti-toxin is available it is given I V in doses of 50000 units stat and repeated after 2 hours. This vaccine is not freely available in India.

Infant Botulism

This is caused by *Clostridium botulinum* colonizing in the colon of infants. They produce the toxin which is absorbed and leads to systemic effects. Infant botulism is defined as an illness consistent with paralysis typical of botulism

toxin. The typical organisms are cultured from feces or enema material. Treatment consists of giving botulinum immune globulin containing neutralizing antibodies.

Anaerobic Food Poisoning

C. perfringens food poisoning: The usual source of contamination is meat. Heat resistant spores survive improper cooking. They germinate when the food is cooled. On reaching the intestine they sporulate and produce exotoxin which causes abdominal cramps and diarrhea.

INFECTION TYPE OF FOOD POISONING

In this group, organisms enter along with contaminated food and multiply in the gut to produce the lesions after an incubation period ranging from 24-72 hours. The organism may be noninvasive or invasive depending on their action on the intestinal mucosa. The organism may be noninvasive such as *enterotoxigenic E. coli* or *Klebsiella*. They produce diarrhea by locally acting enterotoxins, which stimulate adenyl cyclase and cyclic AMP mechanisms.

The intestinal mucosa is not destroyed. Stools are watery and generally devoid of inflammatory cells. Clinical features of severe dehydration predominate with relatively mild constitutional symptoms.

Invasive group includes organisms like *Shigella*, *Salmonella typhimurium*, *Salmonella enteritidis*, *Yersinia enterocolitica*, invasive strains of *E.coli* and *Vibrio parahemolyticus*. They produce inflammatory lesions. They destroy the intestinal mucosa and the feces contain abundant inflammatory cells and erythrocytes. Constitutional symptoms of varying severity accompany this syndrome.

In the infection type of food poisoning antimicrobial therapy is indicated to arrest the multiplication of the organism in the gut. Systemic antibiotics are indicated in the invasive type. General measures of treatment of gastroenteritis are indicated.

Chronic Food Poisoning

Some cases of chronic food poisoning, caused by repeated exposures to fish contaminated by industrial effluents, have been reported.

1. **Haff disease** is produced by eating fish poisoned by toxic resinous acids from cellulose. This condition produces myoglobinuria in the affected persons.
2. **Minimata disease** is caused by consumption of fish, which has ingested methyl mercury compounds. Out-breaks of mercury poisoning occurred in cats and people living in fishing villages in Japan.

Due to the rapid growth of industry and the present day tendency to interfere with natural ecosystems, such examples are likely to be on the increase, unless sufficient care is taken to prevent them.

MUSHROOM POISONING

Mushrooms are delicacies on the table. In India, they are grown commercially in Himachal Pradesh and many other parts including the southern states. Many people eat wild mushrooms collected seasonally and some of them cause accidental poisoning. The common toxic mushrooms include - *Amanita phalloides*, *Amanita verna*, *Amanita virosa*, *Helvella esculenta* and *Galerina species*. All these species contain amatoxin, which is a potent cytotoxin. Deaths have resulted from the ingestion of even 50 g of mushrooms. The toxic principles vary in different species.

Amanita muscaria contains three toxic principles. (1) A parasympathomimetic alkaloid- muscarine, (2) a neurotoxic substance, and (3) an alkaloid with atropine like action. The toxins of *Amanita phalloides* and related species are cytotoxic alpha amanitin and phalloidine. These toxins inhibit protein synthesis. The toxic principles are thermostable and, therefore, resist cooking.

Pathogenesis The toxin leads to severe cholinergic overactivity similar to organophosphorus poisoning. Autopsy shows extensive cellular degeneration, necrosis, edema and hemorrhage in the liver, kidney, gastrointestinal tract and brain.

Amanita muscaria Signs of toxicity develop sometime after the consumption of contaminated food. Symptoms may be atropine like including, excitement, delirium, flushed skin, dilated pupils and muscular twitchings. Other features include hypotension, convulsion, delirium and coma.

Early recognition and treatment give good results with complete recovery within 24 hours. In addition to general measures, specific treatment is with physostigmine 0.5-1 mg IV which corrects the anticholinergic effects of the poisoning.

Amanita phalloides The clinical picture develops in two phases. The first phase starts after a latent period of 8-12 hours and essentially resembles acute gastroenteritis ("belated mycetismus cholericiformis") with muscle cramps, vomiting, profuse diarrhea, dehydration and circulatory collapse. The second phase sets in 2-3 days later even after apparent initial recovery. The features resemble acute yellow atrophy of the liver, progressing to hepatic and renal failure. The prognosis is poor. Mortality may exceed 50%. In those who survive recovery is slow.

Sometimes mushrooms belonging to *Coprinus* species produce an antabuse-like reaction if consumed with alcohol. *Panaeolus* produces atropine toxicity like picture and *Helvella* produces hemolytic reaction.

General Management

Stomach wash should be given early. Oral administration of 25-50 g of activated charcoal helps to bind amatoxin

for which it has high affinity. This simple procedure is very helpful if instituted within 36 hours of poisoning.

Several drugs have been employed as possible antidotes, some of them are still experimental. These include massive doses of penicillin, vitamin C, silymarin and thioctic acid.

Thioctic acid (alpha lipoic acid) is given intravenously in doses of 200-300 mg twice daily. The results are encouraging. Hemoperfusion over charcoal has been found to be beneficial in severe cases. All patients with suspected mushroom poisoning should be observed for at least 24 hours since in a few cases the onset of symptoms could be delayed.

Important points

1. There are different species of Mushrooms with varied toxic principles
2. Most of the very toxic species contain amatoxin, which is a potent cytotoxin and deaths have been reported within minutes of intake.
3. Symptoms vary from gastrointestinal irritation, anticholinergic effects, muscarinic or hallucinogenic effects depending on the species
4. Haemoperfusion using charcoal is beneficial in severe cases and several antidotes have been tried

FISH POISONING

In many parts of India toxicity to fish is encountered seasonally from time to time. This may occur as small outbreaks confined to families or may be widespread. The term 'ichthyotoxism' refers to poisoning by intrinsic toxins in fish. The toxic principles may be sarcotoxic (flesh and viscera are toxic), ootoxic (only the reproductive organs are toxic) or hemotoxic (where the toxicity is predominantly in the blood). Some varieties of fish become toxic to man only in particular seasons.

Several factors such as glandular activity during spawning season, consumption of toxic dinoflagellates or toxic plants in the sea, and contamination by industrial effluents can make the fish toxic. Toxic principles may be confined to the liver in many fishes. During certain seasons, the livers of some fishes may contain very high levels of vitamin A (600,000 units/100g). Ingestion of such livers leads to acute vitamin A toxicity characterized by headache, nausea, vomiting, prolonged sleep or drowsiness followed later by extensive exfoliative dermatitis. Another type of toxicity is related to the very high histidine content of scombroid fish. On storage, due to the action of marine bacterial flora, histamine and saurine are produced. These reach high levels causing an acute histamine intoxication syndrome with headache, flushing, urticaria, vomiting and circulatory failure (scombrototoxicity).

Dinoflagellate-induced toxins lead to neuroparalytic syndromes.

Acute renal failure following consumption of gallbladder of raw carp-*Ctenopharyngodon idellus* has been described from Manipur, India. This presented with vomiting and rapid onset of oliguric renal failure. The pathology is likely to be tubular necrosis due to direct nephrotoxicity. These cases responded well to conservative treatment including peritoneal dialysis.

Singh N.S et al. Acute renal failure following consumption of raw fish gallbladder –*Jl Ass Phys Ind* 2004,52,743-745).

Diagnosis of ichthyotoxism can be made from epidemiological and clinical considerations. Bacterial food poisoning has to be excluded. Treatment is only symptomatic and in majority of cases, complete recovery is the rule.

ACUTE CASSAVA TOXICITY

Cassava or tapioca (manioc) is a staple diet among the poor people in many parts of the world, especially in Africa and Southern States of India. Certain bitter varieties (*Manioc utilis*) are toxic during particular seasons due to *linamarin*, which contains cyanogenic glycosides and a glucosidase enzyme. The toxins are maximum in the outer coat, which can be removed by peeling. Bruising, soaking in water, cooking in insufficient quantity of water or prolonged storage serves to bring together the glycoside and the enzyme and liberate hydrocyanic acid. A lethal dose of hydrocyanic acid (60 mg) may be acquired from 300 G of partly damaged cassava.

Symptoms of acute poisoning include giddiness, headache, mental confusion, coma and collapse. Death occurs because of asphyxia. Convulsions and incontinence of sphincters may precede death, which usually occurs within 2 hours of the meal.

Treatment Early gastric lavage with 1% sodium bicarbonate should be given. Specific measures are those for cyanide poisoning. These are :

1. Oxygen inhalation
2. Specific antidote is amyl-nitrate, which is given by inhalation every 2 minutes. This is followed by intravenous administration of 10 mL of 3% sodium nitrite, taking 5 minutes for the injection and later 50 ml of 25% sodium thiosulphate over a period of 10 minutes.
3. This course should be repeated if required. Blood level of methemoglobin should be estimated and this should be kept below 40%.
4. Dicobalt-acetate in a dose of 300-600 mg given intravenously in one minute is a chelating agent used for removing cyanide.

Cassava toxicity should be prevented by avoiding bruised tubers and taking care in storage and cooking. Boiling the tuber in a large quantity of water and

discarding the supernatant removes the toxic content. The increased content in cassava has been implicated in the causation of several conditions such as calcific pancreatitis, Konzo- which is a form of tropical myelopathy first detected in Africa, and possibly other conditions as well.

In India the Tuber Crops Research Stations have helped to develop newer less toxic varieties of cassava, which have become very popular. The occurrence of cassava toxicity has come down in recent times. Far from its original position as poor man's staple, at present cassava has gained the position of being a delicacy on the table.

Important points

1. The toxicity of cassava is due to linimarin which contains cyanogenic glycosides and a glucosidase enzyme
2. Acute poisoning may produce giddiness, headache, mental confusion, coma and collapse.
3. Treatment is as for cyanide poisoning
4. Cassava toxicity has been implicated in calcific pancreatitis, tropical myelopathy etc

Onyala

This is an acute purpuric disease, characterized by hemorrhagic bullae inside the mouth, seen in Africa. It is attributed to the mycotoxin of *Bhoma sorghina* isolated from the cereals, millet and sorghum, though its etiology is not fully known.

Hepatic Veno-occlusive Disease

Syn: Veno-occlusive disease of Jamaica

Though originally described from Jamaica, cases have subsequently been reported from all over the world. The toxic principles of *senecio* and *crotonaria* are responsible for this syndrome. These plants are taken as bush teas. Malnourished children in the age group 2-5 years are particularly vulnerable. The toxin causes proliferation of intimal cells and swelling of subintimal tissues. This leads to occlusion of centrilobular veins of the liver. Liver cells atrophy and are replaced by centrilobular fibrosis. Outbreaks have been reported from Central and North India.

Clinical features varies in severity. In the acute form hepatomegaly, ascites, and rapidly progressive hepatic failure develop. Many cases recover completely. Rare sequelae include asymptomatic hepatomegaly or gradual progression to cirrhosis liver and portal hypertension.

Treatment consists of prompt withdrawal of the offending materials and dietary supplementation with high quality protein. No specific antidote is available (see also section 9, chapter 87).

Aflatoxicosis

Aflatoxins are products of fungi particularly those of *Aspergillus flavus*. These are widespread in several articles of human and cattle food and, therefore, aflatoxicosis involves wide population groups. Groundnuts, cereals or pulses are invaded by the fungus, especially when stored in damp environment. The damaged grains show obvious abnormalities. The toxin contains several components (B_1 which is most toxic, B_2 and G_2). Acute toxicity occurs when mouldy cereals, pulses or nuts are consumed. Aflatoxin is hepatotoxic to many animals and birds. Fungus affected grains are likely to be consumed during periods of drought, famine and non-seasonal rains. Generally, the poor socioeconomic sections of the communities are affected. The clinical picture may be that of acute hepatitis, cirrhosis of the liver or hepatoma depending on the dose and duration of exposure. The outbreaks reported from western India and Rajasthan resembled viral hepatitis and mortality ranged from 10-25%.

Diagnosis In all outbreaks of acute hepatitis, aflatoxicosis should be considered. Diagnosis is based on the clinical picture, exclusion of other conditions, and the epidemiological evidence. Treatment is supportive with rest in bed, adequate supply of glucose and B complex factors and maintenance of fluid and electrolyte balance. Complications have to be treated symptomatically as they occur. Chronic aflatoxin exposure is an important etiological factor in the production of hepatocellular carcinoma in India.

Important points

1. Aflatoxin is a product of fungus *Aspergillus fumigatus*
2. Aflatoxin is hepatotoxic and may produce hepatitis, cirrhosis liver or hepatoma
3. Chronic exposure is an etiological factor for hepatocellular carcinoma
4. Treatment is with symptomatic measures

Epidemic Dropsy

Syn: Toxicity due to *Argemone mexicana*- Yellow Mexican Poppy

Argemone mexicana grows wild in the cold season all over India and is known by different names as *Bharamdandi* or *Pildhatura* (Maharashtra), *Sialkanta* (Bengali), and *Satyanashi* (Gujarati). The seeds resemble mustard seeds. Argemone oil is used as an adulterant of mustard oil, more during times of famine and drought. The toxic principles are sanguinarine and dihydrosanguinarine, the former being more toxic. Poisoning occurs due to consumption of adulterated mustard oil used as cooking medium. Several outbreaks have occurred and are still being reported in Bengal, Bihar, Orissa, Madhya Pradesh, Uttar Pradesh, Gujarat and Maharashtra.

A outbreak which occurred in Delhi in August-September 1998 in which 212 adults were studied is reported in the Journal of Association of Physicians of India (JAPI- 2000-48, 877-880). It also followed the classic description.

Clinical features The onset is insidious with loss of appetite, diarrhea and pitting edema over the legs. Sometimes the edema may be massive and effusion into pleura and pericardium may occur. Cardiac enlargement and failure develop. The extremities are warm due to vasodilatation. Subcutaneous telangiectasia or even hemangiomas develop. These are seen on the mucus membrane of the cheek, gums, tongue, and nose as fleshy dark red or warty growths (sarcomas). Tingling and numbness of the extremities and calf tenderness are present. About 10% cases develop glaucoma. Electrocardiogram reveals nonspecific changes resembling myocarditis. Serum albumin is lowered and alpha-2-globulin is raised. Death is caused by cardiac failure. Withdrawal of the toxic oil leads to recovery in most cases.

Treatment The treatment is supportive with nutritional supplements. Cardiac failure should be treated symptomatically. A simple method to detect the presence of argemone oil is to mix the suspected sample with an equal volume of nitric acid, when a crimson colour develops in case of contamination.

Lathyrism

Syn: Epidemic spastic paraplegia

Chronic ingestion of the toxic principles of *Lathyrus sativus* leads to spastic paralysis of the lower limbs. This pulse is known in various parts of India as *Kesari dal*, *Teora*, *Matra*, *Batura*, *Gharas*, *Lang*, *Lakh* and *Latri dal*. Lathyrism is more prevalent in Madhya Pradesh, Bihar and Uttar Pradesh in India. It has also been reported from Greece, Iran, Russia, Italy, Spain and parts of Africa. Men are more affected than women. The toxic principles are probably *B-n-oxalyl aminoalanine* or *alkaloids like B-amino propionitrile*. The latter is present in the weed *akta*, which contaminates lathyrus peas. Pathological lesion is demyelination of the pyramidal tracts in the lumbar region and some degeneration of the anterior horn cells.

Clinical features The onset is acute or subacute in 90% of cases with muscular pain in the back followed by paraplegia or paraparesis within days to weeks or even after several months. In those with acute onset cramping pain in the calf muscles and muscles of the thigh may occur. This may be followed by rapid onset of paralysis of varying degrees. In those with subacute onset stiffness and heaviness of the lower limbs start after about a month and paralysis sets in and proceeds to varying severity. In the typical case, paralysis and spasticity progress to cripple

the patient. Sensations and autonomic functions are normal. The paralysis tends to be permanent.

Treatment It is symptomatic. There is no specific antidote.

Prevention The toxin can be removed by steeping the cereal in four times its volume of hot water for one hour before cooking. Education of the public on the methods to identify *Lathyrus sativus* will help in wiping out this disease.

Important points

1. Chronic ingestion of toxic principles of *Lathyrus sativus* leads to lathyrism
2. Pathology is demyelination of pyramidal tract and degeneration of anterior horn cells at the lumbar level
3. In a typical case paralysis and spasticity progress to crippling
4. No specific antidote is available

Ergotism

This is caused by the toxin of the fungus *Claviceps purpurea*, which infects rye and other cereal grains. Ergot alkaloids are highly variable mixtures of toxins, the most important one being ergotamine. When ingested, the toxin produces either cardiovascular or neurological manifestations. The former includes vasoconstriction, mental confusion and convulsions. Ergot alkaloids and their derivatives are widely used in therapeutics for their various actions. One of the alkaloids lysergic acid diethylamide (LSD) is a hallucinogen.

LEAD POISONING

Lead poisoning may occur in households among children and in industrial workers. Lead is widely used in paints, storage batteries, petrol and several industries. Ingestion, inhalation or absorption from the skin may lead to acute poisoning. Workers engaged in printing, lead smelting, ship building, tank cleaning are at risk of developing chronic toxicity. Children may eat flaked paint as a form of pica. Lead accumulates in the body and it is deposited in bone and other tissues.

Acute lead poisoning Initial symptoms are metallic taste, irritation of throat, salivation and intense thirst. These are soon followed by colicky abdominal pain, painful spasm of abdominal muscles, hematemesis and constipation. The stools are black due to the formation of lead sulphide. More serious cases develop drowsiness, headache, muscular cramps, convulsions, paralysis of lower limbs, hemolysis and renal failure.

Treatment Calcium disodium versenate (EDTA) in a dose of 1 g in 250 to 500 mL of 5% dextrose intravenously twice daily (50 mg/kg/d) for 8-10 days or longer helps to eliminate the lead. Symptomatic treatment is indicated as the condition warrants.

Chronic lead poisoning (Plumbism) The main symptoms are abdominal colic, constipation, hemolytic anemia, paralysis and cerebral, cardiac and renal damage. It manifests initially as tubular damage going on to chronic renal failure. There is no threshold level for lead to initiate toxicity. Severe intestinal colic and constipation may be mistaken for other alimentary disorders.

Most of the lead in blood is present in erythrocytes. In chronic lead poisoning the lead is deposited in cortical bone. Lead impairs the enzyme delta-aminolevulinic acid dehydrogenase which is needed for haem synthesis. Moderate to severe hemolytic anemia occurs. The peripheral blood shows punctate basophilia and reticulocytosis. In long term lead poisoning the lead is deposited in cortical bone. Motor neuropathies manifest as wrist drop and foot drop. Shoulder girdle muscles may be affected rarely. Sensory symptoms are usually absent. Lead encephalopathy manifests as headache, loss of memory, epileptiform convulsions and coma. Optic neuritis may occur. Urine may show protein, delta amino levulinic acid, and coproporphyrin III. Blood pressure is elevated. Deposition of lead in the gingival margins results in the formation of a black line in people with poor oral hygiene. In edentulous subjects this lead line (*Burtonian line*) does not form. Chronic renal failure may develop. It manifests initially as tubular damage, later, tubular atrophy and interstitial nephritis. Exposure to lead during intrauterine life leads to erosion of cognitive skills with subclinical but permanent reduction in IQ. This may result in permanent impairment in performance standards in adult life.

Ref: Grandjean P, Landrigan PJ: Developmental neurotoxicity of industrial chemicals. The Lancet 2006; 368 2167-78.

Diagnosis The clinical diagnosis is confirmed by the elevated levels of lead in blood. Levels above 80 mcg/dL are diagnostic. A test for chronic lead accumulation is EDTA mobilization test. Urinary loss of >600 mcg of lead in 72 hours indicates lead poisoning.

Treatment In severe toxicity EDTA is administered as described earlier. In less severe cases, other than EDTA an oral chelator, Succimer (dimercaptosuccinic acid) has been used in a dose of 10mg/kg orally every 8 hours for 5 days.

Prevention Proper washing of the hands before eating and provision of protective clothing and masks reduce absorption of lead. Provision of 300 mL of milk to such workers may be helpful in reducing toxicity. Persons working in risky occupations should be periodically monitored. Pollution of the environment by lead salt is a major concern in recent years. The use of lead in automobile fuels has resulted in the discharge of appreciable amounts of lead into the atmosphere. In many states of India the use of leaded petrol is restricted.

Important points

1. Acute lead poisoning presents with predominantly GI symptoms and in serious cases drowsiness-convulsions, hemolysis and renal failure may occur
2. Chronic lead poisoning is characterized by abdominal colic, constipation and basophilic stippling of RBCs
3. Motor neuropathies, optic neuritis and lead encephalopathy can also occur in chronic lead poisoning
4. EDTA is the mainstay of treatment

25

Endemic Fluorosis

T.K. Suma, K.V. Krishna Das

Chapter Summary

Epidemiology 132

Clinical Features 132

Treatment 133

Endemic fluorosis is caused by chronic fluoride intoxication acquired by ingestion of water containing high concentration of fluorides. It is characterized by dental and skeletal changes.

EPIDEMIOLOGY

The disease is present in many states in India where fluoride content of drinking water exceeds 2 ppm. Andhra Pradesh, Punjab and North Karnataka show high prevalence. Endemic areas have also been found in Tamil Nadu, Haryana, Rajasthan, Uttar Pradesh and Delhi and its surrounding areas. In Kerala three districts are affected. The disease is present in certain parts of China, Japan, South Africa, Saudi Arabia and USA.

The disease is more prevalent in males who are engaged in hard manual work because of their higher consumption of water. Total hardness of drinking water (calcium and magnesium hardness) has a protective role.

Presence of fluoride up to 0.5 to 0.8 ppm in drinking water is considered safe in India. With higher levels, fluoride accumulates in the skeletal system and teeth.

Pathophysiology Ingestion of fluoride causes reduction of ionized calcium. This hypocalcemia leads on to secondary hyperparathyroidism and increased osteoclastic activity. Increased levels of lactic acid and citric acid are produced from the osteoclasts thereby increasing the hydrogen ion concentration and lysis of lysosomes. Lysosomal enzymes like protease, collagenase and hyaluronic acid produce disintegration of hydroxyproline and other ground substances of bone and other calcified tissues like teeth. This is responsible for the signs and symptoms of fluorosis like dental hypoplasia with areas of hypocalcification, hypomineralization and softening. The bones are heavier and irregular. There is excessive subperiosteal bone formation at the sites of muscular, fascial and tendinous attachments. Ligaments show various grades of calcification. The most advanced changes are seen in the spine. There is narrowing of the vertebral canal, which leads to compression of the spinal cord. Marked changes are seen in the ribs, pelvis, sternum, mandible, and skull. Over a period of 10-20 years, the subject develops crippling deformities.

CLINICAL FEATURES

Dental fluorosis Enamel and dentin of teeth have strong affinity for fluoride during the formation of teeth. Mottled enamel is an early, sensitive and easily distinguishable manifestation in children. This has been taken as an index of endemicity in epidemiological surveys. Dental fluorosis develops only if the child has lived in the endemic area during dentition. It can be graded depending on the severity.

- Grade-I: White chalky opacities or patches on enamel without faint yellow lines.
- Grade-II: Distinct brownish discoloration.
- Grade-III: Besides pigmentation there is pitting of enamel surface, sometimes with chipping of edges (Figs 25.1 and 25.2).

Fig. 25.1: White chalky opacities in mild dental fluorosis

Fig. 25.2: Severe dental fluorosis

Premature loss of teeth is not rare. Both permanent and deciduous teeth may be affected.

Skeletal fluorosis Skeletal fluorosis is not easily recognizable in the early stages. The initial symptoms are nonspecific such as pain in the neck and back associated with rigidity, joint pains, and paresthesia of the limbs. These cases may be mistaken for rheumatoid arthritis, ankylosing spondylitis or osteoarthritis.

The physical findings include kyphosis, limitation of movements of the spine and exostoses. Exostoses can easily be palpated along the anterior border of the tibia, over the olecranon, and along the medial border of the scapula. These are diagnostic. In advanced fluorosis, kyphosis, fixed flexion deformities of hips and knees and paraplegia, may develop (Fig. 25.3).

Non-skeletal manifestations: These include neurological manifestations like tingling sensation in fingers and toes, weakness and stiffness of skeletal muscles, nervousness and depression, gastrointestinal manifestations like non ulcer dyspepsia, abdominal pain, diarrhea and/or constipation. The red blood cell membrane becomes more pliable due to decreased calcium and forms into echinocytes. Early destruction of echinocytes results in anemia. Fluoride has inhibitory effect on iodine uptake and so may cause enlargement of thyroid.

Fig. 25.3: Fluorosis advanced skeletal changes

Fig. 25.4: Skiagram forearm showing calcification of interosseous membrane

Complications About 8-10% of cases show compression of spinal cord and the roots by protruding osteophytes. The vertebral arteries may also be occluded. The clinical picture may resemble cervical myeloradiculopathy, cervical myelopathy or radiculopathy, dorsal myelopathy and peripheral neuropathy. Bladder involvement manifests as precipitancy of micturition or retention of urine.

Occasionally, peripheral neuropathy manifests as acroparesthesia, but with only minimal sensory or motor defects. Cranial nerve involvement is rare.

Investigations Radiologic and biochemical investigations should be carried out.

Radiology The classic features are osteosclerosis, irregular osteophyte formation, and calcification of ligaments, especially in the vertebral column. In advanced cases, the bones look chalky white. Irregular subperiosteal new bone formation may be observed along the muscular, fascial, and tendinous attachments. Interosseous membrane of the forearm shows calcification and this has been taken as a definite radiological index of skeletal fluorosis (Fig. 25.4). Skull shows thickening and sclerosis of the vault.

CT and MRI CT of the bones may show prominent cortical thickening and increased density with irregular contours. Bony excrescences are detected in both the pelvic bones and the lower extremities. The sacroiliac joints may be narrowed. MRI may show reduction in the intervertebral disc spaces and multiple disc prolapse. The medullary canal may be narrowed by bony excrescences and by the ossified posterior longitudinal ligament.

Biochemistry Fluoride content is increased in the blood, urine, and bone ash. Serum fluoride level varies from 0.05

to 0.8 mg/dL. Serum alkaline phosphatase is moderately raised (15-30 KA units). Serum calcium, phosphorus and magnesium are normal.

Treatment

Endemic fluorosis is a preventable disease, which can be eradicated by providing fluoride-free drinking water. Defluoridation of water may be affected by using bone meal and metasilicate of magnesium (serpentine) but this is not yet widely used. Vitamins and antioxidants have been tried in many cases. Changing the dietary habits by restricting use of fluoride rich food is also important.

There is no effective treatment for the established case. Patients with skeletal fluorosis, when fed with fluoride-free drinking water, seem to improve over the years. Improvement in the dental changes is reported within weeks. Cases of spinal compression require laminectomy.

Prevention of Endemic Fluorosis

In endemic areas fluorosis can be prevented by reducing the fluoride content of water to less than 1 ppm. Two methods are available for defluoridation of water, the Nalgonda technology and the activated alumina technology. In Nalgonda technique alum and lime are used in various proportions depending on fluoride content of water. In activated alumina technology activated alumina is used in domestic filters. Encouraging the use of calcium, vitamin C and vitamin E may help to reduce the skeletal changes.

Important points

1. Ingestion of water having high fluoride content over several years results in fluorosis
2. Fluorosis leads to reduction in the level of ionized calcium. Osteoclastic activity increases

3. Dental fluorosis, skeletal fluorosis and non skeletal manifestations occur.
4. Established skeletal lesions tend to be permanent.
5. Fluorosis can be prevented by defluoridation of drinking water

Tobacco and Health

T.K. Suma, K.V. Krishna Das

Chapter Summary

General Considerations 134

Smoking and Chewing 135

Occupational Health Problems among Tobacco Workers 135

GENERAL CONSIDERATIONS

Man has started using tobacco from very ancient times. At present tobacco is consumed for smoking (beedi, cigarette, pipe, cigar, hookah, etc.) or for chewing with or without other constituents such as betel, arecanut, and lime or as snuff applied to the nasal or oral mucosa. All these habits are very much prevalent in all societies in India.

The Indian Council of Medical Research (ICMR) estimates that about 8,00,000 death are due to tobacco related diseases in India annually. In India among smokers men predominate. In all countries, the prevalence of smoking in women is increasing. About a third of the world population use tobacco in one form or other. World Health Organization (WHO) estimates that there are 3.5 million deaths occurring annually all over the world from tobacco related diseases. This figure is likely to go up to 10 million by 2030 AD if the present situation is not rectified and tobacco related morbidity will top the list of global disease burden.

In India about 4,20,000 hectares are under tobacco cultivation, with an annual production of 6,00,000 tonnes of tobacco and contributing 7% to the total world production. More than 3.4 million persons are engaged in the tobacco cultivation and industry. Over 20 companies

manufacture more than 100 brands of cigarettes. In addition beedies are made in smaller establishments as cottage industry. Twenty percent of tobacco produced in India is used for cigarettes, 40% go into beedies and the rest used for chewing. Developed countries have been successful in reducing the prevalence of smoking while developing countries including India have not done so. Multinational tobacco manufactures are selectively targeting developing countries for sales promotion.

Tobacco smoke contains several constituents, which irritate the respiratory tract and inhibit ciliary action. The tar that is produced is carcinogenic to the respiratory tract. Depending upon the brand of cigarette and the manner of smoking the level of carbon monoxide in the smoke may vary from 1-5%. Nicotine present in tobacco is responsible for the addiction. Sympathomimetic effects of nicotine give rise to higher heart rate, elevation of systolic and diastolic blood pressure, increase in cardiac output and peripheral vasoconstriction. The threshold for ventricular tachycardia and ventricular fibrillation is lowered. By increasing platelet aggregation, platelet adhesion, plasma fibrinogen and viscosity of blood, nicotine favors intravascular thrombosis. There is reduction in platelet survival and clotting time. Atherogenesis is favored by the rise in total cholesterol, low density lipoproteins and free fatty acids, and also fall in high density lipoproteins (HDL) brought about by nicotine. Blood levels of carboxyhemoglobin are elevated. Oxygen carrying capacity of blood is reduced. Rise in blood carbon monoxide leads to intimal hypoxia, increase in the permeability of arterial intima and lipid deposition.

Cigarette smoking is associated with mild airway obstruction and impairment of lung function in

adolescents. Females are affected more. Heavy smokers suffer from tachycardia, palpitation, cardiac arrhythmias, hypertension, tremors, anorexia, agitation and insomnia.

In those who practice the chewing habit, in addition to absorption of nicotine from the buccal mucosa the local irritation caused by the cud leads to precancerous and cancerous changes.

SMOKING

Tobacco is a highly habit forming agent. Several studies have been shown that the first cigarette exposes the individual and the addiction will occur even with the second or third 'smoke'. Children of smoking parents acquire this habit more freely.

The harmful ingredients taken up by the smoker and exhaled by him depend upon several factors such as the number of cigarettes smoked and their frequency, depth of inhalation, smoking the cigarette only partially or fully and the environment in which the smoker smokes - whether open or confined space. Inhalation of the exhaled smoke by others nearby is termed passive smoking, which is also associated with adverse effects in various degrees.

There is irrefutable evidence that smoking is a major risk factor for chronic bronchitis, emphysema and cancers of lung, larynx, esophagus, bladder, kidney, pancreas and cervix uteri. Coronary heart disease, hypertension, strokes, peripheral vascular occlusions, thromboangitis obliterans, peptic ulcers and several other conditions are directly or indirectly attributable to tobacco. Tobacco is the most important cause of cancer and cancer death, affecting several organ systems. Both main stream and second hand smoke are group-1 carcinogens, i.e. included among the highest cancer causing agents in humans. Lung cancer is several times more common in smokers compared to nonsmokers. 90% of bronchogenic carcinoma is related to smoking, either direct or passive. Smoking contributes to 50% of the death of cigarette smokers, with half of these deaths occurring in middle life. Smokers lose 10 years of their life expectancy, compared to non-smokers.

In India oral cancer, which is the most common cancer, shows a strong association with tobacco chewing or smoking habit. One-third of the cancers reported from western countries are probably tobacco related.

Smoking by parents has an adverse effect on their children. Smoking mothers have an increased risk of spontaneous abortion and their children have lower birth weights, higher perinatal mortality and a greater risk of sudden infant death syndrome. Medical associations of several countries have urged their governments to undertake measures to restrict the spread of tobacco habit. These include restriction of sales of tobacco to those below the age of 18 years, ban on advertisement, education in schools and through public media, prohibition of smoking in public places and public transport, heavy

taxation on cigarettes and withdrawal of aids to tobacco industry.

The role of the physician is paramount in controlling the smoking habit. He should set the example by giving up the habit of using tobacco. Smokers should be motivated to give up smoking by counselling and providing information on the ill effects. Governmental measures to restrict sales by imposing penal taxes and statutory directions to exhibit the dangers caused by smoking on the cigarette packs have made only minimal impacts. Many governments in Indian states have prohibited smoking in public places. Assistance to smokers to give up the habit, by replacing nicotine chewing gums and nicotine skin patches have helped to a small extent. *The WHO has declared the 31st of May every year as the "No tobacco day". During 2005 WHO had developed a "code of practice" on tobacco control for health professional organizations (Ref: <http://www.who.int/tobacco>).* Despite all the vigorous efforts, reduction in smoking habit is coming down only slowly. More of youth and females are probably taking to the habit.

Nicotine replacement products like nicotine gum, nicotine patch, nicotine nasal spray, nicotine inhaler, nicotine lozenges, and the antidepressant drug bupropion have been approved to help people to quit smoking.

Tobacco Chewing

There are recent reports from India that chewing tobacco is also associated with increased risk of cardiovascular morbidity. Further studies are needed. Betel chewing as a cause of oral cancer is well known. Several brands of such proprietary preparations (Pan Masalas) are available in the Indian market. These are being used by a large number of persons, especially the youth. Their role in the genesis of oral cancer and other systemic diseases is not yet fully assessed.

Occupational Health Problems among Tobacco Workers

In India tobacco is cultivated mainly in Gujarat and Andhra Pradesh. The varieties of tobacco include Virginia tobacco (cigarette tobacco) and non-virginia tobacco. Persons may be exposed to tobacco during agricultural operations or curing processes. Ill effects of tobacco are considered to be due to absorption of nicotine through the skin or respiratory tract. The levels of nicotine and its metabolic product cotinine are increased in urine.

The symptom complex occurring in the exposed workers is collectively known as *green symptoms*. These consist of neurological symptoms like headache, giddiness, nausea, vomiting, prostration and respiratory symptoms such as cough and dyspnea. Usually, these symptoms are transient. The occurrence of *green*

symptoms is associated with raised urinary levels of nicotine and cotinine. Virginia tobacco is less toxic than the non-virginia variety. The respiratory symptoms may be aggravated by aero-allergens such as pollen and fungi belonging to the species *Gladosporium* and *Altemaria*.

The nature of contact with tobacco also partly determines the clinical manifestations. Persons who pluck the leaves generally get headache and giddiness, while those carrying the leaves for curing get nausea and vomiting. In agricultural workers engaged in curing, entry of tobacco is through the respiratory tract.

Treatment Since the symptoms are usually mild, and last only for a few hours, removal from the surroundings is

itself curative. The local practice among the workers is to take tea and jaggery followed by rest.

Important points

1. It is estimated that 3.5 million deaths occur annually all over the world from tobacco related diseases
2. Nicotine present in tobacco increases sympathetic activity, favors vascular thrombosis and atherogenesis
3. Smoking is a major risk factor for acute bronchitis, emphysema, carcinoma of lungs, larynx, urinary bladder, coronary artery disease, stroke and peripheral vascular disease
4. Nicotine replacement products and bupropion are being given as treatment for cessation of smoking.

Nutrition:
General Considerations

K.V. Krishna Das

5

Chapter Summary

Assessment of Nutritional Status 138

Malnutrition 139

Functions of Food 140

Standard Nutrition Tables 142

Bioactive Phytochemicals in Food 142

Prescription of a Balanced Diet 145

The term Nutrition came from the Latin Word 'nutrire' meaning-to suckle, nurse or nourish. In the English language it meant supplying or receiving nourishment. Hippocrates advised "let your food be medicine and your only medicine be your food." The close relationship between food, life and health has been amply stressed in the Indian Vedic texts. Ayurveda discusses the role of food and specifies elaborate dietary management of several diseases.

Modern Concepts in Nutritional Science

Nutritional science has been defined as the science of foods, and other substances, their use, actions, interactions and balance in relation to health and disease: the process by which the organism ingests, digests, absorbs, transports and utilizes nutrients and disposes their end products. A simpler definition will be "the area of knowledge regarding the role of food (dietary inputs) in the maintenance of health.

The essential requisites (dimensions) of health should include the following:

1. Achieving optimal growth and development reflecting full expression of the genetic potential.
2. Maintenance of the structural integrity and functional efficiency of body tissues necessary for an active and productive life.
3. Mental well-being.
4. Ability to withstand the inevitable process of aging with minimal disability and functional impairment, and

5. Ability to combat diseases such as:

- a. Resisting infections,
- b. Retarding the progress of degenerative diseases and cancer, and
- c. Resisting the effects of environmental toxins and cancers.

This newer concepts of nutritional science has come out as a result of the progress made in the studies of immunology, molecular biology, oncology, geriatrics, phytochemistry and similar others.

Assessment of Nutritional Status

Nutrition of communities can be assessed by large surveys. These surveys are of epidemiological importance. The methods employed to assess the nutritional status in communities are listed below:

- i. Studies on food production or total food availability in relation to total food needs.
- ii. Measurement of food and nutrition intake.
- iii. Studies on dietary habits and practices.
- iv. Special studies on foods to assess biological value and prevalence of interfering substances like toxins and goitrogens.
- v. Studies based on sociocultural parameters.
- vi. Vital statistics like morbidity and mortality rates.
- vii. Studies on health conditions indirectly related to the nutritional status of the population such as infections and parasitic diseases.

Nutrition in individuals can be assessed by clinical examination, anthropometric measurements and biochemical and other laboratory tests.

Clinical assessment This forms an important part of all nutrition surveys (Table 27.1).

Anthropometry: Anthropometry, which involves measurement of growth and physical development, is particularly useful in children. The most commonly employed measurements are: (i) height (Ht-linear growth), (ii) weight (Wt-body mass), (iii) head circumference (HC-possible relationship to mental development), (iv) mid-

TABLE 27.1

Prominent clinical features in undernutrition

General signs	Apathy, loss of weight and recent emaciation, dependent edema, delayed puberty
Hair	Lack of lustre, sparseness or thinness, straightness, dyspigmentation, easy pluckability
Face	Diffuse pigmentation, nasolabial dyssebacia, moon face
Eyes	Pale conjunctiva, Bitot's spots, conjunctival xerosis, corneal xerosis, keratomalacia, angular palpebritis
Lips	Angular stomatitis, cheilosis
Teeth	Mottled enamel
Gums	Spongy and bleeding gums
Skin	Xerosis, follicular hyperkeratosis, pellagrous dermatitis, flaky paint dermatosis, scrotal and vulval dermatosis
Nails	Koilonychia
Muscular and skeletal	Muscle wasting, craniotabes, frontal and parietal-bossing, epiphyseal enlargement, systems beading of ribs, persistently open anterior fontanelle, knock-knees, bow-legs
Systemic signs	Hepatomegaly, alteration in mental functions, peripheral neuropathymyelopathy, cardiac changes

arm circumference (MA-variations being mainly due to changes in muscle mass and fat calories), (v) chest circumference, and (vi) skin fold thickness (fat calories). The measurements are related to expected standards for age. When the exact age of the child is not known, age-independent indices are made use of. These are wt/ht, wt/ht², wt/hC, MA/HC, etc. The Indian Council of Medical Research (ICMR) has laid down norms for the Indian subjects.

The traditional gold standard to estimate the fat content in the body has been hydrodensitometry under-water weighing—which is not practicable universally. Fat is less dense than muscle and bone. Dual energy X-ray absorptiometry (DEXA) is now replacing densitometry on account of its precision and availability. Other methods used to assess body fatness are the circumference of the waist and the hip and their ratio, the body mass index (BMI), also known as quetelet index which is the weight in kilograms divided by the square of the height in meters. The BMI has gained popularity on account of its reliability, relationship with morbidity and mortality and ease of performance. BMI above 25 suggests fatness, values below 20 should suggest under-weight.

Laboratory examination At present sensitive methods are available for the accurate determination of vitamins and trace elements in body fluids and tissues, but these are expensive and cannot be employed universally. Moreover, the values of nutrients in blood and tissues show a wide range of levels in normal individuals. No test is specific for a particular kind of malnutrition. Conditions of collection, storage, and technique of estimation can all introduce variations. Table 27.2 lists the main tests employed.

Malnutrition

Malnutrition results from deviations from normal nutrition. Frank clinical signs and definite biochemical abnormalities occur in gross malnutrition, but only borderline changes occur in the majority of cases.

Malnutrition may be primary when it is caused by defective intake, or secondary when it results from other disease processes. In clinical practice one seldom comes across isolated deficiencies. More often the malnutrition is generalized, but one or other nutrient deficiency predominates.

Malnutrition results basically from inadequate or improper food consumption. The abnormality may be quantitative, qualitative, or both. In addition to poverty which is the main cause, social, cultural, agricultural and educational factors modify the form and extent of malnutrition. Diarrhea, helminthic infestations, and other infections aggravate malnutrition resulting in high mortality and morbidity.

Social aspects of nutrition In addition to the nutritive values of diet, food is a part of security, social behaviour and civilization. Occurrence of malnutrition in an individual is only an index of the same disorder in the household and the community as well. So identification of an index patient should be the starting point for further case detection and the treatment should cover the entire community.

Etiological Factors

1. Inadequate supply of food due to poverty
2. Ignorance of dietary principles
3. Wrong practices of cooking and storage of food
4. Malabsorption of nutrients

TABLE 27.2

Biochemical investigations in malnutrition

Nutrient deficiency	Tests
Proteins	Serum protein fractions, especially albumin, amino acid imbalance, hydroxyproline excretion. urinary urea, urinary creatinine excretion/unit time
Vitamin A	Serum vitamin A, serum carotene
Vitamin D	Serum alkaline phosphatase (in young children), calcium, phosphorus, serum vitamin D metabolites
Ascorbic acid	Serum ascorbic acid, leukocyte ascorbic acid, urinary ascorbic acid-load test
Thiamine	Urinary thiamine, blood pyruvate-lactate, RBC transketolase load test
Riboflavin	Urinary riboflavin, erythrocyte riboflavin loading test
Niacin	Urinary NI-methyl nicotinamide load test
Folic acid	Hemoglobin, serum folate, RBC folate—'Figlu' test
Vitamin B ₁₂	Hemoglobin, serum B ₁₂ , Schilling's test
Iodine	Urinary iodine tests for thyroid function
Minerals	Calcium: serum calcium, bone calcium, calcium turnover studies, serum alkaline phosphatase Iron: serum iron, iron binding capacity, tissue iron, serum ferritin
Trace elements	Analysis of hair

* Note: Recently the importance of chemical analysis of the hair in determining levels of trace elements has been recognized. The advantages are: (1) It reflects the variation in the level of trace element over a long period, (2) hair is easy to be preserved and transported. Trace elements are concentrated in the hair.

5. Parasitism
6. Loss of nutrients through urine, stools, bleeding, etc.
7. Increased demands due to pregnancy, intercurrent illness, or repeated deliveries
8. Interference with metabolism
9. Other environmental factors like general insanitation, intercurrent illness, overcrowding; rapid population growth, and political instability

Nutritional disorders often present as multiple deficiencies and only rarely as isolated entities. The most pronounced deficiency manifests clinically, the others remain subclinical. In such cases supplementation of the missing nutrient without overall dietary correction leads to temporary improvement, but sooner or later another malnutrition becomes evident. Irrespective of the type of nutritional disorder, overall dietary correction is mandatory. The presenting symptoms should be treated with additional supplementation of the deficient factor.

Care should be taken to prescribe a proper diet suitable to the patient's cultural and economic state, and made up of articles cheaply and freely available in the locality. Prescription of a diet unsuitable to the socio-cultural background of the patient is the most common cause for non-compliance.

In health, many nutrients are stored in the body and therefore, dietary deprivation initially leads to depletion of the stores. This period is totally asymptomatic. Symptoms occur only when the deficiency is far advanced. Hence, it is essential to continue nutrient therapy for at least 4-6 months after full correction of the clinical condition to replenish the stores. Natural foods are more palatable, but they are slow in action and several factors

influence their absorption and utilization. Therefore, therapeutic preparations are employed for immediate correction and thereafter dietary measures are continued. It is absolutely essential to detect the primary cause in each case otherwise many underlying serious diseases like cirrhosis of liver or malignancy may be missed, till the condition becomes advanced beyond treatment. All cases of secondary malnutrition should be fully investigated to detect the primary cause.

Functions of Food

Living organisms cannot create energy but can only transform energy. The food provides calories for energy needs, proteins to build and maintain the body tissues, and vitamins and minerals to regulate the biochemical processes essential to maintain health and offer resistance against disease.

Carbohydrates, fats and proteins together are called the proximate principles. These substances share the common property of chemical degradation with the release of utilizable energy. Under normal dietary conditions, however, the contribution of proteins to energy supply is minor. The unit of energy used at present in nutrition is the joule, though till recently the unit was kilocalorie (Kcal).

1 kcal = 4.184 kJ.

Energy value of the proximate principles The value of energy yielded by carbohydrates, proteins, and fats are 4.0, 4.0, and 9.0 kcals respectively.

Carbohydrates Carbohydrates are the main sources of energy. They are not indispensable if other sources of energy are available, but in most parts of the globe carbohydrates are the most easily available and cheapest food sources.

Carbohydrates account for 45% of total energy in the western diets and over 80% in the diets of many communities in India. In India most of the carbohydrates are in the form of unprocessed starches, along with dietary fiber, whereas in the West the starches have been progressively replaced by sugars.

Glycemic index of a carbohydrate relates to its rate of absorption and elevation of post-prandial blood glucose levels. High-glycemic-index foods are characterized by rapid absorption, attainment of high postprandial blood-glucose level and insulin response. They are particularly harmful if given to diabetic patients.

Fats Dietary fats are composed of triglycerides, phospholipids and sterols. Triglycerides which supply energy are made up of fatty acids and glycerol. Most of the fatty acids occurring in nature are even carbon atom fatty acids.

Functions of Fats

1. Source of energy
2. Body building
3. Vehicles for fat soluble vitamins A,D,E and K
4. Source of antioxidants, e.g. carotene, tocopherols
5. Addition to taste and acceptability of food.

Fatty acids are classified as saturated and unsaturated according to the presence and number of double bonds. Saturated fatty acids have no double bonds, e.g. myristic acid (14C), palmitic acid (16C), and stearic acid (18C). Unsaturated fatty acids may contain one or more double bonds. Oleic acid contains one double bond. Poly-unsaturated fatty acids contain two or more double bonds. They can be further divided into Omega 6 and Omega 3 families according to the position of the omega terminal double bond. Of these, linoleic acid (18C-2), linolenic acid (18C-3), and arachidonic acid (20C-4) are named essential fatty acids, since they have to be supplied at least in small quantities in the diet. The essential fatty acids are the precursors of the prostaglandins and they are required for formation of cell membranes and phospholipids. Vanaspathies and margarines are prepared by hydrogenating oils with high content of poly-unsaturated fatty acids. In this process they are converted into saturated fatty acids.

In India the poor sections of the population derive only 10% of their energy needs from fats whereas up to 35% of the energy requirement may be provided by fats in the diets of the affluent groups. Visible fat comprises the oils and fats used for cooking and on the table whereas invisible fat consists of lipids incorporated in articles of

food such as cereals, spices, nuts, oil-seeds, coconut, vegetables and others. The invisible fat accounts for up to 10% of the total energy needs in all groups. ICMR has recommended the addition of visible fat at 5% of energy needs for adults and children, 12.5% for pregnant women, and 17.5% for lactating women.

Consumption of fats has increased in affluent countries, since fats increase the taste and acceptability of food.

Vegetable oils with the exception of coconut oil and palm oil provide adequate amounts of poly-unsaturated fatty acids. Animal fats except fish liver oil are generally saturated, with very little of poly-unsaturated fatty acids. Fish liver oils contain good amounts of poly-unsaturated fatty acids, eicosapentaenoic acid and docosahexaenoic acid which lower VLDL in plasma.

Functions Attributed to Essential Fatty Acids

1. For cell membrane mechanisms and messenger actions.
2. Immune response: PUFAs have antibacterial, antiviral and antifungal properties. They indirectly modulate T-cell response.
3. Possibly anticancer activity.
4. Inhibits the development of atherosclerosis.
5. For normal brain development and neurological functions in the fetus and newborn.

Several beneficial effects of EFAs are being recognized and they have attained a place in modern therapeutics.

Increase in the total quantity of saturated fats in the diet above 25% of energy needs elevate serum cholesterol levels and also adversely affect the HDL/LDL ratio. Ideally at least 3% of the dietary fat should be poly-unsaturated. Apart from the total quantity, the quality of the fat also plays a role. Hydrogenation of vegetable oils convert the unsaturated fatty acids into saturated trans fatty acids. Trans fatty acids elevate LDL and reduce HDL thereby promoting atherogenesis in arteries and increasing the risk of coronary and cerebral vascular occlusions.

By a regular process of dietary education in the community and the provision of health foods, most of the developed nations have brought down their per-capita consumption of dietary fat. The population has been rendered diet conscious. Even items of confectionary such as chocolates and ice creams are made to contain less fat. Such measures have served to bring down the incidence of coronary artery disease and myocardial infarction. Attempts in this direction are only in the initial stages in India at present.

Proteins Proteins, together with water, form the basic building units of tissues. In addition, they function as enzymes and hormones and also take part in transport mechanisms. Of the twenty amino acids present in

BV, NPU and chemical score of proteins			
Food	BV	NPU	Chemical score
Whole egg	96	91	100
Cow's milk	84	75	66
Liver	77	65	66
Meat	80	76	70
Fish	85	72	60
Rice	64	57	60
Wheat	58	47	42
Bengal gram	56	45	42
Groundnut	54	45	44
Coconut	67	56	52

proteins, eight have to be supplied to man through dietary sources almost continually. For adults the essential amino acids are lysine, methionine, valine, leucine, isoleucine, tryptophan, phenylalanine, and threonine. For infants histidine is also essential. Animal proteins are rich in essential amino acids, whereas vegetable proteins are deficient in one or more of them.

An ideal protein is one which contains all essential amino acids in optimal amounts and is completely digestible and utilizable. For the human infant, mother's milk fulfills these requirements. Whole egg proteins are considered the next best and this is given a rating of 100 arbitrarily. Other proteins are compared with whole egg protein. Biological value (BV) and net protein utilization (NPU) are most popular indices used for comparison. In addition, chemical method, i.e., chemical score (CS), is also widely employed to assess dietary protein quality.

Vegetable proteins have lower quality ratings than animal proteins. In the ordinary Indian diet, cereals, pulses and other vegetable sources also contribute proteins. The biological efficiency of such a mixed protein source is far higher than the average to be expected. The enhancement in protein quality resulting from a mixture of vegetable sources is known as the supplementary value of proteins.

Protein deficiency in the later part of fetal life and early childhood will lead to structural and functional derangements in the development of neural structures in the brain. This may lead to permanent impairment of cognitive and other higher functions. The importance of the adequacy of protein supply in pregnant and lactating women cannot be overemphasized.

Protein deficiency leads to T-cell dysfunction and immunological deficiency. Malnutrition related diabetes mellitus (MRDM) has been attributed mainly to protein malnutrition. Normocytic anemia may occur rarely as a result of protein deficiency.

Well-balanced traditional Indian diets are quite adequate to supply the protein requirements. An important reason for protein deficiency in India is the availability of foods in amounts far too short to supply energy needs.

Standard Nutrition Tables

The Indian Council of Medical Research (ICMR) has prescribed standard dietary allowances for the Indian people at different stages of life (Tables 27.3 to 27.7).

Table 27.8 gives the standard height and weight for Indian subjects.

Bioactive Phytochemicals in Food

In addition to the proximate principles, several articles of food contains substances which alter cellular metabolism and thereby promote or impair health and well being, e.g. beta carotene, ascorbic acid, tocopherols and selenium. In addition to their primary nutritional roles, they help to promote health, and prevent disease process. Nearly twenty such substances have been identified. These belong to the classes.

- 1. Phenolic compounds—indoles
- 2. Flavonoids—anthocyanine
- 3. Isoflavonoids—isothiocyanates
- 4. Coumarins—diterpenes
- 5. Lignans

Groundnuts	—	—	50*	50*	—	—

* An additional 30 g fats and oils can be added in place of groundnuts

Food items such as cabbage, cauliflower, carrots, tomatoes, chillies, onions, garlic, citrus fruits, amla, guava, green leafy vegetables, ginger, cloves, sesame, tea, sunflower oil and palm oil contain them. Bioactive phytochemicals acts as antioxidants, detoxifying agents and anticancer agents.

Substances such as carotinoids, ascorbic acid and tocopherols present in green leafy vegetables, fruits, palm oil and others act as antioxidants.

Normal cellular metabolic processes involve reactions requiring pre-oxidants and antioxidants. The former promote the release of O₂ for energy and cellular metabolism. The latter neutralize deleterious oxidants and free radicals generated during normal metabolism and environmental stresses such as smoke, carcinogenic-chemicals, industrial effluents, food additives and the like. Free radicals promote peroxidation of membrane lipids. They impair cellular function and damage cellular proteins and DNA. Peroxidation of circulating lipoproteins convert

them into more harmful substances. Cumulative tissue injury caused by free radicals lead to aging, atherosclerosis, cancer and so on.

Toxic molecules are detoxified and converted into excretable forms by microsomal oxidase and conjugase enzymes. Indole derivatives present in various foods such as cabbage, tomatoes, strawberries, pineapple, green peppers and tea are mainly involved. Garlic can inactivate carcinogens present in food. The various dimensions played by food in addition to the nutritive value has led to the concept of “total health value of food”. The present day recommendation is to consume 800-1150 g of fresh vegetables and fruits daily. This helps to reduce the incidence of ischemic heart disease, strokes and cancers.

The term “functional foods” is coined by food processors, in order to promote their sales. Functional foods are those which exert beneficial effects beyond their nutritional effects on specific body functions which promote health and well being and prevent disease. Some

of the common examples include bran which relieves constipation and low sodium high potassium foods which lower blood pressure.

Immunological competence and nutritional status are two of the most important determinants of morbidity and mortality. Malnutrition, immunodeficiency and infection create a vicious cycle in which each factor contributes to the adverse outcome. Primary immunodeficiency may also lead to secondary nutritional disorders.

Prescription of a Balanced Diet

Energy Energy requirements are determined by: (1) physical activity, (2) body size and composition, (3) age and sex, (4) physiological state, and (5) climate and

environment. Generally, the energy requirement of people living in tropical countries is lower than those in the colder climates.

Pregnancy, lactation and repeated infections and infestations widely prevalent in India increase the need for protein. Since the nutritive value for proteins varies widely, it is convenient to express the requirements of protein in terms of a reference protein with an assumed NPU of 100, which is fully digested and utilized. The reference protein can be converted into proteins of customary diets using the formula:

$$\frac{\text{Ref. protein requirement}}{\text{NPU of dietary protein}} \times 100$$

The NPU of Indian diets is approximately 65.

28

Starvation

K.V. Krishna Das

5

Chapter Summary

- General Considerations 146
- Clinical Features 146
- Treatment 146

GENERAL CONSIDERATIONS

Severe starvation on a mass scale occurs during special situations like prolonged war, drought, and other natural or political calamities. Chronic starvation of different grades affects large number of people in the developing countries, even during normal times. Several famines have occurred during the 19th and early part of the 20th centuries. Famines were a regular occurrence in Bengal during the colonial rule. Though acute and chronic food shortage occur from time to time in various parts of India as a result of floods, drought or earthquakes, widespread famine has not occurred in the latter part of this century. In addition to food shortage, inability to ingest or digest and absorb food also results in starvation. Individuals may resort to starvation voluntarily or this may result from psychiatric abnormalities.

Loss of weight amounting even up to 50% of body weight is the most prominent feature. The weight loss is initially caused by the loss of fluid. Later on it is owing to catabolism of tissues to meet energy needs. The body stores of carbohydrate (liver and muscle glycogen) are depleted within two to three days and fat is mobilized in the form of free fatty acids which is used as fuel by the muscles. Glucose is spared for the brain. Tissue proteins are also broken down in order to meet the energy needs.

Protein synthesis is diminished and alanine is released by the muscles to the liver for conversion to glucose, which is made available to the brain. During prolonged starvation, brain metabolism can adapt to use beta-hydroxybutyrate and acetoacetate also as fuel. Generalized emaciation results. Liver and intestines are the first to lose tissue, and this is followed by muscles and skin. The brain is preserved right till the end.

CLINICAL FEATURES

The patient is apathetic and irritable. The loss of fat around the buttocks, thighs, back, and buccal region gives the characteristic appearance with prominence of bones and dry, thin, inelastic, loose skin. A brownish, patchy pigmentation is generally encountered. The hair becomes characteristically dry and easily pluckable. During cold weather cyanosis of extremities may develop.

Systemic disturbances Cardiovascular changes include bradycardia, lowered systolic and diastolic pressure, and reduction in venous pressure and cardiac output. The heart size is also reduced. Respiratory rate is lowered, so also the vital capacity. Growth hormone level is decreased. Basal metabolism is lowered. Corticosteroid is normal. In both sexes sexual function is diminished leading to loss of libido in males and amenorrhea in females. Hypothermia may develop on exposure to cold. Though personality changes may be manifest, the intellect usually remains clear till the end. Capacity for work is reduced due to loss of muscle mass. Mild normocytic normochromic anemia is not uncommon.

In some individuals dependent edema appears even without lowering of plasma albumin. Nocturnal polyuria is common though the renal function is not grossly affected.

TREATMENT

The course of treatment should depend upon the severity of the disorder. Mild cases of starvation require only oral feeds. Overzealous dietary supplementation may lead to diarrhea and death. In the early stages, gradual introduction of easily absorbable and predigested food may be necessary till the alimentary functions return to normal. Fats and fatty foods have to be avoided to prevent diarrhea. Skimmed milk is superior to whole milk. Skimmed milk powder reconstituted to give 10-15% strength is well tolerated if given as small feeds (up to 100 mL) frequently. A daily intake of about 3,000 kcal

and 100 g proteins should be aimed at. Severely debilitated patients should be fed using an intragastric tube in order to ensure adequate intake. After the initial rapid gain in weight due to correction of dehydration, a steady increase of 1-1.5 kg/week can be considered as adequate response.

In all cases of severe starvation especially if complicated by intercurrent illnesses and diarrhea,

parenteral nutrition should be resorted to without delay. If starvation occurs on a wide scale, relief camps have to be organized to provide shelter, food, potable water and general sanitation.

Community kitchens may have to be set up to provide food. In these endeavours, the medical personnel have to work in close liaison with social service organizations and governmental agencies.

Protein-Energy Malnutrition

K.V. Krishna Das

5

Chapter Summary

- General Considerations 147
- Marasmus 147
- Kwashiorkor 148
- Marasmic Kwashiorkor 148

GENERAL CONSIDERATIONS

Protein-energy malnutrition (PEM) has been defined by WHO and FAO (1973) as “a range of pathological conditions arising from coincident lack of protein and calories in varying proportions occurring most frequently in infants and young children and commonly associated with infections”.

The clinical spectrum includes a variety of clinical syndromes, with ‘marasmus’ and ‘kwashiorkor’ at the two extremes and the intermediate forms (marasmic kwashiorkor) and nutritional dwarfism in between. Mild cases may present only with apathy and retardation of growth. Childhood malnutrition has been graded taking the weight for age as the criteria (Table 29.1).

Etiology and pathogenesis: Protein-energy malnutrition is an environmental disease, caused by deficient intake of protein and calories. It results from the combined influences of low food availability, poverty, ignorance, illiteracy and cultural taboos, frequent infections and poor environmental sanitation.

TABLE 29.1

Grades of PEM	
Grade	Percentage weight to the reference standard (Harvard)
I	71-80%
II	61-70%
III	51-60%
IV	50% and below

Note: ‘K’ in front of a grade denotes kwashiorkor. (Recommendation of the nutrition subcommittee of the Indian Academy of Pediatrics).

CLINICAL FEATURES

Marasmus (Fig. 29.1 (2))

Severe restriction of food in an infant, as in cases of gross inadequacy of breast milk, leads to arrest of growth. Due to starvation the subcutaneous fat and muscles are used up as energy sources. The baby becomes emaciated. Unlike as in kwashiorkor, there is no edema. Loss of the buccal pads of fat give the infant a withered and ‘old man’s’ look. The weight is below the sixtieth percentile. The height depends upon the onset and duration of undernutrition. In the early stages the infant eats well but appetite is lost as the condition progresses. Initially, inadequacy of food leads to constipation, but later on diarrhea sets in with green stools containing mucus. In the well-established form the baby is apathetic.

Fig. 29.1: (1) Kwashiorkor, and (2) Marasmus

Moderate anemia may develop. The skin and hair are usually normal.

KWASHIORKOR (FIG. 29.1 (1))

This name was coined by Dr Cicely Williams in 1933, to denote 'disease of the child deposed from the breast by the conception of a new fetus'. Children between the ages of 1 and 3 years are affected more. The disease starts when the baby is weaned from the breast.

Pathology Main changes are seen in the small intestines, liver, pancreas and thymus. Small intestinal mucosa shows blunting of villi and atrophy of brush border, so that the columnar epithelium appears to become cuboidal. The total absorbing surface is reduced. Lactose intolerance is common because of disaccharidase deficiency. Liver shows fatty infiltration of the parenchymal cells. The pancreatic acini are atrophic and enzyme activity is reduced. Thymus is markedly atrophied and this may contribute to deficiency of cell mediated immunity.

Clinical features This child is stunted and skeletal muscles are wasted. The presence of fairly normal amounts of subcutaneous fat and edema give a deceptively plump appearance. Pitting edema is a prominent feature. The child is apathetic, irritable and drowsy. Characteristic skin changes occur in many and when present; these are diagnostic. These include flaky paint dermatosis seen over areas of pressure and trauma, fissuring and ulceration at the flexures and a mosaic like appearance (crazy pavement appearance). The hair becomes thin, sparse, brownish and lusterless. They may fall off. Regrowth of normal pigmented hair heralds nutritional recovery. Since periods of nutritional deprivation and partial correction of nutrition alternate in many cases, the hair shows alternate bands of pigmentation and depigmentation (flag sign). The appetite is poor. Diarrhea is a frequent feature. There may be concomitant deficiencies of iron, folate, fat soluble vitamins and B complex factors. Hepatomegaly occurs in

a third of the cases. This is due to fatty infiltration. With recovery the liver reverts to normal without sequelae.

MARASMIC KWASHIORKOR

In this condition, features of marasmus and kwashiorkor are present simultaneously. The body weight is less than 60% of the normal. Dependent edema is present. Mental changes, skin and hair changes and hepatomegaly are evident.

Secondary infection is very common in protein energy malnutrition. This is due to the fact that both humoral and cellular immunity are defective. The intestinal flora is altered and this may account for the diarrhea. Episodes of infection further jeopardize the nutritional status.

Laboratory investigations The total protein content of the body is reduced, and this is reflected most prominently as hypoalbuminemia. The plasma levels of essential amino acids are low, but the non-essential amino acids remain normal or even elevated. Basal metabolic rate is reduced. Hypoglycemia occurs commonly.

Total body water is increased and all the compartments show increase of fluid. The plasma osmolality is reduced. Renal plasma flow is diminished and this results in impairment of renal function. Plasma sodium is increased with reduction in potassium and magnesium. Gross reduction of serum sodium is associated with a poor prognosis.

Prognosis depends on the severity of the disease at diagnosis and promptness of treatment. Marked weight loss, severe infections, fluid and electrolyte imbalance, hypoglycemia, hypothermia, cardiac failure, elevation of serum bilirubin and liver enzymes, drowsiness and xerophthalmia indicate poor prognosis. In severe cases mortality goes up to 20%. The disease is entirely preventable by ensuring adequate caloric and protein intake to the growing child in the first three years of life. Proper management in the established case gives rise to full recovery, catch up growth and restoration of normal parameters. Recurrence is likely if the adverse environment is not corrected.

Treatment

Treatment is aimed to supply a diet rich in calories, proteins and other essential nutrients. For success of treatment supplementation should be with natural foods available locally. 150 Kcal/kg of energy and 3.3 g/kg of proteins are optimally required for catch-up growth. Fats are administered to supply adequate calories without increasing the bulk. Children with lactose intolerance do not tolerate carbohydrates, but they tolerate fats. As the child gains appetite the frequency of feeding is increased. If there is severe anorexia, forced feeding has to be resorted to. Salt should be restricted to avoid congestive cardiac failure. The National Institute of Nutrition,

Hyderabad has formulated an energy-protein rich mixture to treat PEM at home. It consists of whole wheat 40 g, Bengal gram 16 g, groundnut 10 g, Jaggery 20 g (total 86 g). This supplies 330 calories and 11.3 g proteins. Skimmed milk, eggs and cereals are added as the condition improves. In addition to nutritional correction, intercurrent infections have to be controlled simultaneously.

Initial recovery is heralded by the disappearance of edema. The major biochemical abnormalities are corrected within 2-3 weeks. Complete correction of all reversible changes, referred to as 'clinical recovery' occurs only in 2-3 months.

Prevention and Rehabilitation

PEM is a preventable disease. Three levels of prevention have been formulated. Primary prevention is achieved by

nutrition education to prevent occurrence of PEM. Secondary prevention is aimed at early detection and proper treatment. Tertiary prevention consists of nutritional rehabilitation of an established case.

The importance of breast feeding as a prophylactic against protein calorie malnutrition cannot be overemphasized. Correct feeding practices, both during health and disease, proper sanitation, deworming and family planning methods have to be employed simultaneously to achieve lasting benefit.

Nutrition rehabilitation is employed to prevent residual nutritional handicap and prevent recurrence of protein energy malnutrition. Even at the initial stages of treatment the mother should be made to participate in the selection, preparation and administration of food. This measure helps to impart nutritional education to her, prevent recurrence and detect relapse early.

Fat Soluble Vitamins

K.V. Krishna Das

Chapter Summary

Vitamin A	149
Vitamin D	151
Rickets	152
Osteomalacia	153
Hypervitaminosis D	154
Vitamin E	154
Vitamin K	154

Vitamins are organic substances which have to be supplied in food in minute quantities to maintain the biochemical and structural integrity of many cells and tissues. The human body cannot synthesize them. Most of them are integral parts of certain coenzymes required for biochemical reactions at tissue levels.

The vitamins have been classified into fat-soluble and water-soluble groups based on their presence in natural foods. By synthetic processes water soluble, preparations of some of the fat soluble vitamins have been produced,

e.g. vitamin K. The fat-soluble vitamins are A, D, E and K. The water-soluble vitamins are C and B complex group consisting of thiamine, niacin, riboflavin, pyridoxine, biotin, cyanocobalamin, folic acid and pantothenic acid.

Vitamin A

Syn: Retinol

Vitamin A has a crucial role in normal visual processes and the maintenance of health of epithelial cells. Deficiency of vitamin A is one of the major causes of preventable blindness occurring in many developing countries. This deficiency is widely prevalent in India and about 10% of school children are affected. Its prevalence is higher in the southern states.

Source of intake Vitamin A is found exclusively in animal foods. Rich sources of animal origin are liver, especially fish, liver, butter, ghee, cheese, egg yolk, and milk. Vegetable sources contain the precursor for vitamin A, i.e. carotene especially beta carotene. Rich sources of

carotene include dark green leafy vegetables such as spinach and amaranth, yellow vegetables like carrot and pumpkin, and fruits like mangoes and papaya. Red palm oil is a very rich source of carotene. In the body carotene is converted into vitamin A. Six parts of carotene are equivalent to one part of vitamin A. Vitamin A is stable at temperatures below 100°C. Vitamin A is stored in the liver as retinyl esters and these stores can last for 6-9 months.

Mechanism of action Vitamin A aldehyde is present as rhodopsin in the retina. The changes undergone by rhodopsin form the molecular basis of visual excitation. Vitamin A is required for growth, reproduction and maintenance of life. Synthesis of glycoprotein, essential for proper epithelial function also may be a major function of vitamin A. Vitamin A is essential for proper metabolism and integrity of epithelial cells in many sites. In the absence of vitamin A the epithelium undergoes squamous metaplasia and the flattened epithelial cells are heaped upon one another. Dryness of the eyes leads to xerophthalmia. Bitot's spots develop as whitish scaly plaques on the sclera and they consist of heaped up metaplastic epithelium. The cornea softens, opacifies, ulcerates and necroses and this condition is called keratomalacia. This leads to blindness.

Even in subclinical vitamin A deficiency the conjunctival epithelium shows changes in 90-95% of cases. The conjunctiva is made up of epithelial and goblet cells. Conjunctival impression cytology using a multipore filter (pore size 0.45/μm) applied to the conjunctiva for 2-3 minutes is diagnostic. On staining this with PAS, the epithelial abnormality can be made out.

Daily requirements	
Man	750 μg
Woman	750 μg
Infants	300-400 μg
Children	400-600 μg
Adolescents	750 μg

A dose of 1 μg of retinol is equivalent to 3 international units of vitamin A and 6 μg of carotenoids. An additional 400 μg should be provided during lactation.

Primary vitamin A deficiency generally results from inadequate intake of the vitamin or the carotenoids in the diet. Deficiency of other nutrients usually coexists.

Secondary vitamin A deficiency occurs due to intestinal malabsorption, liver diseases like cirrhosis and enhanced renal excretion.

Clinical features Earliest symptom is night blindness, followed by degenerative changes in the retina. The bulbar conjunctiva becomes dry, and rough greyish triangular foamy raised patches appear (Bitot's spots). A solution of 1% Rose Bengal instilled into the eye stains Bitot's

spots dark pink and makes them stand out prominently. Both night blindness and xerosis of the conjunctiva readily disappear on administering vitamin A. When the cornea also becomes dry and lusterless it is called xerophthalmia. More serious complications are keratomalacia involving the cornea with ulceration and necrosis. These changes follow if xerophthalmia is left untreated. Keratomalacia is more common in children aged 1-5 years. It leads to perforation, prolapse of the iris, and endophthalmitis leading to blindness. Skin changes include dryness and hyperkeratosis. A variety of infantile hydrocephalus has been attributed to vitamin A deficiency.

Vitamin A deficiency should be suspected in all malnourished children. Normal serum level of vitamin A is 20 μg/dL. Serum levels less than 10 μg/dL are indicative of deficiency.

Several secondary benefits are attributable to proper Vitamin A nutritional status. Epidemiological studies report increased mortality due to diarrhea and measles in children who are deficient in Vitamin A.

Treatment A mixed diet with adequate amount of protein is recommended. Vitamin A may be administered orally as retinol, 30 mg (9,000-10,000 IU) for 3 days. In more advanced cases retinol acetate or palmitate may be intramuscularly in a dose of 5000-10,000 units. The corneal lesions clear up within 48-72 hours. The vitamin preparation in a dose of 8-10 mg/day should be given for a month and thereafter maintenance dose of 1.5 mg/day should be continued regularly. Patients with ocular complications should be referred to the ophthalmologist.

Prevention The diet should contain at least 100 g of green vegetables and adequate amounts of animal products. Occurrence of vitamin A deficiency in 5% or more of the population calls for mass treatment. In poor communities 60 mg retinol palmitate or acetate administered orally once in 6 months or 300,000 IU once a year under supervision has been found to be extremely useful. Vitamin A deficiency occurring during pregnancy and lactation leads to poor vitamin A stores in the fetus and low vitamin A content of breast milk. These can be prevented by adequate supplementation during pregnancy.

Treatment schedule for xerophthalmia for all age-group-children.

Time schedule	Vitamin A dosage
Immediately on diagnosis	
6 months of age	50,000 IU
6-12 months	1,00,000 IU
12 months	2,00,000 IU
Next day and two weeks later	Same doses to be repeated

High dose universal distribution schedule for prevention of vitamin A deficiency.

Age	Vitamin A dosage
Infants < 6 months	50,000 IU/orally
Infants 6-12 months	100,000 IU/oral once in 4-6 months
Children >12 months	200,000 IU/orally once in 4-6/months
Mothers	200,000 IU orally within 8 weeks of delivery

Overdosage of carotene Excessive intake of carotene containing foods, principally carrots, leads to hypercarotenemia. It is a cosmetic problem due to yellowish pigmentation of skin. The serum is yellow but sclera is white. The pigmentation disappears with the elimination of excessive carotene from the diet. Hypothyroid patients are very susceptible to hypercarotenemia. Hypercarotenemia does not lead on to hypervitaminosis A.

Vitamin A toxicity This may be due to self-medication or large scale ingestion of livers of fish or polar bear having enormous quantities of vitamin A.

Acute toxicity Symptoms include abdominal pain, nausea, vomiting, headache, and desquamation of the skin. Recovery occurs spontaneously on removing the source of the vitamin from the diet.

Chronic toxicity This is seen in people who take 40,000 units or more of vitamin A daily for a prolonged period. It is characterized by bodyaches, arthralgia, hair loss, anorexia, benign intracranial hypertension, weight loss and hepatomegaly. Chronic overdose of Vitamin A may be associated with osteoporosis and increased incidence of hip fractures, have been reported in Scandinavian countries.

Clinical diagnosis can be confirmed by demonstrating raised vitamin A concentration in the serum and normal retinol binding protein. Withdrawal of the vitamin from the diet brings about prompt relief.

Vitamin D

Syn. Calciferol

Vitamin D is required for normal metabolism of calcium and phosphorus and for bone formation. It enhances the absorption of these minerals from the gut, their mobilization from bone and the reabsorption of phosphorus by the kidney. Vitamin D₁ is the essential precursor for 1-25 alpha dihydroxy vitamin D₁ which is the steroid hormone required for the development of bone, growth in children, maintenance of bone mass in adults and also for the retardation of osteoporosis and prevention of fractures in the elderly.

The two different forms of vitamin D active in man are vitamin D (calciferol) obtained by ultraviolet irradiation of ergosterol (also called ergocalciferol or

provitamin D₂) which is of plant origin, and vitamin D₃ (cholecalciferol) which is formed by activation of 7-dehydrocholesterol present in the epidermal cells of human skin as a provitamin D₂. This activation is effected by the ultraviolet rays ranging in wavelength from 296 to 310 Å obtained from sunlight naturally. Exposure to sunlight for 20-30 minutes daily ensures adequate supply of Vitamin D. Excessive exposure does not lead to overdose of the vitamin. Skin damaged by burns will not be capable of producing Vitamin D on exposure to sunlight.

Vitamin D₂ is obtained from the diet and vitamin D₃ is formed endogenously. On an average the endogenous source supplies about 80% and diet about 20% of the total requirement. Vitamin D₂ and D₃ which are identical in potency, differ only in the configuration of the side chain. Vitamin D₃, though formed in the skin is also absorbed through the small intestine. Further metabolism of vitamin D₂ and D₃ is identical and these together are referred to as vitamin D.

In the liver vitamin D undergoes its first metabolic change, being hydroxylated to 25-hydroxy vitamin D (25-OH D) which is the major component in circulation. In the plasma the vitamin remains bound to a protein called vitamin D-binding protein. In the proximal convoluted tubule of the kidney several metabolic changes occur, and the most active end product 1,25-dihydroxy vitamin D₂ (1,25-(OH)₂D) is formed, which is about 1000 times more active than the parent substance. The enzyme 25 hydroxyvitamin D₃ 1-alpha hydroxylase present in the kidney is the key enzyme regulating the formation of the active product.

Vitamin D supply depends on the amount of exposure to sunlight and the dietary intake. Conversion of vitamin D to 25-hydroxy vitamin D is not rate controlled and therefore the circulating level of 25-OH D indicates the amount of vitamin available to the body. On the other hand conversion of 25-OHD to 1,25-(OH)₂D is rate-controlled by several factors such as serum phosphate levels, concentration of parathormone and levels of other hormones such as prolactin and sex hormones. Fall in the serum phosphate levels and rise in parathormone stimulate the formation of 1,25-(OH)₂D. Vitamin D and its metabolites are all conjugated to form glucuronides and sulphates in the liver during enterohepatic circulation. Since vitamin D is itself biologically inactive and have to be converted into active metabolites in the system, it is often referred to as a pro-hormone.

Biological actions of vitamin D metabolites:

1. Increase the absorption of calcium and phosphate from the small intestine by promoting active transport.
2. Increase mobilization of calcium from bone by promoting osteoclastic activity.
3. Stimulation of reabsorption of calcium and phosphate at the renal tubules.

The overall result of all these processes is to increase serum calcium and phosphate. Deficiency of vitamin D results in impairment of mineralization of bone leading to nutritional rickets in children and osteomalacia in adults.

Dietary sources of vitamin D are milk, butter, cheese, egg yolk and fish liver oils. This vitamin is heat stable. One international unit (IU) is equivalent to 0.025 µg. The daily requirement varies depending on the age.

Daily requirement	
Infants and children	400 IU
Age 19-50 years	200 IU
51-70 years	400 IU
71 and above years	600 IU

RICKETS

Prevalence Rickets is prevalent in India, more so in the north than in the south. Premature babies are more vulnerable. The disease is more florid during winter months when exposure to sunlight is minimal. Prevalence is more among the poor and illiterate classes. Indians who have emigrated to affluent countries still show a higher prevalence of rickets. Osteomalacia is more common in multiparous women who have nursed their babies repeatedly. Rickets has been ranked among the most frequent childhood diseases affecting children in the developing world. There is evidence that dietary deficiency of calcium may also lead to rickets.

In rickets, the arrangement and normal regenerative processes of cartilage are abnormal. Subsequent calcification of the cartilaginous matrix and osteoid do not proceed normally. The osteoid and cartilage which remain uncalcified are deposited irregularly. These give rise to a wide irregular frayed zone of non-calcified cartilage and osteoid termed rachitic metaphysis. These in turn account for many of the skeletal deformities. In the subperiosteal region also, while resorption of cortical bone continues normally, new bone is not laid down, resulting in softening and rarefaction of the bone shaft.

In vitamin D deficiency, since absorption of calcium and, phosphorus from the gut is defective, serum calcium and phosphorus levels fall. Lowered level of serum calcium stimulates the secretion of parathyroid hormone which in turn, leads to mobilization of calcium from the bone. Thus, the serum calcium is usually maintained normal for considerable periods, tetany developing only rarely. Since parathyroid hormone (PTH) decreases reabsorption of phosphorus by the renal tubule, the serum phosphorus falls. The serum alkaline-phosphatase is elevated due to increased osteoblastic activity.

CLINICAL FEATURES

Early manifestations These include irritability, flabbiness of muscles, prominence of abdomen and delay in the appearance of milestones, except speech.

Skeletal manifestations These are the most characteristic features. They develop several months after the deficiency is established. The bones which have the maximum rate of growth at the time of onset of the deficiency show gross abnormalities.

In children below the age of 1 year the lesion is cranio-tabes, characterized by abnormal softening of the skull in the occipital region. In children aged 2 years or more epiphyses of the wrists and ankles are widened and costochondral junctions are enlarged and beaded.

In advanced rickets, deformities of bones are aggravated because of muscular action, gravity and weight bearing.

Head Craniotabes disappears by 1 year of age, but the excess of osteoid and non-calcified cartilage gives rise to frontal and parietal bossing giving the skull a ‘hot cross bun’ appearance. Due to softening of the skull bones the calvarium is asymmetric. The head may be larger in size and closure of the anterior fontanelle may be delayed. The teeth erupt late; show defective enamel, and are more susceptible to develop caries. Permanent teeth also show grooving, pitting and hypoplastic enamel.

Rib-cage Costochondral junctions are thickened (rachitic rosary) and the sternum projects forwards (pigeon chest deformity). A horizontal groove (Harrison’s sulcus) develops along the diaphragmatic attachment due to muscular pull of the diaphragm on the softened bone.

Spine This shows kyphosis and scoliosis when the baby starts sitting and later lordosis in the erect posture.

Pelvis In lordotic subjects the pelvis shows a corresponding deformity. The pelvis is small and deformed (triradiate pelvis), and in female subjects the obstruction caused to the pelvic outlet gives rise to dystocia during parturition.

Extremities The femur, tibia and fibula bend producing deformities like knock knees, coxa vara, etc. The thickened epiphyseal ends may be more prominent. Deformities of upper limbs develop if rickets sets in when the infant is crawling. Long bones may develop green stick fractures and pseudofractures. The sum total of bony deformities of the spine, pelvis, and legs leads to rachitic dwarfism.

Other general manifestations include hepatosplenomegaly, tetany, laryngismus stridulus, convulsions and frequent respiratory infections.

Diagnosis Rickets should be suspected in any child showing deformities of skull, long bones and ribs and in those with apathy, flabbiness, delayed milestones of development, laryngismus stridulus or convulsions.

The clinical diagnosis is supported by the history of inadequate vitamin D in the diet or chronic diarrhea interfering with absorption of vitamin D, and it is confirmed by radiological investigations and biochemical tests.

X-ray findings in active rickets Routine skiagrams of the wrists give clues in diagnosis and are helpful for following the progress. The distal ends of radius and ulna appear concave (cupping), widened (flaring) and irregular (fraying). The distance between the distal ends of the ulna and the radius and the metacarpal bones is apparently increased since the uncalcified rachitic metaphyses is translucent to X-ray. Shafts of long bones show decreased density and prominent trabeculations. Subperiosteal osteoid may give a double contour to the shaft.

With treatment, the lesions tend to heal. A line of preparatory calcification (LPC) appears. This is separated from the distal end of the shaft by a zone of translucency caused by the uncalcified osteoid. As healing progresses, the osteoid becomes calcified and shaft apparently grows towards the LPC and unites with it.

Measurement of serum 25 hydroxy vitamin D gives a reliable indication of the adequacy of the nutritional status. Normal values are above 15 ng/mL. Values below 8 mg/mL indicate severe deficiency.

Biochemical changes In florid cases the serum phosphorus is low (1.5-3.5 mg/dL) Serum calcium may usually be normal, but in advanced cases it is reduced especially in cases with tetany. Serum alkaline phosphatase is raised to 20-60 KA units/dL (Normal 5-15). With correction of the lesion alkaline phosphatase level falls and serum phosphorus level goes up.

Normal serum vitamin D levels range from 35 ± 3.5 ng/mL (80 nmol/L) and $1,25(\text{OH})_2\text{D}$ is 35 ± 3 pg/mL. In active rickets these levels are lowered.

Prognosis for growth and cosmetic recovery is excellent if the condition is recognized early and treated before deformities develop. Intercurrent infections make the prognosis worse. If treatment is started after the bony deformities are established and the epiphyses are ossified, the deformities tend to persist.

Treatment Oral administration of vitamin D in doses of 1500-5000 IU daily brings about rapid improvement in the vast majority of cases. Radiological improvement will be demonstrable in 2-4 weeks. A single dose of 600,000 units is preferable for advanced cases. The dose may be given orally or as in intramuscular injection. An oily preparation is available for intramuscular injection which is effective for 3 months. Three to four injections are given at intervals of two weeks. Parenteral administration is mandatory in cases showing malabsorption. If there is no improvement even after two parenteral doses of vitamin D, the case is considered to be resistant to vitamin D.

After complete healing of the lesion vitamin D should be given in doses of 400 units daily for preventing recurrence. **Children should be encouraged to get exposure to sun for 20-30 minutes daily.** Early bone lesions will be corrected with simple medical treatment. If treatment is started late and deformities are permanent, orthopedic correction is indicated.

Vitamin D-resistant rickets This may be acquired, as in chronic renal failure or inherited as in congenital enzyme defects.

In chronic renal failure conversion of 25-OH D_3 into the active metabolite $1,25(\text{OH})_2\text{D}_3$ becomes defective due to the progressive deficiency of the enzyme in the renal tubules. Such patients develop features of rickets (renal rickets) forming part of renal bone diseases.

Inherited forms of rickets Pseudo-vitamin D deficiency: Two types are known. Rickets develop early in life. Hypotonia, weakness, seizures and growth failure develop.

Vitamin D dependent rickets type I This is an autosomal recessive trait in which the gene for expressing the renal enzyme 25 hydroxy vit D_3 1-alpha hydroxylase is defective, and so this enzyme level is low or absent. Plasma levels of $25(\text{OH})\text{D}_3$ are normal, but $1,25(\text{OH})_2\text{D}_3$ are low. The gene is located on chromosomes X 12 q 13.3.

Vitamin D dependent rickets type II Two forms exist. In one form, the gene for vitamin D receptor is mutated. Hypocalcemic rickets develops. In the second form, also known as X-linked hypophosphatemic vitamin D resistant rickets the phosphate regulating gene (PEX gene) with homology to endopeptidases on the X chromosome is defective. All these forms respond to $1,25(\text{OH})_2$ vitamin D.

OSTEOMALACIA

Definition Osteomalacia denotes those disorders where mineralization of newly formed bone matrix (osteoid) is defective.

Etiology Osteomalacia may be of two different types:

1. Nutritional inadequacy of vitamin D, calcium or both.
2. Vitamin D-resistant osteomalacia. The latter occurs in the following conditions.
 - a. In renal tubular defects which produce hypophosphatemia and chronic metabolic acidosis.
 - b. Chronic administration of diphenylhydantoin which leads to excessive metabolism of vitamin D.
 - c. Osteoporosis.
 - d. After parathyroidectomy for osteitis fibrosa or hyperthyroidism in which rapid formation of new bone outstrips bone resorption.

Clinical features Osteomalacia presents with vague pain which starts as aches and pains insidiously, in the lumbar

spine and thighs and spreading later to the arms and ribs. The pain is frequently felt over the bones themselves, and not at the joints. The pain is usually symmetrical and non-radiating and is accompanied by tenderness of involved bones. Proximal muscles are weak and there is difficulty in climbing up stairs and getting up from squatting position. Occasionally, localized acute bone pain develops rapidly. These sites correspond to the development of pseudofractures. Classical radicular pain may develop due to compression fracture of the vertebra.

Physical signs include deformities, which may be missed if not specifically looked for. The usual deformities are triradiate pelvis and spinal kyphosis (due to action of gravity). Pathologic fractures due to weight bearing and avulsion of tendinous attachments may develop. Biochemical features resemble those of rickets.

Characteristic radiological features are the appearance of “pseudofractures” (Milkman’s lines and Loser’s zones). These are linear zones of decalcification which tend to be symmetrical and extend perpendicular to the cortex. The common sites are the pubic rami, ischium, the neck of the femur, the outer edge of the scapula, ribs and vertebrae. Occasionally, Loser’s zones may extend right across a long bone simulating complete fractures. They are called pseudofractures because the gap is bridged by uncalcified osteoid tissue. They do not reveal any discontinuity of bone clinically. The pseudofractures are caused by the decalcification along the course of the major arteries entering the bones especially in areas of muscular attachment, namely the adductor insertion in the pubic ramus and attachment of gluteal muscles to the trochanters of the femur.

Vertebral bodies show compression and widening of intervertebral spaces to produce biconcave or “cod-fish” vertebrae.

However, in patients who develop osteomalacia secondary to renal tubular disorders or chronic renal failure, there is marked cortical thickening and increased density of trabeculae in spongy bone. The reason for this hyperostosis is not clear. Despite the radiological appearances the bone is abnormally brittle and prone to develop fractures.

Treatment Nutritional osteomalacia responds well to daily administration of 2000-4000 IU of vitamin D (0.05-0.1 mg) for 6-12 weeks followed by maintenance doses of 400-600 IU daily.

Dietary supplementation of calcium in the form of milk 500 mL per day hastens recovery. Medicinal calcium in the form of calcium gluconate, lactate or carbonate can be given as tablets or suspensions orally in doses of 250 to 500 mg daily. Supplementation has to be continued as long as the diet is deficient in calcium.

Adequate supplements of calcium are provided in the form of milk 500-750 mL per day or calcium lactate tablets 1 g along with food.

HYPERVITAMINOSIS D

Prolonged administration of massive doses of vitamin D results in vitamin D intoxication. This causes hypercalcemia. Symptoms include nausea, vomiting, constipation, drowsiness, and signs of renal impairment. Metastatic calcification occurs in several tissues including the kidneys, lungs, gastric mucosa and blood vessels. Renal function may deteriorate before other signs of toxicity are manifest. Subjects receiving high doses of vitamin D should have regular monitoring of serum calcium and if it is above 2.6 mmol/liter (10.5 mg/dL), the intake of the vitamin should be stopped.

Vitamin E

Syn: Anti-sterility Vitamin

Vitamin E is a tocopherol. Among the tocopherols alpha tocopherol is the most easily absorbed and biologically most active compound. All vegetable oils, wheat-germ, cotton seeds, egg yolk, butter and peas contain this vitamin and the average Indian diet contains the daily requirement which is 15 IU or 5 mg. Vitamin E which is a strong antioxidant prevents the peroxidation of cellular and subcellular membrane phospholipids. It is probably involved in preserving the integrity of cell membranes. In cattle and poultry, vitamin E deficiency may lead to infertility. Nutritional deficiency of vitamin E is rare. Excess of free fatty acids in the diet increases the requirement for vitamin E. In premature infants fed on artificial diets containing iron and high concentrations of fatty acids, conditioned deficiency may develop, leading to the production of hemolytic anemia.

In doses of 400-800 mg, vitamin E acts as an effective antioxidant, thereby retarding the development of atheromatous changes in arteries.

Vitamin K

Syn: Coagulation Vitamin

This vitamin which is chemically a substituted naphthoquinone is present in adequate amounts in vegetable oils and green leafy vegetables as vitamin K₁ (phytomenadione). Vitamin K comprises of several molecular forms that have a common 2-methyl-1, 4-naphthoquinone ring, but different side chains at the 3-position. In green leafy vegetables and legumes and vegetable oils such as rapeseed oil and soyabean oil vitamin K occurs as phyloquinone (old name K₁). Bacteria synthesize vitamin K which is named menaquinone (MK-n) which occurs in several molecular forms. Milk is a poor source. The colonic bacteria synthesize this vitamin (Vitamin K₂) and this supplements the dietary source. Naturally occurring vitamin K is fat soluble. The synthetic form of this vitamin is vitamin K₃.

which is water-soluble. This can be given intramuscularly or intravenously, unlike the oily preparations which can be given only intramuscularly. Daily requirement is not clearly known, but is probably 1 µg/kg body weight. Body sources are limited and, therefore, signs of deficiency develop within 3 to 4 weeks of dietary deprivation.

Oxidative phosphorylation processes which take place in cellular mitochondria require the presence of vitamin K. Vitamin K occurs in large amounts in liver and bone. In the liver it takes part in the synthesis of precursors for coagulation factors, protein C and protein S. Vitamin K-dependent coagulation factors (factors II, VII, IX and X) are produced in the inactive form by the liver, and vitamin K is required for their biological activation. The inhibitors of coagulation—Protein C and Protein S are also produced in the liver and these are also vitamin K dependent. Coumarins inhibit the enzyme vitamin K epoxide reductase and thereby inhibit further actions of Vitamin K.

Prothrombin (factor II) is synthesized in the liver as an inert precursor, termed *protein induced by vitamin K absence (PIVKA)*. This is carboxylated to form prothrombin by the vitamin K dependent enzyme—*gamma carboxylase*. In the absence of vitamin K or after administration of vitamin K antagonists such as coumarin PIVKA appears in the plasma.

Vitamin K is needed for the formation of several proteins concerned with calcium homeostasis. Vitamin K promotes the conversion of protein-bound glutamate residues to gamma-carboxy glutamate (Gla). Proteins containing Gla are present in several tissues such as bone, kidneys, placenta, pancreas, spleen and lungs.

Vitamin K also takes part in bone metabolism—both bone formation and resorption. *Two of the important Vitamin K dependent proteins are osteocalcin and matrix Gla protein.*

Vitamin K Deficiency

Vitamin K deficiency occurs in conditions associated with malabsorption of fat such as obstructive jaundice and mal-

absorption states. Prolonged treatment with broad spectrum antibiotics destroys the colonic bacteria which synthesize this vitamin. Deficiency manifests as mild or severe bleeding tendency occurring from injection sites, mucous membranes, and skin. Injections of vitamin K in doses of 5-10 mg corrects the defect, if hepatic parenchymal function is normal. In the presence of hepatic failure, vitamin K may not be effective.

HEMORRHAGIC DISEASE OF THE NEWBORN

Hemorrhage may develop in newborn infants occasionally. Prematurity predisposes to this condition. Vitamin K deficiency in the mother and anticoagulant medication aggravate this disorder. Hemorrhagic tendency develops on the second or third day of delivery. This is due to exaggeration of the physiological hypoprothrombinemia which develops before the colon is colonized by bacteria. A dose of 1 mg of vitamin K₁ given intramuscularly to the baby brings about relief. Synthetic vitamin K is also effective. Larger doses have to be avoided since these lead to hemolysis. Administration of 5-10 mg vitamin K to the mother in late pregnancy abolishes this risk in the newborn.

Anticoagulant therapy Use of coumarin drugs or warfarin leads to alteration in the synthesis of coagulation factors. As a result proteins antigenically similar to factors II, VII, IX and X are produced but they lack the procoagulant properties. Excess of anticoagulants leads to hemorrhagic tendency.

Bleeding occurs from injection sites, urinary tract, gastrointestinal tract and uterus. Intramuscular injection of 10 mg vitamin K is usually effective. When the bleeding tendency is severe, large intravenous doses (50-75 mg) may be required. For severe cases transfusion of fresh blood or vitamin K-dependent coagulation factors may also be necessary. See also Chapter 165.

Water Soluble Vitamins

K.V. Krishna Das

5

Chapter Summary

Thiamine	156
Riboflavin	157
Niacin	157
Pellagra	158
Pyridoxine	158
Pantothenic Acid	158
Biotin	159
Cyanocobalamin	159
Folic Acid	159
Ascorbic Acid and Scurvy	160

Thiamine**Syn: Vitamin B₁—Aneurine**

Thiamine plays an essential part in the metabolism of carbohydrates by acting as a coenzyme required for the decarboxylation of pyruvate to acetyl coenzyme A. It also takes part in other steps of the Krebs's tricarboxylic acid cycle. Cereals contain the vitamin, which is maximal subjacent to the bran. Thiamine content of rice is lost during milling and polishing. Parboiling allows the vitamin to penetrate the grain and conserves it to some extent. Other good sources of the vitamin are sprouting pulses, green leafy vegetables, liver, pork, and legumes. Part of the vitamin is lost by washing or discarding the water used for cooking. The daily requirement is 0.4 mg/1000 kcal, i.e. 1.2 mg/day. Requirement is partially influenced by the intake of carbohydrates.

Deficiency States

Pathology of deficiency In thiamine deficiency the cells cannot utilize glucose aerobically. Nervous system is affected first. Pyruvic and lactic acids accumulate and this leads to vasodilation. The myocardium shows loss of striation, vacuolation of fibers, fragmentation and edema. Cardiomyopathy, encephalopathy and peripheral neuropathy may develop. Sensory, motor and autonomic nerves show demyelination and degeneration.

Clinical features Cardiovascular involvement results in 'wet beriberi' and nervous system involvement results in 'dry beriberi' (see also Chapter 187).

Cardiovascular system Peripheral vasodilation leads to high output circulatory state, myocardial failure and retention of sodium and water leading to edema. The pulse is of high volume. The extremities are warm owing to vasodilation and tender owing to neuropathy. Acute fulminant cardiac failure may be rapidly fatal. *Wet beriberi* may occur in breastfed infants aged 2-8 months. The child presents with edema, oliguria and an aphonic cry. If not clinically suspected, this condition may be missed. Sudden death may occur.

Neurological involvement This manifests as symmetrical sensori-motor polyneuropathy with muscle wasting. Foot-drop and wrist-drop are common. Deep hyperaesthesia occurs and it manifests as calf tenderness.

Wernicke's encephalopathy This is an acute neurological manifestation which is more common in alcoholics. Pathological changes occur in the upper part of the mid-brain, hypothalamus and the walls of the third ventricle which show congestion and petechial hemorrhages, most marked in the mammillary bodies. The onset is sudden with vomiting, confusion, bilateral ophthalmoplegia, loss of consciousness, nystagmus, ataxia and psychological disturbances. Confusion proceeds to coma and death. Korsakoff's syndrome is characterized by retrograde amnesia, impaired ability to learn and confabulation. Wernicke's encephalopathy is associated with high mortality. Prompt administration of thiamine rapidly restores normalcy (see also Chapter 187).

Diagnosis of thiamine deficiency The condition has to be suspected clinically. It can be confirmed by demonstrating raised levels of blood pyruvate. Normal blood pyruvate is 62.5 to 125 mmol/liter and it may rise to 375 mmol/liter (3.3 mg/L). Measurement of erythrocyte transketolase activity, before and after the addition of thiamine pyrophosphate gives the most reliable diagnostic test.

Treatment: When beriberi is suspected or diagnosed, 50 mg thiamine should be given intramuscularly daily for several days. After controlling the acute symptoms 2.5-5 mg should be given orally as maintenance. Wet beriberi and Wernicke's encephalopathy have to be treated as medical emergencies. A dose of 25-100 mg of thiamine should be given intravenously to save life. Dramatic recovery with diuresis occurring within hours of injection confirms the diagnosis.

Infants with beriberi should be given 10 mg thiamine intramuscularly followed by oral doses. The mother also should be treated with oral doses of 10 mg twice daily for several days. Since polyneuropathy and Korsakoff's psychosis are more resistant to treatment, the vitamin has to be given for prolonged periods. Once neuropathy is established, residual paralysis persists even after therapy. Adverse side effects to thiamine include sensitization and anaphylactic shock.

Riboflavin

Syn: Vitamin B₂

Riboflavin is essentially required in all oxidation reduction reactions involving the coenzymes flavin mononucleotide and flavin adenine dinucleotide which take part in tissue oxidation and respiration. It is moderately heat resistant, but boiling in alkaline media or exposure to sunlight destroys this vitamin.

Good dietary sources include liver, meat, eggs, kidney, milk, other dairy products, green leafy vegetables, and sprouted cereals and pulses. Daily requirement is 0.60 mg/1000 kcal, i.e. a total of 1.5-2 mg.

1. **Signs of deficiency** Angulostomatitis, cheilosis, nasolabial seborrhea, and possibly vascularization of the cornea are the characteristic features. Angulostomatitis may also occur in deficiencies of niacin and folic acid. Mucosa of the lips appears red and denuded in cheilosis. On taking hot and spicy food there may be soreness. Vascularization of the cornea has been described in some surveys. In glossitis the mucosa over the tongue is red, swollen and painful (Fig. 31.1). This responds to riboflavin therapy. Some cases show lesions in the oral mucosa, eyes, and genitals (oculo-oro-genital syndrome) (Fig. 31.2). *The oculo-oro-genital syndrome* presents as blepharo-conjunctivitis, angular stomatitis, bright red atrophic tongue and dermatitis of the pubic region. This syndrome may occur in pyridoxine deficiency as well.
2. **Treatment** Riboflavin in a dose of 2-5 mg thrice a day cures the condition in a few days. The drug can be given orally as tablets or syrup or by injections. Treatment of oculo-oro-genital syndrome is to give riboflavin up to 100 mg/day and pyridoxine 150 mg/day. The lesions clear within 7-10 days.

Fig. 31.1: Glossitis and angulo stomatitis

Fig. 31.2: Angulo stomatitis

Niacin

Syn: Nicotinic Acid, Nicotinamide, Antipellagra Vitamin, Vitamin B₃

Nicotinic acid forms an integral part of nicotinamide adenine dinucleotide (NAD) and its phosphate (NADP) which act as coenzymes in the metabolic pathways of glucose and proteins. Nicotinic acid and nicotinamide have equal biological potency and are together referred to as niacin. Tryptophan is converted into niacin in the body, 60 mg of tryptophan giving rise to 1 mg niacin. Dietary sources include liver, pulses, whole cereals, fish, meat, groundnuts, milk, eggs, and to a smaller extent, vegetables. Coffee contains appreciable amounts of this vitamin. Rice and other cereals contain this vitamin, major portion of which is lost by milling. In maize niacin is present in an unabsorbable form 'niacytin'. Moreover, maize is poor in its content of tryptophan. One-fourth of

the vitamin may be lost in washing and cooking, though cooking alone does not destroy it. Daily requirement is 6 mg/1000 kcals (15-18 mg/day). Deficiency of niacin causes pellagra.

PELLAGRA

This disease was widely prevalent in India among the maize eating communities in all states, especially Andhra Pradesh, Tamil Nadu and Rajasthan. Consumption of sorghum or jowar also predisposes to this tendency. Newer varieties of maize and sorghum with better nutritive value have helped to reduce the incidence of pellagra. Alcoholism and malabsorption states precipitate pellagra. Inborn disorders of metabolism such as Hartnup disease in which the absorption of tryptophan is impaired lead to pellagra in rare cases.

Pathology Dermatitis, changes in the oral and intestinal mucosa and degenerative changes in the central nervous system are seen. Ulcers may develop in the intestines. Chromatolysis of ganglion cells occur in the central nervous system. Patchy demyelination occurs in the spinal cord.

Clinical features Generalized malnutrition is evident in most cases. The most well-known features are the three Ds—dermatitis, diarrhea and dementia, but these characterize the very advanced stage of the disease. Pellagra should be diagnosed much before this classical picture develops, since the advanced stage is associated with high mortality.

Skin changes These are seen over areas exposed to sunlight. These start with erythema which may resemble sunburn. This progresses to vesiculation, ulceration, secondary infection, and crusting. In chronic pellagra the skin becomes rough, thickened, scaly and pigmented. In home-bound patients not exposed to the sun, pellagra may develop without the skin changes—“*Pellagra sine pellagra*”.

Mucous membrane changes are evident in the mouth and vulva. Skin of the perianal region shows degenerative and inflammatory lesions. The tongue is raw and beefy in appearance. Angulostomatitis may be present.

Alimentary symptoms Vague alimentary symptoms like anorexia, nausea, vomiting, and dyspepsia are invariably seen. Diarrhea is common but not always present. The stools may be watery or rarely dysenteric.

Neurological features Anxiety, depression, irritability and failure to concentrate are early symptoms. Advanced cases show delirium, dementia and psychiatric manifestation. Mental symptoms may be mistaken for primary psychiatric disorders.

Course and prognosis Advanced cases are fatal due to diarrhea, secondary infections, or other associated

nutritional disorders. Early treatment reverses the symptoms completely.

Treatment Well-balanced diet containing adequate supply of proteins should be instituted. Nicotinamide is well absorbed if given orally. It is given in a dose of 100 mg every 6 h for 2-3 weeks. In the advanced cases 50-100 mg may be given intramuscularly or intravenously. Supplements such as the other B complex vitamins and iron should be concurrently administered. Local application of antihistamine creams and protective clothing gives relief to the skin lesions.

Prevention In maize eating communities other sources of niacin should be provided along with. In non-endemic areas pellagra may develop in the elderly, inmates of mental homes, etc. Such groups require vitamin supplementation.

Pyridoxine

The active form of this vitamin is pyridoxal. Pyridoxal phosphate acts as a coenzyme in several reactions, especially in the metabolism of amino acids and biological amines such as catecholamines and 5-hydroxytryptamine. It takes part in the biosynthesis of gamma-amino-butyric acid in the brain. Yeast, liver, meat, whole grain cereals, peanuts, bananas and legumes are good dietary sources. Normal daily requirement is 1.25 mg and it is present in the ordinary Indian diets and hence nutritional deficiency is rare. Drugs like INH, oral contraceptives and hydralazine may interfere with the metabolism of this vitamin and produce conditioned deficiencies.

Clinical features include dermatitis, cheilosis, angulostomatitis, glossitis, dizziness, vomiting and peripheral neuropathy. Infantile convulsions have been attributed to nutritional pyridoxine deficiency. Pyridoxine deficiency is known to produce one form of sideroblastic anemia which responds to high doses of this vitamin. Concurrent administration of 6 mg of pyridoxine prevents the development of neuritis in subjects treated with INH (see also Chapter 187).

Pantothenic Acid

Pantothenic acid is converted to coenzyme A in the body. This vitamin is widely distributed in animal and vegetable foods and hence dietary deficiency is very rare. Though the exact requirement is not clearly known, 10 mg may represent an adequate daily intake. Deficiency in experimental animals leads to dermal and hair changes, neuromuscular degeneration and fatal adrenal hemorrhage.

Calcium pantothenate has been used for other conditions like paralytic ileus, and streptomycin toxicity based on empirical findings. There is no conclusive proof to support these claims.

Biotin

This is an organic acid functioning as a coenzyme in several carboxylation reactions. It is present in several articles of food and is also synthesized by intestinal bacteria. Daily requirement is about 100 mcg. Naturally occurring deficiency is rare, but conditioned deficiency may develop by overfeeding exclusively with white of egg. This is due to the presence of avidin which antagonizes biotin. Infants who are on parenteral feeding with biotin deficient diets may develop symptoms such as lassitude, irritability, paresthesiae, anorexia, rashes, and hair loss. All these improve with the administration of biotin.

Inherited disorders of biotin metabolism occur rarely. Two types are known. One type may present in the first few weeks of life with metabolic acidosis and a rash. The other presents in the first few months of life with rash, keratocconjunctivitis, alopecia, ataxia, hypotonia, and metabolic and lactic acidosis. Both groups respond dramatically to large doses of biotin.

Cyanocobalamin

Syn: Vitamin B₁₂

Deficiency of vitamin B₁₂ or folates leads to abnormality in DNA synthesis, characterized by megaloblastic erythropoiesis and similar changes in many tissues in the body. Due to its fatal outcome in pre-vitamin B₁₂ days, it was called pernicious anemia.

Absorption of B₁₂ The dietary vitamin B₁₂ which is bound to proteins has to be liberated from them to enable absorption. Cooking converts a part of these into dialysable form. Low pH achieved in the stomach helps further liberation of this vitamin. After liberation, cobalamin is bound to the intrinsic factor (IF) which is a glycoprotein with a molecular weight of 44,000 present in the gastric juice. Proteolytic enzymes of the pancreas play a part in this process.

The vitamin B₁₂-IF complex is taken up by receptor sites present in the microvilli of the ileum by passive absorption. In the plasma cyanocobalamin remains bound to a polypeptide of molecular weight 38,000 known as transcobalamin II (TC II). This complex passes into cells and its B₁₂ is liberated by lysosomal enzymes. Liver can store up to 2 mg of vitamin B₁₂ which is adequate for several years. The daily requirement of B₁₂ is 1-2 mcg. Meat, liver, eggs, dairy products, and yeast contain adequate amounts of this vitamin. Purely vegetable sources are deficient in vitamin B₁₂. Therefore, vegans (persons who do not take any form of animal foods or dairy products) suffer from nutritional deficiency. Normal levels of vitamin B₁₂ in serum ranges from 120-900 pg/mL in Indian subjects.

Vitamin B₁₂ deficiency is less common than folate deficiency.

Etiology of Vitamin B₁₂ Deficiency

1. Malabsorption states—diseases of the ileum.
2. Dietary inadequacy—vegans.
3. Intrinsic factor deficiency—pernicious anemia. This is usually acquired, rarely this may be congenital.
4. Chronic disorders destroying the gastric mucosa and partial or total gastrectomy.
5. Blind loop syndromes-with colonization of the small intestine by bacteria.
6. Pancreatic insufficiency.
7. Familial deficiency of transcobalamin II.
8. Inherited disorders of vitamin B₁₂ metabolism.
9. Interference with absorption of vitamin B₁₂ by drugs, e.g. PAS, colchicine, phenformin, neomycin.

Effects of B₁₂ Deficiency

Megaloblastic anemia develops owing to diminished red cell production and dyserythropoiesis. In addition, cells from other organs with rapid cell turnover such as the gastrointestinal tract and cervicovaginal mucosa also show similar abnormalities. The central nervous system and peripheral nerves are also affected. The neurological lesions include subacute combined degeneration of the spinal cord, optic neuritis, and demyelination of the cerebral white matter and peripheral nerves.

Neurological damage occurs due to impaired DNA synthesis and myelin formation (See also Chapter 187). The occurrence of neuropathy does not bear any direct relationship to the severity of anemia.

Treatment Dietary deficiency can be corrected by giving 1-2 µg of vitamin B₁₂ orally. If megaloblastic anemia has developed, larger doses are required (100 µg/day) oral, if absorption is reliable. Otherwise 1000 µg of hydroxocobalamin is given intramuscularly once a week for 3-4 weeks, and thereafter the daily dietary supplementation of 1-2 µg is continued.

There is evidence that vitamin B₁₂ can be absorbed from the buccal mucosa when applied sublingually. This route can be made use of for therapy in mild deficiency states.

Folic Acid

Syn: Pteroylglutamic Acid

Folic acid molecule consists of a pteridine ring, para-amino benzoic acid and l-glutamic acid. The free form does not occur commonly in nature. Foods and tissues contain several folate compounds (pteroylpolyglutamates). The main form present in human plasma and CSF is 5-methyltetrahydropteroyl monoglutamate. Rich dietary

sources are yeast, liver, nuts, green vegetables, and chocolate. Folic acid is lost by boiling the articles of food in a large volume of water. Average requirement is 200-300 µg/day. The vitamin is absorbed in the proximal small intestine after hydrolysis of polyglutamates. Human body can store about 6-10 mg, especially in the liver. Megaloblastic anemia has developed in volunteers after 10-20 weeks of dietary deprivation. Dietary deficiency is widely prevalent in India. It is seen most in pregnant women and children. A study conducted in Balrampur dist in UP, India by Anil Cheriyan et al 2002-2003 revealed neural tube defects in 6.57-8.2 children out of 1000 live birth. This figure is one of the highest in the world. The main reason was deficiency of folates, vit B₁₂ and other deficiencies such as Vit B₆ together or singly (The Lancet 2005. 366- 930-931).

Causes of Folate Deficiency

1. Dietary inadequacy of animal foods and green vegetables.
2. Malabsorption states.
3. Increased demands due to pregnancy, lactation, growth and intercurrent illnesses in children.
4. Alcohol intake increases folate requirements.
5. Accelerated erythropoiesis as in hemolytic anemia.
6. Other disorders like tuberculosis, rheumatoid disease, and malignancy increase folate requirements.
7. Several drugs interfere with the metabolism of folates, e.g., amethopterin, pyrimethamine, trimethoprim, hydantoins, oral contraceptives.
8. Folate losses may occur in several disorders of skin and the intestinal tract.
9. Inborn errors of metabolism may interfere with the utilization of folate.

Folate deficiency leads to megaloblastic anemia and similar changes in several rapidly proliferating tissues. In the body the metabolic pathways of folates and vitamin B₁₂ are closely interrelated. In many cases of nutritional anemias, combined deficiencies of iron, folate and to a smaller extent B₁₂ operate.

Normal serum folate levels are 4-10 ng/mL and red cell folate is above 100 ng/mL.

Folic acid deficiency occurring in the early period of gestation when the neural tube of the embryo develops, may result in the higher incidence of neural tube defects such as spina bifida and anencephaly. Supplementation of 400 mcg of folate starting from 28 days before and continuing for 28 days after conception reduce the risks of neural tube defects substantially.

Treatment: Dietary deficiency can be corrected by giving 5-10 mg of folic acid orally, in addition to the dietary improvement. Pregnant and lactating women, children and alcoholics require prophylactic supplementation. In poor communities routine folic acid supplementation in

pregnancy (1 mg/day) reduces the incidence of premature births. Premature infants should be given folate supplementation.

Folate and vitamin B₁₂ deficiencies are known to elevate serum homocysteine levels and this may lead to abnormal thrombotic tendency.

Ascorbic Acid and Scurvy

Syn: Antiscorbutic Vitamin—Vitamin C

James Lind, a Scottish naval physician, recognized the antiscorbutic properties of citrus fruits in 1753 and this was considered an important discovery with far-reaching effects.

Dietary sources Ascorbic acid is present in a wide variety of foods. In the process of cooking about 50% of vitamin C passes into water and 20% gets destroyed. Fresh fruits, green leafy vegetables and germinating pulses are rich in ascorbic acid. The Indian gooseberry and guavas are particularly rich sources. Animal food like milk and meat contain only small amounts of this vitamin. The vitamin is present in potato in the layer just below the skin. If the potatoes are boiled whole with the skin, the vitamin diffuses into the deeper layers.

The minimum daily requirement for an adult is 30-40 mg and for infants 5 mg per kg body weight. Normal plasma levels vary between 0.7 and 1.5 mg per dL. Leukocytes, platelets, and adrenal glands contain large amounts of vitamin C. Deficiency of vitamin C causes scurvy.

Physiological actions Vitamin C is a strong reducing agent. It takes part in biological oxidation-reduction reactions. Vitamin C is required for the formation of collagen by the hydroxylation of proline. It takes part in the formation of hemoglobin, erythrocyte maturation and the conversion of folic acid to tetrahydrofolate. Ascorbic acid reduces ferric iron to ferrous iron which is more easily absorbed. Body stores of ascorbic acid are small and, therefore, dietary deficiency leads to the development of scurvy.

SCURVY

Deficiency of vitamin C in the diet over a few weeks or months will lead to scurvy.

Clinical features of scurvy Classic scurvy is seen only infrequently in India since small amounts of vitamin C are obtained in vegetables and pickled berries which form essential items of the Indian diet. Cases do occur among inmates of mental homes, elderly persons and among the very poor.

Manifestations of scurvy vary in children and adults. Early symptoms include weakness, lassitude, and normocytic normochromic anemia. In infancy and

childhood subperiosteal hemorrhages occur, which lead to painful swellings over long bones. Scurvy in infancy produces pseudoparalysis owing to pain. This condition may mimic arthritis, osteomyelitis, or poliomyelitis. X-ray abnormalities may develop over the sternal ends of ribs and ends of long bones. Bleeding from the gums occurs commonly at the sites of erupted teeth. Retrobulbar, subarachnoid, and cerebral bleeding may develop in a few cases.

In adults early manifestation is follicular hyperkeratosis over the skin of the lower limbs. The lesions are papular with perifollicular hemorrhages which appear as purpura. Hemorrhage into the deep tissues of the thighs and legs cause tense induration ("woody leg"). Other sites of hemorrhage include joints, nail beds and viscera. The gums are hypertrophied and the interdental papillae are red and prominent (scurvy-buds). They bleed easily. Edentulous subjects do not get gingival abnormalities. The gum changes are aggravated by infection. The teeth become loose and may fall off. The hair assumes cork-screw shape since the follicles are obstructed by keratin

plugs. Wound healing is delayed and resistance to infection is reduced. The condition is fatal if untreated.

Treatment Scurvy is a potentially fatal disease and sudden death may occur unexpectedly. Treatment should be started without delay. In infants and children 25-50 mg of ascorbic acid given daily three times a day is sufficient to replete the body stores. In adults 500 mg is given daily in divided doses up to a total of 4 g. A diet rich in vitamin C should be given to prevent relapse.

Prevention Infant foods should contain fruit juices or vitamin C supplements. Children, convalescent subjects and elderly people who are liable to be neglected, should receive 25 mg of vitamin C daily. As an alternative, 500 mg may be given once a month.

Adverse effects of vitamin C Side effects like digestive upsets and hypoglycemia occur if the drug is given in doses exceeding 3 g/day. Oxaluria and oxalate stone formation in the urinary tract may result from prolonged overdosage.

32

Minerals

K.V. Krishna Das

Chapter Summary

Calcium 161
Phosphorus 162
Iron 163
Iodine 165
Fluorine 166
Copper 166
Magnesium 167
Zinc 167
Selenium 167

Fourteen elements are absolutely essential for normal body metabolism. These minerals are sodium, potassium, calcium, magnesium, iron, iodine, copper, zinc, cobalt, phosphorus, sulphur, chromium, selenium and fluorine.

Though several other elements are detectable in tissues, their role in nutrition is not clearly understood the term trace elements denote these elements whose concentration in biological fluids does not exceed 1 mcg/mL.

Calcium

(See also Chapter 72)

The total body content of calcium is 1200 g in an adult. This is present in the skeleton, teeth, plasma, and in all tissues. Of the total body calcium, 98% is present in the bones as calcium phosphate (hydroxyapatite) held in a protein matrix (osteoid). Calcium gives the strength and rigidity to the skeleton. In the plasma calcium is present as the free ions, albumin-bound form and as complexes which are diffusible. In health, serum calcium level ranges from 9-10.5 mg % (2.2-3.6 mmol/L). Calcium and phosphorus levels vary inversely with each other and the

product $\text{Ca} \times \text{P}$ is almost constant around 40. The normal function of cell membranes and the electrical activity of excitable tissues like the muscles, nerves, and heart depend upon ionized calcium. Calcium ions facilitate the release of acetylcholine from the vesicles in the motor end plates. Coagulation processes require small amounts of calcium.

The main sources of calcium is the diet. Milk, cheese, eggs, meat, peas, beans, certain leafy vegetables, dried fruits and nuts contain good amounts of calcium. Milk protein (casein) is the richest and most reliable source. One liter of milk contains about 1.2 g calcium. An egg contains about 30 mg of calcium. Drinking water may also contain a variable, but significant, amounts of calcium in many areas. Calcium from vegetable foods is not well absorbed since it is present as oxalate. In cereals calcium is found in the form of phytates which are not absorbed and hence excepting millets the cereals are poor sources.

Calcium is absorbed actively from jejunum and passively from the ileum. Intake of vitamin D, acidic pH and presence of proteins in the food favour absorption. In growing children, and pregnant and lactating women absorption is increased. In older age groups absorption falls. High fat diet, phytates, oxalates and alkaline pH impair calcium absorption. Normally 70-80% of ingested calcium is lost in feces unabsorbed. In steatorrhea calcium soaps are formed and excess calcium is lost in stool. Calcium is also lost in the urine.

Urinary calcium level depends on the blood levels. Normal adults excrete 300-400 mg calcium in 24 hours. Lowering of dietary calcium does not lower urinary calcium correspondingly. As a result, very low calcium intake results in negative balance. Lowering of serum calcium stimulates the secretion of parathyroid hormone which mobilizes calcium from bones. The metabolism of calcium is intimately related to those of vitamin D, parathyroid hormone and calcitonin (See also Chapter 99).

Recommended daily intake is 500 mg for adults, 1200 mg for pregnant and lactating women and 700 mg for adolescents. Postmenopausal women should have 500 mg of elemental calcium (available form 1250 mg of calcium carbonate or other calcium salts in suitable doses) as supplement to diet. Daily administration of 1000 mg of calcium carbonate with 400 units vitamin D_3 has shown to reduce hip fracture in post menopausal women. There was a slight increase in the incidence of urinary calculi.

Hypercalcemia leads to anorexia, nausea, vomiting, constipation, hypotonia, mental depression, lethargy, and coma. Persistent hypercalcemia leads to calcification around joints, ligaments, gastric mucosa, cornea, and kidneys. Hypercalcemia further depresses the renal function. Hypocalcemia leads to tetany.

Phosphorus

(See also Chapters 72 and 99)

Most of the phosphorus (85%) in the body is present in bones and teeth. In all tissues this element is present intracellularly as phosphates. The total body content of phosphorus is 800-900 g. In the plasma it occurs as inorganic orthophosphate at a concentration of 2.8-4.5 mg/dL (0.8-1.5 mmol/L). Around 88% of phosphorus is in ionic form and the rest is present in the protein-bound form. Phosphorus is widely distributed in dietary articles and hence dietary deficiency is rare. Though the exact requirement of phosphorus has not been determined, probably it is the same as calcium. Dairy products, eggs, cereals, and meat are rich sources.

About 80-90% of ingested phosphorus is absorbed. The serum level is controlled mainly by the renal excretory mechanism. Around 85% of filtered phosphate is absorbed at the proximal tubule and only 10-15% is lost in urine. Negative phosphate balance is usually caused by the abnormalities of renal clearance. In renal failure, serum phosphate goes up and in renal tubular dysfunctions it may fall. Aluminium hydroxide binds phosphates and makes it unabsorbable so that in prolonged antacid therapy, phosphorus absorption may suffer.

Facts about Phosphorus

85% in skeleton
15% in extracellular fluid and soft tissues
Normal diet supplies 800-1400 mg/day
Absorption from gut is passive. 60-80% absorbed.
 $1\text{-}25(\text{OH})_2\text{D}_3$ promotes absorption
Normal plasma levels 2.8-4.5 mg/dL or 0.89-1.44 mmol/L
Plasma levels are higher in children and they fall with age.

Hypophosphatemia

The serum level is below 2.5 mg/dL (u) 0.8 mmol/L.

Causes

- Redistribution between internal compartments*
e.g.: respiratory alkalosis, recovery from starvation, recovery stage of diabetic ketoacidosis, endocrinopathies, avid uptake of phosphorus by bone (hungry bone syndrome)
- Increased urinary losses*
e.g.: hyperparathyroidism, vitamin D deficiency, renal tubular defects, alcoholism, metabolic and respiratory acidosis. (See also Chapter 99).
- Diminished absorption*
e.g.: malabsorption states, fall in dietary phosphorus, vitamin D deficiency, antacid over use.

Manifestations include proximal myopathy, dysphagia, intestinal ileus, rhabdomyolysis, thrombocytopenia, respiratory muscle weakness and encephalopathy.

Management: If the serum phosphorus level is near about 0.32 mmol/L, oral supplementation with sodium or potassium phosphate in a dose of 2-3 g/day is sufficient. Cow's milk contains 1 mg phosphorus per mL. In an emergency sodium phosphate can be given I.V. as infusion in a dose of 2.5 mg/kg body weight over a period of 6 hours. Infusion of phosphate leads to fall in plasma calcium level.

Hyperphosphatemia

Plasma level of phosphorus exceeds 1.5 mmol/L.

Causes

- Increased exogenous load**
I.V. infusion, heavy oral intake, feeding cow's milk to premature babies, vitamin D overdose, abuse of phosphate-containing enemas, acute phosphorus poisoning.
- Increased endogenous production**
Tumor lysis syndrome, rhabdomyolysis, bowel infarction, hemolysis, malignant hyperthermia, lactic acidosis, diabetic ketoacidosis, respiratory acidosis.
- Reduction in urinary elimination**
Renal failure, hypoparathyroidism, acromegaly, vit. D intoxication, phosphonate therapy, magnesium deficiency.

Pseudo-hyperphosphatemia

This is the condition in which spuriously high blood levels are seen if colorimetry is adopted for estimation. This occurs in multiple myeloma, hypertriglyceridemia and if haemolysis occurs in the blood sample after collection.

Clinical features Acute hyperphosphatemia depresses plasma calcium levels and precipitates tetany. Chronic elevation of the $\text{Ca} \times \text{P}$ level above 70 leads to metastatic calcification.

Treatment Induce intestinal malabsorption of phosphate by administering phosphate binding salts of aluminium, magnesium or calcium. In the presence of renal failure, aluminium salts should be used with caution.

Iron

The total content of iron in healthy adults is 4.2 g. Of this, 58-66% is present in hemoglobin. Part of the iron is present in myoglobin which is present widely in cardiomyocytes and skeletal myofibrils. It is a small monomeric cytoplasmic tissue hemoglobin which facilitates the transport of oxygen from erythrocytes to the mitochondria to maintain oxidative phosphorylation for myocardial contractility. Neuroglobin is a tissue hemoglobin discovered in vertebrate brains. It is likely that it may function during hypoxemic episodes and protect against damage.

Iron also exists in combination with the iron storage proteins such as ferritin and hemosiderin, in the macrophages seen in the muscles, liver, and bone marrow. Stored iron is demonstrable by Prussian blue reaction histochemically. Stored iron available for erythropoiesis is about 1.2-2 g. Tissue iron is mainly present in enzymes. This amounts to 300 mg and is not available for erythropoiesis. Total plasma iron is 3-4 mg and the levels range from 80-120 µg/dL. Animal foods like meat, liver, kidney, fish, and egg yolk are rich in iron. Vegetable sources are green vegetables and fruits, onions, cereals, pulses, oil seeds, jaggery, raisins, grapes, apricots, and dates. The daily average intake of iron is 10-20 mg, out of which 1-2 mg is absorbed. Significant amounts of iron may be obtained from water sources and from iron cooking vessels (See also Chapters 148 and 149).

Absorption and further metabolism of dietary Iron

Iron is one of the most highly conserved elements in the body. Dietary iron occurs in two forms

- Heme iron found in hemoglobin and myoglobin, obtained from animal foods and
- Non-heme iron present in green vegetables, fruits and cereals. They are absorbed by different mechanisms. All forms of dietary iron are absorbed in the duodenum and upper jejunum where the contents are acidic.

Heme iron bound to proteins is released by acid and proteases in the stomach. Ferrous iron in the heme is oxidised to ferric iron and heme is converted to hemin which is absorbed as such without interaction with other dietary factors and without any regulatory mechanisms. The enterocytes – (lining cells of the small intestine) play a crucial role in iron absorption. Heme enters the enterocytes with the aid of heme receptors. It is degraded into free iron, bilirubin and carbon monoxide by the action of heme oxygenase.

Non-heme iron is present as green vegetables, fruits and cereals. Non-heme iron is released from food by the action of acid either in the ferrous or ferric state. Iron is absorbed only in the ionic state. In the alkaline pH of the duodenum ferric iron salts are insoluble whereas ferrous iron is soluble. Therefore most of the absorbed iron is in the ferrous form. Absorption of iron is influenced and moderated to a great extent by the availability of iron stores and the needs of the body.

Passage into the gut-epithelium and circulation

The enterocytes which line the epithelium of duodenum and upper jejunum play a major role.

Absorption occurs in 3 stages

- Entry of iron into the apical cell membrane

- Intracellular processing of the iron and transfer to the baso-lateral membrane
- Transfer of the requisite amount of iron through the basolateral membrane into the portal circulation

The enterocyte regulates the entry of iron into it and transport across it to the portal circulation. When enterocytes are shed after their life span of 2-3 days the iron contained within them are lost in feces.

Iron entering the enterocyte is either temporarily stored in the cell or transported across the basolateral membrane to the capillary network. The fate of the iron entering the enterocyte depends on the availability of body stores and the body's need for iron.

5

Factors participating in iron metabolism

Hemoglobin: Each molecule of hemoglobin has a central ferrous iron to which oxygen is loosely attached. Each molecule of hemoglobin contains 0.34% iron by weight (i.e.) 1 mL of packed erythrocytes contain 1 mg of iron. Major portion of the absorbed iron is used for the formation of hemoglobin.

Hemosiderin is the storage form of iron seen mainly in the monocyte-macrophage system. It is composed mainly of ferric hydroxide crystals which are deprived of their apoferritin coat. It contains 25-30% of iron by weight. It is demonstrable by Pearl's staining.

Ferritin

It is an alpha 2 globin which binds iron. It is a compound formed from apo ferritin and ferric hydroxide (FeOOH). It is a very efficient storage form of iron- Ferritin contain two types of monomers- the light (L-monomer) and the heavy (H-monomer). The L-monomer which is basic, binds very readily and tightly to iron. This property makes it suitable for storing iron. L-monomer-rich ferritin is seen mainly in the liver, spleen and serum. L-monomer is in excess of H-monomer.

H-monomer which is acidic takes up and releases iron readily. It is found in the heart, kidney, placenta, monocytes lymphocytes and erythrocytes. There are 20 isoforms of ferritin. Apart from its storage function, ferritin has a role in metal detoxification and diversion of excess iron. Unbound iron is toxic to tissues since it causes free-radical injury. The level of apoferritin in blood regulates the absorption of dietary iron.

Transferrin

Transferrin is the most dynamic part of the iron-metabolic chain. It is a glycoprotein which binds to ferric iron and can exist in monoferric or diferric forms. It is synthesized in the liver as apotransferrin. By combining with iron it becomes transferrin. Its rate of synthesis is inversely proportional to the iron stores.

Transferrin Receptor (TfR)

These are transmembrane glycoproteins which exist in two forms TfR1 and TfR2. They both bind to transferrin. TfR1 has high affinity, TfR 2 has only low affinity. TfR1 binds to plasma transferrin and delivers it to the erythroblasts. The TfR1- transferrin complex is internalized into the erythroblast via an endocytic vesicle. In the cell, the iron dissociates from the complex- the iron is delivered to the cytoplasm and the TfR1 goes back to the cell surface. All cells in the body have TfRs on their surface, but maximum number (80%) is on erythroblasts.

TfR2 which has low affinity to transferrin is seen mostly in hepatocytes and erythroid cells. It has also a role in regulating iron metabolism. Most tissues regulate their iron content by modulating TfR expression Truncated portions of TfR are shed into the circulation. These can be estimated using laboratory kits as serum transferrin receptor (sTfR). Concentration of sTfR is directly proportional to the rate of erythropoiesis. In iron deficiency anemia, sTfR levels are high, whereas they are low in anemia of chronic disease.

Mobiliferrin

This is a cytosolic protein that transports iron across the enterocytes and other cells in the body. It is also responsible for receiving iron from transferrin which transports iron in the plasma.

Ferroportin-1 and hephaestin

These are also transport proteins subserving iron transport across cells. Their functions are being studied further.

Hereditary Hemochromatosis Gene Product (HFE)

HFE binds transferrin receptor with an affinity equalling that of transferrin and competes with transferrin binding. HFE might facilitate the sensing of the need for iron absorption across the enterocyte. In hereditary hemochromatosis there is decrease in the amount of functional HFE protein.

Hepcidin

This is a newly identified iron regulator that appears to communicate the status of the body's iron stores and the demand for erythropoiesis to the enterocytes and thereby regulate iron absorption. Hepcidin levels are low in iron overload and high in iron deficiency.

The absorption and utilization of iron which are complex processes can be summarized as given below

- Absorption of ferrous iron through the apical membrane of the enterocyte; The rate of absorption

depends directly on the level of apoferritin in blood.

2. Transport across the enterocyte; The iron that is absorbed is either stored in the enterocyte or transported across the basolateral membrane to the circulation as an active process. The cells lining the intestinal crypts (base of the villi) act as sensors of the iron status of the body.
3. Transferrin transports the iron in ferric form in the circulation and delivers it to cells, with the aid of TfR
4. Most of the iron is utilized for heme synthesis in erythroblasts. Iron is also taken up by macrophages by the process of erythrophagocytosis. This iron in the macrophages does not re-enter the circulation.

Excretion of iron occurs through shedding of enterocytes, exfoliation of skin, sweat and urine. Loss of blood from the body contributes to the major source of blood loss.

Development of Iron Deficiency

The bioavailability of iron in the average Indian diet is low. Milk is a poor source of iron and hence babies fed solely on unfortified milk develop iron deficiency within 6 to 12 months. Iron from animal foods is absorbed better (11-22%) than that from vegetable sources (1-7%). Animal proteins and vitamin C enhance iron absorption, while phytates and phosphates retard it. Iron is absorbed from the duodenum and upper jejunum. Iron is lost in desquamated epithelial cells of the gastrointestinal tract, urinary tract and skin, and through the loss of nails and hair. Menstruation, pregnancy, parturition and lactation account for further losses in women who suffer from iron deficiency more than men. Dietary requirement is higher for women. Daily requirement is 10-20 mg for men and 30-40 mg for women. Infants require 1 mg/kg body weight.

Considerable periods elapse between the onset of iron deficiency and the clinical manifestations. Since large stores are present normally, clinical symptoms do not occur till the stores have been depleted. Pure nutritional deficiency manifests clinically only a few years after institution of a diet poor in iron. In actual practice, anemia manifests much sooner since in the vast majority of cases there is also concomitant blood loss.

In India about 20-40% of pregnant women show iron deficiency. Depletion of iron in the mother during pregnancy results in diminution of iron stores in the fetus. Premature infants have lower iron stores and are vulnerable to develop iron deficiency states.

Effects of iron deficiency Iron deficiency state manifests in different stages. The earliest stage is depletion of iron stores, during which time the condition is asymptomatic. The second stage is one of tissue iron deficiency. This

manifests as subtle disturbances of function of many organ systems.

At this stage, general symptoms such as fatigability, disinclination for work, poor mentation in children and diminished performance at school are common. Often these are overlooked and therefore many cases go on to more severe forms of iron deficiency. The third stage is one of iron deficiency anemia.

Microcytic hypochromic anemia occurs on account of diminished hemoglobin synthesis. Non-hematological manifestations include koilonychia, dysphagia, glossitis and rarely raised intracranial tension.

Iron deficiency is one of the most widespread nutritional disorders present all over the world.

Prevention of iron deficiency Vulnerable groups of persons require prophylactic iron supplementation. These include premature infants, persons after upper gastrointestinal tract surgery, pregnant and lactating women, and those with chronic blood loss.

At the community level, iron deficiency can be prevented by fortifying food with iron. Several articles like bread and infant foods have been fortified in many countries. The Indian Council of Medical Research has suggested fortification of cooking salt with iron. Initial field trials are encouraging.

Siderosis

Siderosis denotes excessive accumulation of iron which is seen in persons who have excessive inputs of iron over prolonged periods. The iron is deposited in the liver, which may undergo fibrosis. Excessive dietary intake occurs in South African Bantus who ingest about 100 mg of iron derived from iron cooking and brewing pots. Iron overload can occur in persons having thalassemia, sickle cell disease or aplastic anemia, who are repeatedly transfused with blood (usually more than 100 transfusions). Iron absorption is very high in hemochromatosis and thalassemia. Elimination of iron can be enhanced by chelating agents such as desferrioxamine.

Note: Refer to the topics Nutritional anemias (ch. 150), hemochromatosis (ch. 93) and thalassemias (ch. 151).

Iodine

Iodine is widespread in nature and it is obtained especially from sea water, salt, sea fish, vegetables, drinking water, and milk. The daily requirement is about 150-250 µg. Adolescents and adults require about 150 mcg iodine daily. For pregnant and lactating women the requirement goes up to 200 mcg/day. Calcium retards absorption of iodine.

Iodine is concentrated by the thyroid gland for the formation of thyroid hormones. Though the diets of the majority of Indians supply adequate amounts of iodine, the iodine content of diet and water is low over vast areas on the globe and iodine deficiency goiters are widespread. More than 400 million people are affected in Asia alone. In India such goiter belts occur in the foothills of the Himalayas, several parts of north India and midlands and highlands of Kerala. In man and animals chronic iodine deficiency produces characteristic responses. A wide spectrum of iodine deficiency disorders are seen.

The importance of widespread iodine deficiency has been brought out by recent work. Several developmental disorders are prevalent among goitrous communities. Iodine deficiency is the single most important and prevalent cause of preventable brain damage. During pregnancy the fetus does not produce thyroxine during the first trimester and it is entirely dependent on maternal thyroxine. During the subsequent two trimesters it derives thyroxine from its own thyroid, and it is supplemented by maternal thyroxine. In endemic iodine-deficient areas the maternal and fetal thyroid function is subnormal. In mild cases it leads to mental retardation in the child. In severe cases neurological consequences such as spasticity, ataxia and deaf-mutism also develop. Provision of iodine supplements to the mother even in the latter half of pregnancy allays the ill effects in fetus. There is increased total mortality, abortion rates and congenital malformations in the endemic regions—all of which clear up with supplemental iodine.

Goitrous Cretinism

Goitrous cretinism is common in iodine deficiency areas. The thyroid gland hypertrophies under the influence of increased levels TSH, and tries to trap more iodine. Iodine turnover is faster. The urinary loss of iodide is reduced. The cretinism take two forms (1) neurological and (2) myxedematous. Prevention of iodine deficiency disorders has been achieved to some extent in India and other countries by fortification of common salt with potassium iodide at the rate of 60 p pm. It is estimated that with the introduction of this program the global population at risk of iodine deficiency has come down from 28.9 to 13.7% during the years from 1994 to 1997. The aim is to give 150 mcg iodine daily.

Another intervention is to give an annual injection of iodized oil intramuscularly to susceptible population at risk. Poppy seed oil and rapeseed oil have been used as vehicles. **Brassidol** which is derived from rapeseed oil contains 376 mg/mL of iodine. Early goiters will also recede with iodine supplementations.

Iodine induced hyperthyroidism (IIH) syn: Jod Basedow phenomenon. This is caused by the increased proliferation of thyrocytes, and increase in the mutation rates of the cells. This leads to hyperthyroidism.

Other adverse effects include the development autonomous thyroid nodules and possibly autoimmune thyroiditis.

Despite minor adverse effects, iodine supplementation has served to reduce iodine-deficiency disorders, especially brain dysfunction in the young. Strong political lobbies working against the 'universal iodisation of salt' programme have resulted in slowing the progress in this direction (See also Chapter 98).

Fluorine

Fluorine is present in small amounts in human bones and teeth. Fluoride is obtained from drinking water, tea and sea fish. Water sources are more important. Daily requirement is 1 to 2 mg. Fluoride is deposited in the enamel of developing teeth. Once the teeth are fully developed, fluoride is not further incorporated. Low levels of fluoride in drinking water are associated with higher prevalence of dental caries. In many countries addition of 1 ppm fluoride to drinking water has served to reduce the incidence of dental caries. Such a legislation does not exist in India. On the other hand in many parts of India, drinking water contains higher amounts of fluoride and this leads to fluorosis. Increase in the content of fluoride in drinking water above 100-150 mg/L gives rise to acute toxic symptoms consisting of nausea, vomiting, diarrhea, abdominal pain and paresthesia. Death may occur at times.

Note: Refer Section—Fluorosis.

Copper

Copper is widespread in all foods and hence dietary deficiency of copper is very rare. Copper is necessary for the proper formation of hemoglobin and several enzymes. Young children fed solely on milk formulas may develop copper deficiency. The main features include anemia, neutropenia, retardation of growth and rarefaction of bones.

Daily requirement is 2-3 mg. Meat, liver, shellfish, nuts seeds, legumes and whole grains contain copper. Copper takes part in the synthesis of hemoglobin in association with iron. It is an integral part of several oxidative enzymes.

Absorption and Metabolism

Copper is absorbed in the upper part of the small intestine and is transported into the epithelial cells through the medium of a copper transporting protein. The copper is incorporated into the intracellular enzymes such as superoxide dismutase, cytochrome oxidase and others.

Excess copper is fixed to the Golgi apparatus and eliminated when the epithelial cell is shed.

Copper reaches the hepatocytes, bound to albumin. In the hepatocytes copper is bound to ceruloplasmin and in this bound form copper circulates in blood. Excess copper, unbound to ceruloplasmin is excreted by the hepatocytes into bile. Both these processes are facilitated by the copper transporting protein.

Normal ceruloplasmin level in blood is 20-40 mg/dL. It is low in Wilson's disease in which the production is normal, but its degradation is accelerated. In Wilson's disease the levels of plasma ceruloplasmin are below 20 mg/dL. Normal level of hepatic copper is below 55 µg/g of dry weight. In Wilson's disease the hepatic copper level may exceed 250 µg/g. Other conditions in which ceruloplasmin levels are low include nutritional hypoproteinemia, nephrotic syndrome, hepatic diseases and congenital ceruloplasmin deficiency. The major regulating mechanism in copper homeostasis is the excretion of excess into bile, which is 1-2 mg/day.

Nutritional deficiency of copper may occur in premature infants, generalized malnutrition, malabsorption states, and prolonged parenteral nutrition. Nutritional supplementation is by giving copper sulphate 2-3 mg tds orally.

Reduction or absence of ceruloplasmin is a genetic abnormality which leads to Wilson's disease. Wilson's disease is an autosomal recessive disorder.

Menkes' disease is an X-linked disease affecting the copper metabolism. It is characterized by features resembling Ehlers-Danlos syndrome. Serum ceruloplasmin is low. Clinical features include mental retardation, abnormalities in bone formation, lability of temperature regulation, susceptibility to develop infections, cutis laxa and tendency to develop vascular rupture. Death occurs in early life.

Note: Refer to Wilsons' diseases. Chapters 93, 191.

Magnesium

(See also Chapter 72)

This is the fourth most abundant cation in the body, next only to sodium, potassium and calcium. It is the second most prevalent intracellular cation. The importance of magnesium in health and disease has been brought out by recent studies.

- Total body content
1000 mmol (22.6 g)
- Distribution
50-60% in bone
The rest is intracellular in all tissues
- Extracellular part 1%
- Serum levels 0.75-0.95 mmol/L
(i.e.) 1.7-2.2. mg/dL
- Dietary intake 300-350 mg/day

Absorption from gut is by passive diffusion.

The total body content is determined by the balance between intestinal absorption and urinary loss. It is absorbed by a process of passive diffusion, which is a self limiting process. The rate of absorption is inversely proportional to the intake.

Dietary sources include a wide range of foods, especially cereals, animal foods and water.

Functions of Magnesium

1. Integral part of several enzymes participating in ATP and DNA metabolism
2. Stabilization of cell membranes
3. Neural transmission
4. Stabilizing calcium channel activity

Both hypo- and hypermagnesemia cause adverse effects. The former is more common. These are described in Section 7.

Zinc

Zinc is present in many enzymes. Highest concentration occurs in the liver, voluntary muscle, bone, prostate, and ocular structures. Foods such as meat, fish, peas and cereals contain zinc. Daily requirement is not clearly known, but is around 15 mg. Dietary deficiency is very rare. Zinc deficiency leads to impairment of maturation and immunodeficiency. In malnourished subjects zinc deficiency may result in thymic atrophy. A syndrome of dwarfism and hypogonadism seen in Egypt and Iran has been attributed to zinc deficiency. Oral zinc sulphate corrected this clinical picture. Acrodermatitis enteropathica is an inherited disorder resulting from the malabsorption of zinc, probably due to an enzymic defect. Administration of zinc sulphate 30-150 mg/day results in complete remission. Oral zinc sulphate 100 mg/day has been found to stimulate the growth of granulation tissue in chronic ulcers. Oral supplementation of zinc 10 mg (5 mg) in children less than 1 year of age for 16 months reduced overall all-cause mortality by 7%. This study is being pursued.

Ref: Sazawal S, et al. The Lancet 2007;369:927-34.

Selenium

Selenium is a constituent of selenoproteins. It has structural and enzyme roles and it acts as an important antioxidant. It is a catalyst for the production of thyroid hormone. Other functions include: (1) proper functioning of the immune system, (2) sperm motility, (3) maintenance of proper mood and mental state, (4) resistance against cancer. Selenium retards the progress of AIDS. Daily

requirement is 400-450 µg/day. Dietary sources includes Brazil nuts, kidney, crab, liver, shellfish, fish, meat, poultry, wheat and some vegetables. In animal foods selenium is present as selenocystine. In vegetable sources it occurs as selenomethionine.

Probiotics and Prebiotics

Micro-organisms especially bacteria can be used to improve health. A bacterium which confers specific health benefits in addition to nutritional improvement is known as probiotic. Yoghurt and butter milk are examples. They contain lactobacilli such as *L. rhamnosus*, *L. reuteri*, *L. casei* and others which help to stop diarrhea, especially after rotavirus infection. Prebiotics are non-digestible food ingredients which selectively affect the gut flora and

Chapter Summary

- General Considerations 168
- Clinical Features 169
- Treatment 171

General Considerations

Increase in body weight of 10-20% above the normal, caused by excess accumulation of fat is termed obesity. Healthy young men and women have a total body fat content below 20 and 25% respectively. When excess calories are supplied in any form, they are stored as fat. In addition to general appearance and weight, measurement of skin fold thickness over the biceps, triceps, subscapular and suprailiac regions is helpful in the assessment of obesity. The skin fold thickness over the triceps for normal Indian subjects is below 20 mm. The proportion of body fat can be assessed from the skin fold thickness using nomograms. Obesity has become the sixth common cause for disease burden world wide. Adipose tissue in the body, in addition to its role as a source of stored energy, is emerging as an endocrine organ producing hormone and cytokines. In general the ideal weight of an individual should be (height in cm minus 100) kg .For example an adult male 175 cm tall should have a weight of 75 kg ± 5%.

Body Mass Index (BMI)

Body weight is only a crude indicator of obesity. A more reliable parameter is the BMI.

TABLE 33.1

Shows the recommended values		
Weight class	global	Asians
Normal	18.5-24.5	18.5-22.9
Over weight	25-29.9	23 – 24.9
Obese	> 30	>25
Severely obese	> 40	

$$BMI = \frac{\text{(Weight in Kg)}}{\text{(height in m}^2\text{)}}$$
 For Asians separate norms have been proposed (Table 33.1)

About 10% of the population in India is obese. Small community-based surveys done in several parts of the country give figures ranging from 17-38% BMI above 28 is associated with higher incidence of strokes, ischemic heart disease and diabetes mellitus. The distribution of fat deposition in the body is also important. For this purpose the circumference at the waist and the hip are taken as reference measurements. Waist is measured after an overnight fast at the mid point between the lower costal margin and iliac crest. Hip is the widest part over the gluteal region. Waist hip ratio above 1.0 in men and above 0.9 in women is an independent risk factor for higher incidence of insulin resistance, hypertension, rise in LDL, lower levels of HDL, hyperuricemia, cardiovascular disease, type 2 diabetes and stroke. Ideal waist to hip ratio is below 0.85 in men and 0.75 in women. The waist circumference above 102 cm (40³) is an independent risk factor. Abdominal obesity with accumulation of fat in the abdominal viscera is more associated with metabolic complications. The waist/hip ratio shows a graded and

highly significant direct relationship with the risk for myocardial infarction.

Etiology

1. *Excessive consumption of food* accounts for the vast majority. Training in early childhood and social factors influence eating habits. Both in anxiety and depression, excessive eating may be resorted to. It is not uncommon to develop obesity after recent bereavement or change of job. An increase of 0.5% in food consumption above the optimal caloric intake can lead to an annual rise in weight of 1 kg. Pregnancy and contraceptive pills tend to predispose to obesity. Persons show strong genetic predisposition to obesity and the amount of food leading to obesity varies widely between subjects. Therefore prescription of dietary management has also to be individualized.
2. *Hormonal and other factors* Obesity may be part of the clinical pictures of well-known endocrine disorders such as type 2 diabetes, hypothyroidism, Cushing's syndrome, gigantism, acromegaly, insulinomas and others. In addition several hormones regulate appetite and modulate intake of food and fat accumulation. Insulin and cholecystokinin acting on the central nervous system retard the appetite regulating mechanism.
3. *Genetic factors* do play a role. Metabolically, some individuals are more efficient in conserving energy and thus they put on fat, while others require more energy for the same amount of work performed. Moreover, obesity may run in families.

The role of leptins There is strong evidence that body fat is biologically regulated. Most cases of obesity probably reflect a multigenetic predisposition for excess intake of food, low level of physical activity and accumulation of excess amounts of fat. Leptin encoded by the *Lcp* gene is a cytokine-like molecule synthesized and secreted by adipose tissue in proportion to adipose tissue mass. It has several biological effects, an important one being reduction of food intake. Leptin deficiency leads to hyperphagia, obesity, and several endocrine abnormalities such as infertility, diabetes, reduction in metabolism, impairment of somatic growth and elevated levels of glucocorticoids. Leptin deficiency and resistance to leptin may be genetically determined.

Several other hormones also influence food intake and body weight. A gut hormone fragment *peptide-Y3-36* (*pYY*) reduces appetite by acting on the appetite centers in the hypothalamus.

Ghrelin is a hormone primarily secreted by the stomach and duodenum. Plasma ghrelin levels are higher before meals and their levels fall after meals. Ghrelin has been implicated in causing hunger at meal

times and also the long-term maintenance of body weight.

Drugs

Several drugs lead to weight gain. Prominent among them are antipsychotics, anti depressants anticonvulsants, oral contraceptives, progestogens, oral hypoglycemic agents, insulin, corticosteroids, beta adrenergic blockers, antihistamines and others.

Childhood obesity occurring below 3 years of age without parental obesity is not a risk factor for obesity in adulthood. On the other hand obesity which persists beyond 6 years of age it is a predictor of adult obesity irrespective of the parental status. Presence of obesity in the parents doubles the risk.

4. *Physical activity* which causes loss of calories is closely related to obesity. Modern amenities such as automobiles and lifts which tend to minimize day-to-day physical exertion favour the development of obesity. Obesity is more evident when there is a sudden cessation of physical activity. Eating habits are also influenced by physical work. Moderate work is associated with optimal food intake whereas both physical inactivity and overexertion lead to overeating.
5. *Alcohol* being a good source of non-diet calories tends to aggravate obesity in the mild and moderate alcoholics. Cessation of smoking leads to recovery of appetite and gain in weight.

Pathology Obese subjects have increase of both fat and non-fat mass. In obesity developing from childhood, there is probably increase in the number of fat cells and a generalized increase in adipose tissue.

In others there is hypertrophy of the fat cells. Distribution of obesity may be android (abdomen and shoulder predominantly) or gynoid (buttocks, thighs, breasts, arm and face predominantly). Obesity leads to impairment of carbohydrate tolerance, elevation of cholesterol level in blood, and mild elevation of blood pressure.

It predisposes to premature atherosclerosis. Obesity is associated with an absolute increase in energy expenditure, lower respiratory quotient and insulin-resistance. Though obese subjects have to spend more energy for the same amount of work done by their normal counterparts, they tend to restrict their physical activity further and accumulate more fat.

CLINICAL FEATURES

Middle-aged persons are more affected though no age is immune. Women outnumber men and the male to female ratio is 1:5. Multiparity is associated with increasing grades of obesity. The patient may not complain of her obesity on account of its gradual development and, therefore, it has to be identified

during general examination. Common symptoms include exertional dyspnea, sluggishness, angina, arthralgias of knees and hips, or any of the complications.

Complications These develop invariably in all cases depending on the severity and duration of the disorder.

1. *Ill effects of increased weight:* Slowness of movement, proneness to falls and accidents, osteoarthritis of weight-bearing joints like knees, hips, and spine.
2. *Skin:* Abnormal skin folds develop and these give rise to fungal infection (moniliasis), recurrent bacterial infections, and chafing of the skin of the thighs and axillae. In extreme obesity, striae may develop.
3. *Cardiovascular system:* Atherosclerosis, hypercholesterolemia, angina, ischemic heart disease, hypertension, varicose veins, venous thrombosis, and recurrent embolism. Increase of 10% of weight above the ideal weight leads to 30% rise in the risk of heart disease.
4. *Respiratory system:* Exertional dyspnea, reduction in vital capacity due to restriction of diaphragmatic movements and the increased mechanical effort required to move the thoracic cage, recurrent bronchitis, and in extreme cases, respiratory failure. 'Pickwickian syndrome' is the condition where obesity is associated with central depression of respiration and somnolence. Sleep apnea and the related complications are more common in them (Figs 33.1 and 33.2).
5. *Abdomen:* The skin over the anterior abdominal wall hangs down as a fold ("abdominal apron"). Hernias develop owing to the increase in the intra-abdominal pressure. Gallbladder lesions are more common.

Fig. 33.1: Nutritional obesity boy 18

Fig. 33.2: Morbid obesity: Woman aged 50 years

6. *Metabolic complications:* Diabetes mellitus, hyperlipidemias, gout, and cholesterol gallstones are more common.
7. *Psychological abnormalities:* Obese persons may develop depression because of their unattractive physical appearance and mechanical disability. They tend to avoid company and become socially isolated.
8. There is evidence that cancer of the colon, breast, uterus, ovaries and prostate may be more common in the obese.

Course and prognosis The condition is gradual in its progress. Complications increase the mortality in them. Mortality rate is 30% higher in persons 25-30% overweight and 50% higher in persons 35-40% overweight. Death is caused by cardiovascular, metabolic or respiratory complications. Obesity is an independent risk factor for higher mortality.

DIAGNOSIS

Clinical diagnosis is based on weight, physical appearance and measurement of skin fold thickness. Sophisticated methods are available to establish the diagnosis in a borderline case. Dual energy X-ray absorptiometry (DEXA) imaging gives a reliable assessment of the adipose tissue mass.

Increase in weight occurring during pregnancy, fluid retention, hypothyroidism, hypothalamic lesions, and other endocrine disturbances should be differentiated from obesity due to nutritional causes. So also overweight may be caused by excessive muscular development in wrestlers, weight-lifters and boxers. Estimation of BMI, and the waist to hip ratio help to assess the risk of complications further. The aim of management is to reduce weight, achieve metabolic and physical fitness, reduce morbidity and achieve cosmetic results. A negative

TABLE 33.2

Subcaloric diet for obesity for adults with moderate activity. Total allowances for a day are given				
Article of food	Vegetarian	Cal.	Non-vegetarian	Cal.
Cereals	150 g	600	150 g	600
Dal or lentils	50 g	200	20 g	80
Fish or lean meat not cooked in oil or fats	—	—	100 g	250
Milk or curd in any form	300 mL	180	100 mL	60
Green vegetables	150 g	80	150 g	80
Fruits: very sweet fruits like grapes, and mangoes, are to be avoided. Papaya, melon, small bananas, guava, and apples, are preferable	150 g	80	150 g	80
Total Calories		1140		1150
Note: 1. Sugar, sweets, honey and similar high-caloric articles of food and alcohol are to be strictly avoided. 2. Timing of the diet and the menu should be adjusted to conform to the occupation and dietary habits of the individual. 3. When the optimum weight reduction has been achieved, graded increases in the diet can be made under supervision, taking care not to restore the original weight and to ensure balanced nutrition.				

balance of 8000-9000 calories has to be achieved to clear 1 kg of adipose tissue.

Treatment

Dietary Regulation

Strong motivation of the patient is absolutely essential for successful management. Dietary regulation is the basis of modern therapy. Calorie intake should be reduced below the basal requirements and the patient has to be kept on negative energy balance over prolonged periods of time. The excess fat is catabolized and weight is lost.

The therapeutic diet should contain 500-1000 Cals less than the energy expenditure of the individual. An ideal weight reducing diet should be:

1. Deficient in calories
2. Otherwise nutritionally adequate, and
3. Acceptable socio-culturally.
4. The diet should be suitably timed to avoid long intervals between eating (Table 33.2).

Since dietary fats account for the palatability of food and they provide the maximum amount of calories the first step should be to cut fat intake to the maximum. This is the most effective single step to bring down weight rapidly in the initial stages. Young and tall subjects lose weight more efficiently than older and shorter people. On an average, daily intake has to be limited to 800-1000 calories. More drastic cuts on foods are frequently resented and result in non-compliance. For optimal results the diet should be acceptable, sufficient in volume and conforming to the general eating habits of the individual.

Bulk is provided by adding moderate amounts of fresh vegetables (not curried) and low-calorie fruits. Vegetables when made into curries with coconut, oil, dhal and condiments become very rich in calories. Clear instructions on the exact quantity of food and its timing are very essential. Regular follow-up is necessary for proper motivation and assessment. Patients put on the sub-calorie diets lose weight steadily after an initial latent period ranging from days to weeks. It is ideal to reduce the weight by 1 kg a week. Vitamin and mineral supplementation is advisable, since the restricted diet may fail to meet these requirements.

Obese persons do not generally comply with diets. The low caloric diet should be maintained indefinitely since the tendency to regain weight persists. Strong motivation of the patient is needed to achieve good results. Initial motivation to reduce weight may be easy, but persistent efforts to maintain the ideal weight are generally slackened and so a major proportion of patients regain their weight and may even overshoot the original levels. Even moderate reduction in weight such as 6-10% of the body weight is accompanied by reduction in metabolic risks and blood pressure.

Exercise Moderate exercise augments the beneficial effect of dieting. Walking slowly up to 4-5 km, day, swimming, or games are ideal, depending upon individual preferences. Prescription of the exercise regime should take into account the cardiovascular status and exercise tolerance of the patient. Preferably it should be supervised by trained staff.

Drugs Several drugs are available which reduce appetite. These anorectic drugs have been employed on short-term basis when the patient is not able to resist the desire to eat. Drugs may be needed when the BMI exceeds 30. Sympathomimetic drugs with amphetamine-like action reduce appetite and increase energy expenditure. These are contraindicated in persons with cardiovascular disease. Serotonin reuptake inhibitors are good appetite suppressants. Fenfluramine and fenoxetone can be given on a short-term basis over weeks to a few months. When given over prolonged periods they may lead to the development of primary pulmonary hypertension. Acquired defects of the mitral and aortic valves may also develop. Dose Fenfluramine 20-120 mg twice a day given orally one hour before meals. Since these drugs cause dependence, they should preferably be withdrawn after 3 months of administration. Side effects include dryness of the mouth, abdominal pain, drowsiness, alopecia, mental depression, confusion and impotence. These drugs are contraindicated in patients with psychiatric illness.

Sibutramine is an appetite suppressant which can be given in doses of 5-15 mg once a day. It produces loss of weight by reducing appetite and increasing energy expenditure. Side effects include dryness of mouth insomnia and constipation. Sibutramine should not be given to patients with ischemic heart disease heart failure, arrhythmia and stroke. Sibutramine leads to a mean weight loss of 4-5 kg.

Orlistat: It is a lipase inhibitor which prevents absorption of dietary fat. The dose is 120 mg t.i.d.

Side effects include flatulence, fecal urgency, and malabsorption of fat soluble vitamins. Orlistat leads to a mean weight loss of 3 kg.

Rimonabant is an endocannabinoid receptor antagonist. The dose is 20 mg given orally daily. It reduces body weight on an average of 4-5 kg. It improves the metabolic syndrome as well. Adverse effects include nausea dizziness, diarrhea and depression. When obesity is extreme and rapid weight reduction is desired, more

drastic measures are employed. These include total starvation programmes and surgical procedures.

Total starvation This can be undertaken under strict medical supervision for 2-3 weeks. Only water, salts and vitamins are allowed during this period. Complications include starvation ketosis, ventricular arrhythmias and sudden death. Due to these risks, total starvation should be undertaken only under exceptional circumstances. Wiring of the jaw to prevent ingestion of solid foods has been practised on persons unable to undertake starvation. Rapid weight loss is achieved by total starvation. Follow-up treatment consists of sub-caloric feeding.

Surgical measures Surgical measures done to produce short-circuiting of digestive and absorptive portions of the intestines may be required for severe cases. The procedures include jejuno-ileal bypass and gastric bypass. Gastric plication may be done with a view to reduce the capacity of the stomach. Extirpation of excessive fat and plastic surgical procedures to remove redundant skin folds remaining after achieving weight loss help to correct cosmetic disability and also to augment the effects of dietary treatment. Liposuction is a surgical technique which removes large amounts of fat from localized areas such as the abdomen, gluteal regions, breasts, arms and face. This procedure is gaining popularity, being safe and cosmetically rewarding. The surgical management of obesity, as a part of cosmetic surgery is known as *bariatric surgery*.

In general, loss of weight up to 5-10 kg is easy but further reduction and maintenance of the optimal weight demand great motivation on the part of the patient and skill on the part of the physician. Once the optimum weight is reached, the patient should slowly increase the diet to prevent further weight loss, and try to adhere to the optimum weight. Even an occasional dietary excess results in rapid weight gain. All the complications of obesity can be arrested and may even regress if normal weight is maintained for long periods. Secondary obesity should be treated by adopting dietary measures and giving due attention to the primary cause.

INTRODUCTION

Microbes are abundant in nature, the vast majority of them harmless to man and many of them essential to life. They are mostly commensals and a few are pathogens. The organisms capable of establishing themselves and multiplying in hosts are called parasites, which may be commensals or pathogens. All our body surfaces have an indigenous bacterial flora. This normal flora protects us from infection by multiple mechanisms 1, compete with pathogens in utilizing nutrients. 2, producing antibacterial substances inhibiting growth of pathogens. 3, inducing host immunity that is cross reactive and effective against pathogens (Table 34.1).

Pathogens lead to adverse effects on hosts while commensals cause no harm to their hosts and exist in harmony. Commensals may cause disease when host resistance is lost or when transferred to an inappropriate site, e.g. oropharyngeal commensals aspirated into lung.

TABLE 34.1

Gives the approximate bacterial count in the human body

Skin general	10 ³ /g
Skin groin/axilla	10 ⁶ /g
Bile, liver	nil
Stomach	10 ³ /mL
Small intestine	10 ⁴ /mL
Large intestine	10 ¹⁰ /mL
Lungs	nil
Nasal secretions	10 ⁵ /mL
Saliva	10 ⁸ /mL
Urine	10 ³ /mL

Infection: Infection is defined as multiplication of microbes in the tissues of the host with or without producing disease. Infections without disease manifestations are called subclinical infections.

Infections remain one of the main causes of morbidity and mortality in man worldwide. Poverty and overcrowding in the underdeveloped countries increase this burden.

Infectious agents include bacteria, viruses, fungi, protozoa, helminths and prions.

Types of Infections

1. *Exogenous infections:* Infection from external source.
2. *Endogenous infection:* Infection by organisms harbored by the individual.
3. *Primary infection:* Initial infection of a host by an organism.
4. *Secondary infection:* Host suffering from an infectious disease invaded by another organism.
5. *Re-infection:* Subsequent infection by same organism.
6. *Focal infection:* Infections confined to one area/organ e.g. Tonsillitis.
7. *Nosocomial infection:* Infection acquired after admission to hospital.
8. *Super infection:* Patient receiving broad spectrum antibiotics get colonized by resistant pathogens and infection produced by them.
9. *Opportunistic infection:* Organisms that ordinarily do not cause infection in healthy individuals but do so in individuals with markedly reduced resistance (Immunocompromised hosts).
10. *Latent infection:* Pathogen remains in the tissue without producing disease but may lead to disease when host resistance is lowered.

Source of infection: Infection may be obtained from human, animal or other sources. When the source of infection is man, the infectious agent may originate from patients or carriers.

A carrier who harbours the pathogenic organism without developing any disease due to it, is called *healthy carrier*.

A **convalescent carrier** is one who harbours the organism for some period after recovering from the disease.

Zoonoses are infections transmitted from wild or domestic animals to man e.g. plague, rabies.

Some infections are transmitted by insect vectors e.g. Anopheles mosquito transmits malaria.

Direct contact is necessary for transmission of organism like *Staphylococci*. Respiratory diseases such as influenza, tuberculosis, pneumonia and others spread by air-borne droplets. Food or Water borne transmission occurs in typhoid, hepatitis A and E, cholera and others. Sexual transmission is the main route for syphilis, gonorrhea and HIV. *Vertical transmission* i.e. from mother to fetus occurs in diseases like rubella and syphilis.

PATHOGENESIS

The pathological lesions, symptoms and signs may be produced by several mechanisms:

1. Caused by the organism directly e.g. Boils, abscesses, pneumonia, dysentery, tuberculosis.
2. Organisms like *C. diphtheriae* and *Cl. tetani* multiply locally without entering the system and elaborate toxins (exotoxins) which are absorbed into the system producing the manifestations.
3. *Vibrio cholerae* elaborates an exotoxin having local effect on the intestinal mucosa producing secretory diarrhea.
4. Many gram negative bacteria produce endotoxins by disintegration in the tissues producing direct effect on tissues and liberation of chemical mediators of inflammation like cytokines which are mainly responsible for the manifestations.
5. Activation of immunological mechanism is one of the most important pathogenic mechanisms of tissue damage in several infections.
6. Infections like HIV and syphilis suppress the immune mechanism of the host by acting upon the lymphocytes.
7. Some infectious agents are oncogenic i.e. giving rise to tumours- e.g. HIV, EB virus, hepatitis B and others. Medical care itself increases the patient's risk of acquiring infection in several ways:
 1. Contact with pathogens in the hospital.
 2. Breach of skin (e.g. incisions, IV devices) or mucous membranes (e.g. endotracheal tube, indwelling catheter).
 3. Alteration of normal flora by antibiotics.
 4. Reduction of immunity by immunosuppressive drugs.

The body's mechanisms to prevent and overcome the infections are local defenses, phagocytic cells, antibodies (immunoglobulins), immunocytes and nonspecific defense aids such as lysozymes, complement and properdin.

Changing scenario of infection worldwide: The pattern of infectious agents and pathogenesis are changing due to several factors such as changes in environment, influence of polymicrobial therapy and alterations in host defences.

Newly recognized infections are AIDS, severe acute respiratory distress syndrome (SARS), avian influenza and others.

Rebound of diseases like, malaria, tuberculosis, rheumatic fever and others thought to have been eradicated from developed countries.

Recognition of role of infectious agents in the causation of diseases previously thought to be non-infectious e.g. *Helicobacter pylori* in the causation of peptic ulcer, *Human papilloma virus* in carcinoma cervix.

Human Polymicrobial Infections

In the immunocompetent state, colonization by one organism inhibits colonization by another. This is known as microbial interference e.g. *S. pneumonia* and *S. aureus*.

At present, due to the prevalence of different kinds of immunosuppressed states, polymicrobial disease caused by combination of viruses, bacteria, fungi and parasites are being recognized. In this situation, presence of one micro-organism causes a niche for the other pathogen to colonize and thrive e.g. measles, tuberculosis and *S. aureus*; EB virus and retrovirus; HBV and HIV; HIV and tuberculosis.

Immunodeficiency states may be congenital or acquired. The latter include malnutrition, extremes of age, loss of surface epithelium, diabetes mellitus, cancer, cancer chemotherapy, chronic renal failure, chronic hepatic failure, immunosuppressant drugs, HIV infection and others. The resultant degree of immune suppression is the total effect of all the contributory factors.

Immunodeficiency may be general or specific towards specific pathogens. Neutropenia and reduction of other phagocyte cells predispose to infection by extra cellular bacterial pathogens, both endogenous and exogenous. Suppression of T-cell mediated immunity predisposes to viral infections. Multiple intubations, hospitalization and management in intensive care facilities predispose to infections.

Clinical features of infection in the immunocompromised host differ from those in immunocompetent hosts. Signs of infection in the immunocompromised hosts include:

1. confusion
2. faint erythematous rashes
3. lymphangiectatic streaks on the skin
4. pleurisy dyspnoea or cough with clear chest X-ray
5. minimal erythema with serosanguineous discharge at sites of insertion of catheters, surgical sites, abscess or drains

Diseases Caused by Infections

- 6. minimally elevated values of liver function tests, and serum levels of LDH (lactic dehydrogenase) and C K (Creatine kinase) and
- 7. unexplained rise or fall of leukocytes and platelet counts.

Antimicrobial resistance: As we developed newer antimicrobial drugs, microbes developed the ability to elude our best weapon. Antibiotic resistance is developing at an alarming rate. Multidrug resistant pathogens such as *E. coli*, *Klebsiella*, *Pseudomonas*, *Staph. aureus*, *M. tuberculosis*, HIV, and others are extremely common. Especially in the ICUs these get disseminated.

Biotorrism: Use of biological infectious agents such as anthrax spores, plague, small pox and others may be resorted to as potential weapons for stealthy warfare.

Eradication of infectious diseases like smallpox totally from the world and polio from most countries has been achieved.

General Symptomatology

Fever

Fever is perhaps the most common manifestation of ill health due to infection. It is an early and non-specific body response to many infectious and non-infectious causes. In humans, metabolic processes are critically temperature dependent. In a healthy individual, body temperature is kept constant around 37°C within a very small range despite larger difference in surrounding temperature.

Normal Temperature

In healthy individuals, normal body temperature varies from 36.6 to 37.2°C, usually 98.4°F (36.9°C). The normal diurnal variation is approximately 1°F with maximum between 4. 00 pm and 8.00 pm and minimum between 2.00 am and 6.00 am. In fever this variation is exaggerated. In old age, body temperature may be lower due to low metabolic rate. Women in the reproductive period show elevation of body temperature 24 to 48 hours after ovulation due to increased progesterone level. Temperature may also increase after exercise if normal heat loss is prevented.

Recording of Temperature

In all conscious, co-operative adults and older children oral temperature is ideal for clinical use. Equilibrium time with mercury- in -glass thermometer is a minimum of 90 seconds. Axillary temperatures are less reliable since they are considerably altered by environmental factors. On an average axillary temperature is 0.3 to 0.6°C (0. 5 to 1°F) less than oral temperature. Temperature of the inner tissues and viscera (core temperature) is about 0.6°C (1°F) higher

than oral temperature. Rectal temperature represents the core temperature. Rectal temperature has to be used in unconscious patients, undergoing intensive care and during major surgery.

Definitions

Normal temperature	37°C (98.4°F)
Fever	>37.2°C
Hyperpyrexia	>41.5°C
Subnormal temperature	< 36.6°C
Hypothermia	< 34.4°C
Note: 1°C = 1.8°F	0°C corresponds to 32°F
C-centigrade	F- Fahrenheit
also called Celsius	

Regulation of Body Temperature

Temperature is regulated by thermoregulatory center in the hypothalamus, which receives information from cold and warm receptors of peripheral nerves and temperature of blood perfusing the area. Heat is produced by metabolic process and muscular activity. Normal heat production by metabolic processes is in excess than is necessary to maintain body temperature and the same is dissipated by heat loss through lungs and skin. Rapid rise in temperature is effected by increasing metabolism, rapid muscle contractions (rigor) and conserving heat by peripheral vasoconstriction. Heat loss by radiation convection and conduction from the surface is slow. Rapid loss of heat is achieved by evaporation of sweat. Presence of cold extremities and rigor preced rapid rise of temperature. Diaphoresis (excessive sweating) accompanies rapid fall of temperature.

Fever is defined as the elevation of body temperature above normal (37°C). This occurs as a result of increase in hypothalamic “set point” for temperature. Once hypothalamic set point is raised neurones in the vasomotor center are stimulated leading to peripheral vasoconstriction especially in the limbs, leading to decrease in heat loss from the skin. The person feels cold. Metabolic processes being slow, they elevate body temperature only gradually, but steadily. If there is need for rapid increase in temperature, shivering occurs. Due to vigorous muscle contraction with rapid heat production temperature rises sharply. When hypothalamic set point is re-set downwards (either by reduction in pyrogen concentration or by antipyretics) heat loss occurs by vasodilatation and sweating. Exposure of the body to the environment, leads to dissipation of heat.

In the vast majority of febrile states, temperature does not exceed 104 to 105°F (40°C).

Hyperpyrexia

This denotes temperatures above 41.5°C (107°F). This may complicate conditions such as malaria, septicemia

heat stroke, pontine hemorrhage and others. The term hyperthermia is at times used synonymously with hyperpyrexia but in general the former denotes elevation of body temperature caused by endogenous heat production combined with exposure to high environmental temperature: e.g. work or exercise in a hot environment, over insulating clothing, thyrotoxic crisis, heat stroke and neuroleptic malignant syndrome produced by drugs like phenothiazines. Uncontrolled increase in heat production far in excess of the body's ability to dissipate heat leads to hyperpyrexia.

Once the body temperature rises above 41°C, the thermoregulatory mechanism fails and the body behaves like poikilothermic organism. Unless managed as an emergency to lower the temperature, hyperpyrexia is fatal due to damage to vital cells.

Pathogenesis of Fever

Pyrogens are substances causing fever. These may be exogenous or endogenous. Exogenous pyrogens are molecules which interact with host cells to induce secretion of pyrogenic cytokines. Most of these are microbial products, microbial toxins or whole micro-organisms. The best example is the lipopolysaccharide endotoxin found in the cell wall of gram-negative bacteria. Enterotoxin of *S. aureus* and Group A and B streptococci are other examples. Endogenous pyrogens are cytokines which are small molecular weight proteins most important being interleukin.1 (IL-1), IL-2 and tumour necrosis factor alpha (TNF α). The synthesis and release of pyrogenic cytokines are induced by a wide spectrum of exogenous pyrogens most of which are of bacterial, fungal or viral origin. In addition, inflammation, trauma, tissue necrosis and antigen-antibody complexes induce production of pyrogenic cytokines. Main source of pyrogenic cytokines are monocytes and macrophages, and to a lesser extent neutrophils and lymphocytes.

Pyrogenic cytokines stimulate production of the prostaglandin – PGE₂ from arachidonic acid near the hypothalamic thermoregulatory centre. Arachidonic acid is released from cell membrane by the enzyme – Phospholipase A2. PGE₂ raises the set point in the thermoregulatory center. Pyrogenic cytokines also induce production of PGE₂ in the periphery which is responsible for myalgia, arthralgia and malaise that accompany fever.

Fever as a Defense Adaptation

There is suggestive evidence that, for some microorganisms at least, a febrile host response may assist in curtailing infection and speedy recovery. Experimental data support the notion that raised body temperature interferes with growth and / or virulence factors of some bacterial and viral pathogens. Fever, slightly increases

immune reaction and increases chemotactic, phagocytic and bactericidal activity of polymorphonuclear leukocytes. In immunocompromised individuals and those at the extremes of age, a prompt febrile response may not develop even in the presence of severe infection. Such persons are at greater risk of succumbing to the infection.

Systemic Responses in Fever

- **Increase in metabolic rate** - Oxygen consumption increases by 13% for each 1°C rise of temperature. Hence fever may aggravate or precipitate pre-existing cardiac, cerebrovascular or pulmonary insufficiency.
- **Increase in heart rate.** For every 1°C rise of temperature above normal, the heart rate increases by 18/minute. In some fevers like pneumonia and rheumatic fever, heart rate may be disproportionately high (*rapid pulse fever*). In typhoid, some viral infections, meningitis, brucellosis, drug induced fever and many cases of leptospirosis; pulse rate may be disproportionately slow (*slow pulse fever*).
- **Blood pressure** may increase during the period of rise of temperature because of vasoconstriction and decrease during the period of defervescence because of vasodilation.
- **Fluid loss increases** due to evaporation and sweating—average of 360 mL excess fluid is required for 24 hours for 1°C rise in temperature.
- **Increase in respiratory rate** occurs with fever. The usual ratio of 1:4 with heart rate is maintained except in the case of primary respiratory diseases such as pneumonia and pleural effusion.
- **Chills occur** in the initial phase because of peripheral vasoconstriction.
- **Rigors** accompany rapid increase in temperature. They are due to vigorous muscle contractions. Repeated occurrence of rigor is most typically seen in malaria, filariasis, urinary tract infections, and abscess formation anywhere in the body. Rigor may occur in many types of continuous fever treated intermittently with antipyretics. When the effect of the drug wanes off rigor occurs in an attempt on the part of the body to resume the high temperature.
- When the high temperature falls to normal or subnormal within a few hours, it is called **Fall by Crisis**, and when the temperature reaches normal slowly over several days, it is called **Fall by Lysis**.
- **Headache** may accompany any type of fever but severe headache and photophobia are characteristic prominent features of intracranial infections and sinusitis.
- **Delirium** – This is toxic confusional state. It is more common in the very young and very old. Fever may induce mental changes in those with organic brain syndrome. The cytokines TNF α and IL-1 cause release

of endorphins in the brain and may precipitate delirium.

- **Excessive sweating** is the regular accompaniment of defervescence. Particular patterns of sweating like “night sweats” are characteristic of tuberculosis and lymphoma. In almost all fevers fall of temperature is accompanied by sweating.
- **Muscle pain** – (*myalgia*) is characteristic of infections such as influenza, enterovirus, dengue fever, leptospirosis and others.
- **Herpes labialis** - Fever may activate the latent viral infection *Herpes simplex* which causes vesicles at muco-cutaneous junctions of the nose and lips. Pneumonia and meningitis are common to produce Herpes labialis whereas typhoid is very rare to do so.
- **Feverishness**: This is a subjective feeling of fever which may be experienced even without rise in temperature. Feverishness has not got the same pathological importance of fever. Therefore it is essential to record the temperature to distinguish between the two conditions.

Approach to a Patient with Fever

In the diagnosis of the cause of fever, science and art of Medicine come together. History is most important. History of travel to a malaria - endemic area may give a clue. Presence of nasal symptoms and sore throat suggest viral etiology. Severe myalgia may suggest Influenza, Dengue fever or Leptospirosis. Eye congestion, sub-conjunctival hemorrhage and muscle tenderness may suggest leptospirosis. Skin rashes and mucous membrane lesions give diagnostic clue. Erythematous blanching rash indicates viral exanthematous fever as the most likely cause. Palatal petechiae along with posterior cervical lymphadenopathy and grey white tonsillar exudate suggests infectious mononucleosis. Enlarged tender tonsillar lymph nodes with tonsillar exudate and neutrophilic leukocytosis suggest streptococcal tonsillitis. *Koplik's spots* in the buccal mucosa indicate measles. Dysuria and loin pain with tenderness suggests pyelonephritis.

Duration of Fever: This is an important point which helps in clinical diagnosis. Regular recording of temperature, pulse rate and respiration rate are routinely done in all hospitals. Fever of more than 5 to 7 days with gastro intestinal symptoms with or without malena and just palpable soft spleen may suggest typhoid fever. Onset may be abrupt in infections like pneumonia or may show a step-ladder type of rise in typhoid. Fever with clubbing of fingers and splinter hemorrhages in the nail bed in a patient with congenital or rheumatic valvular heart disease should suggest infective endocarditis.

Patterns of Fever: Recording the pattern of temperature is an important clinical clue to diagnosis. In the ordinary febrile patient, temperature is recorded thrice daily, but in special cases where large fluctuations occur and in acute care settings temperature has to be recorded more frequently.

Continuous Fever (Fig. 34.1) Temperature is persistently elevated with diurnal variation of less than 1°C e.g. Typhoid in the 2nd week, typhus, viral infections and others.

Remittent Fever – Temperature is persistently elevated with diurnal variation more than 1°C – typhoid in 1st week, brucellosis, leptospirosis and others.

Intermittent Fever – Temperature is discontinuous, touching normal at least once in 24 hours. This may be seen in pyogenic infections, lymphomas, tuberculosis, bacteremias, malaria and others.

Periodic Fever: These show a regular periodicity in their occurrence. Fever occurring on alternate days with one day interval in between is called *tertian periodicity* e.g. vivax malaria (benign tertian). Fever occurring every 4th day with 2 days' afebrile period in between is known as *quartan periodicity* e.g. quartan malaria. Continuous and remittent fevers may be converted to intermittent fever by repeated doses of antipyretics.

Drug Induced Fever Several drugs can produce fever by various mechanisms. These includes allergy, systemic metabolic effects and agranulocytosis. Drug induced fever becomes a diagnostic problem in patients receiving multiple drugs for long periods, especially in hospitals.

Fig. 34.1: Patterns of fever

Of the medications that cause fever, antibiotics are the most frequent—especially penicillins and cephalosporins, sulfonamides, nitrofurantoin, antituberculosis agents and others. Antiepileptic drugs especially phenytoin are also known to cause fever. Drug induced fever does not have specific characteristic features. Most often, it occurs 5 to 10 days after starting the drug, but can occur even after the first dose itself.

Laboratory Investigations

Leukocyte Patterns

Neutrophil Leukocytosis and presence of juvenile or band forms of neutrophils and toxic granulations in neutrophils usually suggest bacterial infections. The severity of leukocytosis may also indicate the severity of sepsis. Total leukocyte counts above 10,000/cmm with more than 70% as neutrophils are very suggestive of pyogenic infection. Leukemoid reaction may accompany severe leukocytosis.

Neutropenia, mild to moderate, is usually seen in many viral infections, about 25%, of typhoid, brucellosis, leishmaniasis, tuberculosis, histoplasmosis and others.

Leukopenia with relative or absolute *lymphocytosis* occurs in several viral infections. Many viral infections show moderate or even severe thrombocytopenia with or without bleeding manifestations.

Atypical lymphocytes – are seen in some viral infections especially Epstein–Barr virus, cytomegalo virus, HIV, dengue, rubella, viral hepatitis, varicella and others.

Monocytosis is commonly seen in typhoid and tuberculosis.

Eosinophilia: Occurs in parasitic infections, filariasis, tropical pulmonary eosinophilia and hypersensitivity to drugs.

1. *Isolation or identification of the infective agent* in blood/urine/body fluids/pus and tissues specimens
 - a. *Culture*: Proper collection of sample without contamination and transport to the lab is important e.g. blood culture in sepsis, urine culture in UTI, CSF in meningitis, sputum in pneumonia, pus in abscess.
 - b. *Gram stain* of specimen may help e.g. sputum, CSF, pus, urethral discharge and others. The findings on gram stain should correspond to the results of culture, to be diagnostic.
 - c. *Demonstration of parasites* like malaria and microfilaria in blood, leishmania in bone marrow and liver biopsy specimens, vegetative amoeba in stool or scrapings from abscess wall.
2. *Demonstration of antibodies to specific pathogen* e.g. Widal in typhoid, IgM antibodies against many viruses like hepatitis A, E and dengue virus.
3. *Detection of bacterial/fungal/viral antigens* in blood/body fluids even when cultures are negative or practically difficult e.g. HBsAg in virus B hepatitis.
4. *Detection of very minute quantities of foreign nucleic acid* by techniques such as PCR (polymerase chain reaction) that allow amplification of specific DNA/RNA sequences.
5. *Histopathology*: e.g. tuberculosis, histoplasmosis, sarcoidosis and others can be diagnosed by biopsy of lymph node, liver and other organs.

Diagnostic Approach to FUOs 180

Investigations 181

Management 182

Syn: Pyrexia of Unknown Origin (PUO)

FUO is the term used to denote fever that does not resolve spontaneously in the period expected for self limited infections and whose cause could not be ascertained even after reasonable investigations.

Diseases Caused by Infections

This presents one of the most difficult diagnostic problems in Medicine. Atypical presentations of common illnesses are responsible for majority of such cases.

Definition

FUO was defined by Petersdorf and Beeson in 1961 as temperature $> 38.3^{\circ}\text{C}$ (101°F), lasting for more than 3 weeks and failure to reach a diagnosis, even after 1 week of inpatient investigations. A subsequent definition in 2003 stated that failure to get a diagnosis after 3 days of inpatient investigations or three outpatient visits should qualify for the term FUO.

Etiology

6

A. Infections: 30–50% are caused by infections. These include the following:

1. **Occult tuberculosis:** Extrapulmonary tuberculosis affecting the lymph nodes, intestines, mesentery, vertebrae, joints, liver, pleura, pericardium, and genital organs may remain latent without any local symptoms; but causing fever. The local lesion may become evident only after several weeks or months.
2. **Intra-abdominal infections:** Renal, retroperitoneal paraspinal, subdiaphragmatic, and pelvic abscesses may remain silent and cause diagnostic problems. Complicated urinary tract infection and infections of the biliary tree may also present as FUO.
3. **Other infections:** Infective endocarditis, brucellosis osteomyelitis, dental and sinus infections, enteric fever with atypical presentation, malaria, amebiasis, syphilis, leprosy, leishmaniasis and prostatitis may present as FUO.
4. **Viral infections:** Infectious mononucleosis and cytomegalovirus infection may present as FUO.
5. **Fungal infections:** Examples are histoplasmosis and cryptococcosis.

B. Malignancy: These form about 20% Leading malignancies presenting as FUO are:

1. Leukemias, lymphomas and multiple myeloma
2. Solid tumours like renal cell carcinoma, liver, colon stomach and pancreatic cancers.

C. Connective Tissue Diseases (About 15%): SLE, rheumatoid arthritis, rheumatic fever, polyarteritis nodosa, temporal arteritis, polymyalgia rheumatica, Wegener's granulomatosis, adult Still's disease and others.

D. Miscellaneous (About 20%): Inflammatory bowel disease, cirrhosis of the liver, granulomatous hepatitis, sarcoidosis, atrial myxoma, thyroiditis, thyrotoxicosis, drug reactions, hemolytic anemias, hematomas, deep vein thrombosis (DVT) and pulmonary embolism.

Undiagnosed: About 15 % may remain undiagnosed.

Factitious fever: This is elevation of temperature, self induced by patients with psychological problems – mostly young women working in health profession. They may induce disease or may devise methods to make the thermometer record higher temperature even when they are normal.

Nosocomial FUO: This term denotes fever above 38.3°C , (101°F) lasting for more than 72 hours, developing in a patient who is afebrile on admission to hospital. Most common causes are pneumonia, urinary tract infection, catheter related infections, *Clostridium difficile* colitis, *Cytomegalovirus* infection, sinusitis, septic thrombophlebitis and pulmonary embolism.

Neutropenic FUO: This is fever more than 38.3°C (101°F) lasting for more than 72 hours in a patient with absolute neutrophil count less than 500/cmm or expected to reach that level in 1-2 days. Most commonly this is produced by bacterial infections – bacteremias, pneumonia and soft tissue infections. Infection of the perianal area is also common. If neutropenia is prolonged, fungal and viral infections also supervene.

Human immunodeficiency virus (HIV) associated FUO: Fever is a common accompaniment of HIV infection when it leads to immunodeficiency. The most common infective agents are *Mycobacterium tuberculosis*, *Mycobacterium avium* complex, *Pneumocystis carinii*, disseminated cryptococcosis, toxoplasmosis and nocardiosis. Uncomplicated HIV infection itself can be the cause of prolonged fever.

DIAGNOSTIC APPROACH TO FUOS

Careful attention to history and a complete physical examination, repeated when necessary may reveal the etiology in many. Enquire about possible recent exposure to sexually transmitted disease, injected illicit drug use, which may predispose to hepatitis B and C, HIV, and infective endocarditis. Travel history may give a clue Occupational history may be significant and give evidence of exposure to birds (psittacosis) or animals (toxoplasmosis, brucellosis). Examination ocular fundi may reveal etiological clues – Roth spots in infective endocarditis, choroid tubercles in miliary tuberculosis and CMV retinitis. It is important to reassess the patient clinically at regular intervals. Look carefully for skin rash, skin nodules, conjunctival petechiae, clubbing and splinter hemorrhage. Digital rectal examination may suggest the cause occasionally – perianal disease suggest inflammatory bowel disease, local sepsis and abscess, rectal carcinoma, prostatitis, prostatic malignancy.

Even though the first clinical examination may be negative, repetition at weekly intervals or (shorter) will

bring out diagnostic clues and therefore this is an important diagnostic procedure.

Investigations: Investigations must be individualised based on the most probable suspected diagnosis. Differential diagnosis will depend upon the geographical area, age of the patient and co-morbid conditions. In general non invasive investigations should be done first before resorting to invasive investigations such as biopsy endoscopy and others.

A complete blood count and erythrocyte sedimentation rate (ESR) is to be done in all cases. ESR above 80 mm/hr is seen in tuberculosis, malignancy, connective tissue diseases and temporal arteritis. A peripheral smear is to be examined for abnormal cells, malarial parasite and atypical lymphocytes.

Mid stream urine is to be collected for microscopy and culture. Bacterial counts above 10^5 organisms/mL indicate urinary tract infection.

Isolation of Infective Agent

Blood culture should be done routinely in all fevers persisting more than a week. Many a times repeated blood cultures may have to be done to isolate the organism e.g. infective endocarditis.

Polymerase chain reaction (PCR) is very valuable in detecting the nuclear or cytoplasmic components of infecting organisms early in the disease. It is specific and reliable, but false positive results may occur.

Rise in serum uric acid level may suggest rapid cell turnover occurring in malignancies like lymphomas. Rise in alkaline phosphatase, especially the hepatic isoenzymes should indicate liver cell involvement.

Mantoux test: This is a commonly done test to detect allergy to tuberculo-protein. Positive Mantoux test indicates the possibility of tuberculous infection – past or active. In active tuberculosis the Mantoux test is generally hyperactive, but it may be misleadingly negative in miliary tuberculosis and immunocompromised persons. The specificity of this test is only moderate.

Imaging Studies

X-ray imaging: This is the most time honoured, almost universally available, relatively cheap and non-invasive imaging modality which is very helpful in the diagnosis of lesions in the chest e.g. pneumonia and tuberculosis, paranasal sinuses, bones and joints and others. Plain skiagrams and specialized procedures are available to delineate almost all organ system.

Ultrasound imaging: The morphology of several organ systems in the body can be imaged by ultra sound using appropriate probes and computer techniques. Abdominal

organs, genitourinary tract, uterus and any other part can be studied in detail. This modality has become a very useful and commonly used investigation to detect organomegaly in the abdomen, detection of fluid in the abdomen and the plural cavities, pericardium, cardiac structures and almost all other organs in some form or other. Examination of the abdomen may detect abnormalities in the liver (tumour, abscess), biliary system, kidneys, retroperitoneal nodes, pus and fluid collations, ascites and organomegaly.

Echocardiography is useful in detecting cardiac vegetations, atrial myxoma, and other cardiac abnormalities. Therefore this is a very valuable investigation to rule out or confirm a diagnosis of infective endocarditis. In infective endocarditis trans-esophageal probes have to be used if the conventional transthoracic probes are not fully informative.

Limited skeletal survey is useful in suspected multiple myeloma.

Other imaging modalities: These include CT scanning, MRI scanning, PET scanning and their further modifications appropriate to the organ and the disease to be studied.

Isotope bone scan is useful in detecting malignancy, osteomyelitis and septic arthritis.

Selected Serological Tests

A. **Infections:** Example typhoid, leptospirosis, brucellosis, dengue fever, Epstein Barr virus, cytomegalovirus, chlamydiae, mycoplasma, Q fever, amebiasis, leishmaniasis, toxoplasmosis and others.

Detection of specific antibodies against infecting organisms or their products, e.g. Widal reaction detects antibodies against Salmonella. Antistreptolysin-O (ASO) titre estimates the antibody to the toxin of streptococcus. Specific serological tests are available for diagnosis of connective tissue diseases, e.g. rheumatoid factor, in rheumatoid disease, antinuclear antibodies (ANA) in systemic lupus erythematosus which all can mimic infective fevers. Nonspecific tests such as erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) indicate the presence of an inflammatory process, non specifically. Once the infection is identified, serial determination of ESR or CRP helps to assess progress.

B. **Diseases of connective tissue and vasculitis:** Antinuclear antibody (ANA), anti ds DNA, anti neutrophil cytoplasmic antibody (ANCA).

Selection of further investigations needs careful consideration of the likely benefit and the cost involved. Gastrointestinal endoscopy with biopsy is indicated if symptoms or findings on imaging studies suggest diseases

Diseases Caused by Infections

of the abdominal hollow viscera such as inflammatory bowel disease, intestinal tuberculosis or cancer.

Bronchoscopy and bronchoalveolar lavage for culture of organisms and cytology for malignant and other pathognomonic abnormalities may be considered in selected cases.

Role of biopsy in the diagnosis of FUO: All biopsy procedures are invasive and associated with at least moderate or serious risks to life and health, even though, small. Therefore biopsy procedure should be reserved for cases where diagnosis is not arrived at by simpler procedures. Biopsy specimen can be obtained either by open biopsy or fine needle aspiration cytology (FNAC). Biopsy specimen should also be sent for culture of the organisms and sensitivity studies as well.

6 Liver biopsy: This procedure may help to diagnose miliary tuberculosis, sarcoidosis, lymphoma, and histoplasmosis if the lesions are generalized and tumours or localized inflammation such as granulomas if they are large enough. Guidance with ultrasound helps to reach the target precisely. Yield is generally low if liver function test and liver imaging are normal.

Bone marrow aspiration and biopsy: This is most useful in diagnosing hematological disorders such as leukemias, myeloma and anemias. Among infections visceral leishmaniasis is diagnosed by bone marrow examination. Typhoid, brucellosis, tuberculosis and other infections can be diagnosed by bone marrow culture and this is done when blood culture is negative.

Lymph node biopsy – This is useful when nodes are enlarged, as in lymphomas, tuberculosis, secondary malignant deposits, and others. In generalized lymphadenopathy it is better to take a node which is moderately enlarged. Since the inguinal nodes are likely to show non-specific changes, they are preferably avoided.

Management

Symptomatic Treatment for Fever

Fever demands treatment on its own right when it becomes uncomfortable or positively harmful as in hyperpyrexia.

Physical methods such as sponging with lukewarm or room temperature water and exposure to breeze, help to dissipate heat and lower the temperature rapidly, but the effect is transient. Ice caps applied to the forehead help to remove heat and provide comfort. Water-cooled beds and cooled baths are available for lowering body temperature in specialized patient care settings. Physical methods assume importance especially so when drugs are ineffective or are contraindicated.

Antipyretics

These are drugs which reduce the body temperature and help to maintain it so.

Paracetamol is a commonly used, safe, and freely available antipyretic and analgesic drug, often obtainable even as a non-prescription drug.

When given in doses of 500-750 mg tds oral, the temperature starts falling within 10-15 minutes with sweating and it remains normal or elevated to a lower level for 3-4 hours after which the temperature shoots up again when the effect of the drug wanes. Adverse effects include allergy, gastrointestinal upsets and in very large doses (exceeding 6g/day), hepatic dysfunction.

Aspirin, in doses of 300-400 mg qid or any non-steroidal anti-inflammatory drug (NSAID) such as diclofenac sodium 50-75 mg given orally are also commonly used analgesic antipyretics. Aspirin and NSAIDs show potent antipyretic effect, but they are not recommended for routine use because of their common side effects like acute gastritis, hemorrhagic gastritis and renal damage in some individuals. Many short viral fevers, especially dengue fever, leptospirosis, malaria and sepsis may be associated with thrombocytopenia. NSAIDs and aspirin may aggravate bleeding in them. Since renal involvement is common in dengue fever, leptospirosis, falciparum malaria and sepsis, NSAIDs which are nephrotoxic should be used with caution. There is no indication to give antipyretics if the fever is tolerated by patient comfortably and the fever itself does not rise to hyperthermic levels. Indiscriminate use of antipyretics lead to the following disadvantages:

- Diagnostic clues from the pattern of fever are lost.
- Beneficial effect of fever in infections is lost.
- Response to specific treatment cannot be assessed.
- The drug may induce rigors with return of fever – once antipyretic effect is over.
- Excess sweating with fluid loss and occasionally hypotension may develop.

Definite Indications for Antipyretics

Hyperpyrexia is the most urgent indication to bring down the temperature.

- Significant somatic symptoms like headache, bodyache.
- Coexisting symptomatic coronary artery disease and cardiac Failure.
- Cerebrovascular disease, nervous system dysfunction and head injury.
- Epileptic patients
- Children with history of febrile convulsions.

Pregnancy and psychiatric illness are relative indications to lower the temperature since complications are more likely in them.

Diet in Fever

Since fever increases metabolism, high calorie diet is recommended. Adequate fluid and electrolyte are also

important to avoid dehydration. Observe oral hygiene. Diet containing at least 1500 Calories and 3.5 -4 L of fluids in various forms should be administered. It is preferable to avoid foods which produce a sense of bloating and discomfort.

Antibiotics

Fever is to be treated with antipyretics and not with antibiotics. It is a common practice to give a trial of empirical antibiotics in short febrile illness. Favourable response is not a proof of bacterial infection. Most of the short febrile illnesses are due to viral infections, which are self-limiting. In immunocompetent subjects antibacterial antibiotics should not be used empirically. They are indicated only if there is clinical or investigation evidence of bacterial infection. There is no need for general use of prophylactic antibiotics except in special situations (Refer Chapter 5). Glucocorticoids should not be used as general antipyretics since they may lead to several adverse effects (Refer Chapter 6). "Shotgun mixtures of antibiotics and steroids are to be condemned, because they usually solve nothing, confuse the clinical picture and are not without hazards."

1. **Treatment of Classic FUO** - If the condition is stable and no etiological diagnosis is arrived – avoid empirical therapy. However, if an undiagnosed patient is too ill to permit prolonged observation, empirical treatment may be considered based on the best clinical judgement. It is also to be emphasized that "Initiation of empirical therapy does not make the end of diagnostic workup; rather, it commits the physician to continue thoughtful re-examination and evaluation" so that the empirical therapy does not cause further harm.
2. **Treatment of Neutropenic FUO** – After sending specimens for culture of organisms, empirical broad spectrum antibiotic coverage for pseudomonas such as ticarcillin/piperacillin with gentamicin/ amikacin is to be initiated. If clinical features point to fungal

infection antifungal drugs such as amphotericin in the usual dose has to be given.

3. **Treatment of HIV Associated FUO** – Acute onset fever with hypoxia in an HIV infected patient is often treated for Pneumocystis carinii infection after sending specimens to confirm the diagnosis. In undiagnosed prolonged fever, empirical antituberculosis therapy is usually given because of the high prevalence of tuberculosis in these patients. Specific treatment for HIV should also be started simultaneously.
4. **Treatment of Nosocomial FUO** – Many patients may be critically ill. IV lines may have to be changed and cultured. Empirical antibiotics may have to be given depending on the microbial prevalence in the environment.

Prognosis: This depends on the success of the investigation to arrive at the specific etiological diagnosis and prompt therapy. The overall mortality in FUO is 20 to 30%. It is higher as age advances. If FUO persists undiagnosed for more than 6 to 12 months, the likelihood of a specific diagnosis diminishes.

Conclusion

Fever of unknown origin is a common challenge to the practicing physician. *Many patients are placed in FUO category, because the attending physician overlooks, disregards or rejects an obvious clue. Physicians who care for febrile patients need to talk to them, observe them, and think about them. There are no substitutes for these simple clinical principles.*

Points to remember

1. FUO is a not- uncommon problem in the medical wards. Invariably, these are due to atypical and unsuspected presentations of common infections.
2. Less commonly rare infections may cause PUO.
3. Dyscollagenoses, malignancy, drug fever and factitious fever may cause problem in diagnosis. Proper clinical examinations, repetition of investigations and clinical follow up will reveal the diagnosis in the majority.

Sepsis and Septic Shock

S. Bhasi

6

Chapter Summary

- Introduction 184
- Epidemiology 184
- Etiology 184
- Pathogenesis 185
- Clinical Manifestations 185
- Diagnosis 186
- Treatment 186

Introduction

The clinical syndrome of sepsis is defined as *infection with evidence of systemic inflammatory response*.

In 1992, the American College of Chest Physicians and the Society of Critical Care Medicine (ACCP/SCCM) developed a consensus statement on the definition of sepsis and its sequelae.

Systemic inflammatory response syndrome (SIRS) may have an infective or non - infective etiology. When sepsis is associated with dysfunction of organs distant from the site of infection, it is termed *severe sepsis*. When severe sepsis is accompanied by hypotension which is not

correctable by appropriate intravenous fluid infusions, the condition is termed *septic shock*. Sepsis, severe sepsis and septic shock can be considered as points on a continuous process, depending on increasing severity of the condition.

Epidemiology

The yearly incidence of sepsis is 50-90 cases/100000 persons and it is on the increase. About 10% of sepsis progresses to severe sepsis and 3% of severe sepsis develops septic shock. Advancing age, diabetes mellitus, malignancy, immunodeficiency and chronic organ failure predispose to the development of shock. Males are more prone than females to develop septic shock.

Etiology

In the past, majority of cases were due to gram negative bacterial infection. At present approximately 50% are due to gram positive organisms as well. Common gram negative organisms causing sepsis are *E.coli*, *Klebsiella*, *Pseudomonas*, *Enterobacter* and *proteus*. Common gram positive organisms include *Staphylococcus aureus*,

ACCP/SCCM Definitions

Term	Definition
Bacteremia	Presence of viable bacteria in the blood
Systemic inflammatory Response syndrome (SIRS)	Severe inflammatory response characterized by 2 or more of the following : Temp > 38°C or < 36°C Heart rate > 90 beats/min Respiratory rate > 20/minute White blood Cell count >12000 cells/mm ³ or < 4000/mm ³ or > 10 % band forms
Sepsis	Presence of systemic inflammatory response syndrome with definitive evidence of infection
Severe sepsis	Sepsis associated with organ dysfunction, hypoperfusion or hypotension (systolic blood pressure < 90 mm Hg) or a decrease of 40 mm Hg from baseline systolic blood pressure
Septic shock	Sepsis with hypotension (systolic blood BP <90 mm Hg) persisting despite adequate fluid resuscitation and the development of abnormalities such as oliguria, altered mental status or lactic acidosis
Multi-organ dysfunction syndrome(MODS)	Presence of altered organ function in an acutely ill patient such that homeostasis cannot be maintained without intervention

enterococcus, coagulase negative *staphylococcus*, *Streptococcus pneumoniae* and *Streptococcus pyogenes*. Less frequently bacterioides and clostridia may cause sepsis. Viruses, rickettsiae and fungi are responsible at times. Polymicrobial infection is not uncommon. 25% of the infections are multidrug resistant. Common sites of infection producing sepsis are lungs, intra-abdominal tissues, other soft tissues such as muscles, fascial planes and anatomical cavities such as paranasal sinuses and peritoneal recesses, traumatic tissue destruction, implanted foreign bodies, indwelling vascular appliances and indwelling urinary catheters.

Pathogenesis

Pathogenesis of sepsis is very complex. Activation of immune system during microbial infection is generally protective, properly regulated and contained, with a balance set between inflammatory and anti-inflammatory mediators.

Th₁ lymphocytes are pro-inflammatory. Tumour necrosis factor alpha (TNFα), interleukins 1 and 2 (IL 1 and 2) and interferon γ (IFN γ) are pro-inflammatory. Th₂ lymphocytes and IL 4 and 10 help to restrain the inflammatory process and reduce tissue damage. In severe sepsis this balance is upset and the inflammation is uncontrolled, poorly regulated, self sustaining, widespread and involving distant organs away from the site of infection as well.

The products of microorganisms include lipoteichoic acid, endotoxins which are lipopolysaccharides-(LPS), exotoxins and various microbial antigens. When liberated, these act directly on the host tissues. They stimulate the production of pro-inflammatory cytokines such as TNFα, IL-1, and IFN and enzymes such as proteases. TNFα and IL-1 produce fever, vasodilation, hypotension, gluconeogenesis, lypolysis, myocardial depression,

hypoxia and increased capillary permeability. This leads to extravasation of plasma and cells with resultant low intravascular volume, hypoperfusion and shock. Nitric oxide is also released producing excessive vasodilation. Endotoxins also activate the alternate complement cascade. This results in the release of anaphylotoxins such as C3a and C5a leading to vasodilation, increased vascular permeability, aggregation of platelets and neutrophils and disseminated intravascular coagulation (DIC). This is the result of activation of factor XII by LPS and decreased concentration and function of the inhibitors of coagulation such as anti-thrombin III, activated protein C and tissue factor pathway inhibitor. TNFα, IL-1 and reactive oxygen species might inhibit mitochondrial respiratory chain leading to tissue hypoxia and lactic acidosis.

Clinical Manifestations

These may be classified as 1. Features of the primary disease and 2. Features of the septic shock.

- 1. Findings at the primary site of disease: These include the organ system which is primarily affected e.g. pneumonia, cellulitis, pyelonephritis, or traumatic lesions.
- 2. General effects of sepsis and septic shock: Varying degrees of fever occur in the vast majority, but in 15% of patients temperature may be normal or even sub-normal. Hypothermia may be seen in 15%. Tachypnea, tachycardia with weak thready pulse, hypotension, cold clammy skin, cyanosis, oliguria and alteration of sensorium are common. Cyanosis may be peripheral in shock or central in ventilatory failure. In the early stages of sepsis the mental state may be normal, urine output normal and extremities are warm due to hyperdynamic circulation. Tachypnea may produce respiratory alkalosis. Metabolic acidosis occurs in later stages.

EFFECTS OF SEPSIS ON INDIVIDUAL ORGAN SYSTEMS	
System	Effects
Pulmonary	Increased microvascular permeability leads to deposition of protein rich edema within lungs and alveolar collapse due to surfactant deficiency. This causes ventilation- perfusion mismatch. Decrease in lung compliance leads to development of ARDS and hypoxia.
Cardiovascular	Sepsis leads to hyperdynamic circulation with increase in heart rate. Later fall in cardiac output and hypotension ensue. Hypodynamic circulatory state occurs with fall in cardiac output and rise in pulmonary vascular resistance. Myocardial oxygen demand increases. Loss of vasomotor regulation leads to inability to maintain adequate blood flow to vital organs. This results in hypo perfusion and hypoxia.
CNS	Inadequate oxygen delivery leads to agitation, delirium, mental confusion and coma. Depression of the cough reflex predisposes to accumulation of secretions in the air way and respiratory infection.
Bone marrow and blood	Hematopoiesis, particularly thrombopoiesis and myelopoiesis are depressed. DIC and alteration in RBC deformability lead to occlusion and thrombosis in the microcirculation.
Renal	Hypoperfusion and ischemic tubular necrosis lead to oliguria and acute renal failure. Use of IV contrast dyes and aminoglycoside antibiotics precipitate renal failure.

The condition deteriorates, shock worsens, multi-organ failure occurs and the condition becomes irreversible. At this stage mortality exceeds 80%. Death is often due to multi-organ failure and DIC.

Diagnosis

A careful history, physical examination and appropriate imaging and laboratory studies are to be conducted in all cases.

Leucocytosis with shift to left with toxic granules in the neutrophils, thrombocytopenia and hyperbilirubinemia are present early in the course. Leucopenia may develop later. The primary site of infection – respiratory, intra-abdominal, urinary tract, soft tissues or intravenous line-related, should be identified.

Investigations

These include all appropriate investigations detailed in Chapter 35.

The circulatory state, the hematological abnormalities, respiratory function, renal function and fluid –electrolyte status should be assessed from time to time in order to institute life saving measures.

Course and Prognosis

Unless recognized early and managed with intensive care or acute care facilities, septic shock is invariably fatal due to circulatory and multi-organ failure. The risk is evaluated from the onset and during the course by Acute Physiology and Chronic Health Evaluation (APACHE) protocols. Higher scores indicate higher risk. The main criteria of APACHE score are given at the end of this chapter.

Treatment

Antimicrobials: Early institution of specific antimicrobial therapy is life saving. Blood and other relevant specimens should be sent for culture before starting antimicrobials. The choice of the agent depends on knowledge of the likely pathogen, the specific site of infection, sensitivity pattern of organisms in the institution, immunocompetence of the patient and whether the infection is hospital acquired or community acquired. The empirical initial choice would be bactericidal broad spectrum antimicrobial drugs with activity against gram positive and gram negative organisms given intravenously in the maximum recommended dosage. Therapy may have to be modified after culture report. Consider coverage of anaerobic flora also when indicated.

Recommended antibiotics are:

- Inj. ceftriaxone– 1-2 g IV bd (ceftazidime / cefepime in neutropenic patients to cover pseudomonas)
- Ticarcillin clavulanate 3.1 g 4 to 6 times daily by IV infusion

- Piperacillin / Tazobactam 3.375 g 4-6 times daily IM, IV or infusion
- Imipenem cilastin 500 mg 4 times day IM or IV or meropenam 1 g by IM or IV injection 3 times a day.

An Aminoglycoside may be added to any of the above drugs in selected cases.

Patient allergic to β -lactum may be given ciprofloxacin or levofloxacin 400 mg IV BD with clindamycin 600 mg 3 or 4 times a day by IV infusion. Vancomycin 500 mg 6 h by slow IV infusion over 60 minutes may be added if MRSA is suspected. Antifungal therapy may be needed in immunocompromised neutropenic patients. The duration of therapy and periodic alteration in dosage have to be based on microbiological investigations.

1. **Attention to the focus of infection:** Drainage of abscesses, debridement of infected necrotic tissue and removal of potentially infected devices and foreign bodies are necessary early in the disease.
2. **Fluid therapy:** Hypovolemia is common in sepsis and early fluid and electrolyte replacement to maintain adequate intravascular volume and to keep central venous pressure (CVP) at 8-12 cm improves survival.
3. **Vasopressors and ionotropes:** These are to be used when hypotension persists despite fluid replacement. Aim is to maintain mean arterial pressure (MAP) > 65 and systolic blood pressure (SBP) > 90 mm of Hg. Noradrenaline is currently the recommended first choice. Low dose vasopressin (0/01 to 0/04 units/kg bw) is a useful add-on drug in selected patients if the hypotension does not improve.

Blood glucose control: Patients with septic shock tend to develop glucose intolerance. Tight blood glucose control around 110 to 120 mg/ dL is absolutely necessary to hasten recovery and reduce mortality. Blood sugar has to be controlled by insulin therapy as indicated.

DVT prophylaxis: Increased incidence of deep vein thrombosis (DVT) occurs in sepsis, requiring suitable preventive measures.

4. **Activated Protein C:** This may be used in severe sepsis with multi-organ dysfunction. It has anti-inflammatory, anti thrombotic, pro-fibrinolytic effects. It is available as Drotrecogin alfa manufactured by Eli Lilly using r DNA technology. In severe cases with APACHE score >25 the drug reduces mortality by 30%. The drug is very expensive and may produce bleeding complications, especially intracranial, in 3-4% of cases. The price for 1 year of life saved is around \$ 50000. In less severe forms of sepsis this drug is not indicated.
5. **Glucocorticoids:** High doses increase mortality. Many patients with severe sepsis have relative deficiency of adrenal cortical function. In such patients hydrocortisone 200 mg/ day in divided doses may be

Drugs commonly used for circulatory support			
Drug	Mechanism of action	Clinical effect	Dose
Epinephrine	Alpha and beta adrenergic agonist	chronotropism,ionotropism, vasoconstriction	5-20 µg/min
Nor epinephrine	Alpha and beta adrenergic agonist	chronotropism, ionotropism, vasoconstriction	5-20 µg/min
Dopamine	Beta adrenergic-agonist, Progressive alpha-adrenergic effect with increasing doses	chronotropism, ionotropism, vasoconstriction	2 to20 µg/kg/min
Isoproterenol	Non-selective beta adrenergic agonist	chronotropism, ionotropism	0.01 µg/kg/min
Dobutamine	Beta- adrenergic agonist	chronotropism, ionotropism,vasodilation	5 to 15 µg/kg/min

beneficial. Levels of serum corticosteroid in normal persons with acute illness range from 10-34µg/dL. Levels below 15µg/dL indicate adrenocortical deficiency.

6. **Ventilatory support:** This improves survival if there is hypoxemia and ARDS.
7. Blood and blood products are life saving if used appropriately with care. Whole blood, packed cells, platelets, plasma and coagulation factors have to be used when indicated.
8. **Renal replacement therapy:** This is needed in those who develop renal failure, best results are obtained with early dialysis.
9. **Nutrition:** Sepsis is a hypermetabolic state. High calorie high protein diet with supplementation of micronutrients and maintenance of electrolyte balance is important. Oral feeling is ideal. If this is not possible parenteral feeding has to be instituted.

Points to remember

Management of septic shock is a very delicate and complicated therapeutic exercise demanding full facilities for acute intensive care, laboratory tests, expensive drugs and coordinated skills of different specialists. It is therefore essential that patients who might develop septic shock or those who have already developed it are straight away transferred to intensive care facilities for prompt management from the beginning. Delay in treatment and inadequate procedures produce dismal results.

Appendix APACHE Score

The Acute Physiology and Chronic Health Evaluation (APACHE) is a system for classifying patients in the intensive care unit. Patients are evaluated by physiologic scores and evaluation of chronic health status. Physiologic scores correlate with severity of illness. Results of the evaluation can be used to estimate the mortality rate for patients in the ICU and during the hospitalization.

Physiologic classes of variables (total 8 classes with 34 variables):

Maximum score		
1. Cardiovascular	7 variables	27
2. Respiratory	3 variables	12
3. Renal	3 variables	12
4. Gastrointestinal	6 variables	18
5. Hematologic	4 variables	16
6. Septic	4 variables	16
7. Metabolic	6 variables	24
8. Neurologic	1 variable	4
Total	34	129

Scoring

- The physiologic data is evaluated during the first 32 hours after admission to the ICU. Each variable is assigned a value of 0 to 4, based on significance of deviation from normal, with more severe deviations given higher values.

APACHE score =The total score obtained by adding the scores for all the eight systems

Preadmission health status: is also taken into consideration and classified as A to D, A being prior good health with no functional limitations and D being severely disabled.

Interpretation

- Minimum score: 0
- Maximum score: 129

Probability of death in hospital based on APACHE score	
Score	Mortality rate
0-5	2.3%
6-10	4.3%
11-15	8.6%
16-20	16.4%
21-25	28.6%
26-30	56.4%
31+	70%

Streptococcal Infections

GENERAL CONSIDERATIONS

Streptococci are among the most common pathogens of man. The lesions which are caused by direct streptococcal invasion include *pharyngitis* (sore throat), *tonsillitis*, *erysipelas*, *cellulitis*, *impetigo*, *scarlet fever*, *septicemia*, *necrotising fasciitis*, *toxic shock syndrome*, and *myositis*. Immunologically mediated postinfectious complications include acute rheumatic fever and acute glomerulonephritis.

Streptococci are gram-positive cocci 1 µm in diameter, non-motile and non-sporing. Many strains are capsulated. Majority are facultative anaerobes, but some are strictly anaerobic. Streptococci are classified on the basis of the type of hemolysis. Beta hemolytic strains possess *streptolysins O and S*. Majority of the pathogenic strains of streptococci are beta hemolytic. These have been further subdivided into broad groups A-H and K-V by Lancefield, based on the group specific polysaccharide antigen of the cell wall. *Str. pyogenes* belongs to group A. This strain is further subclassified by Griffith based on surface protein antigens—M, T and R. Of these M is the most important and it exists in approximately 60 different antigenic forms each of which is present in a different serotype 1, 2, etc. Determination of serotype is important to trace source of infections during epidemiological investigation. Over 80 different serotypes of group A streptococcus have been identified. Based on the serotype and the ability to produce the bacterial products pathogenicity varies.

Principal types of streptococci and enterococci pathogenic to man.

Species	Lancefield group	Type of hemolysis on blood agar
<i>Str. pyogenes</i>	A	beta
<i>Str. agalactiae</i>	B	beta
<i>Str. pneumoniae</i>	none	alpha
<i>Str. mutans</i>	none	none

Humans carry streptococci in the nose, throat, skin and mucous membranes. Common route of entry is the upper respiratory tract or direct inoculation into other sites. Nearly 5% of the population are carriers of pathogenic streptococci. Streptococci spread by inhalation of large droplets or intimate contact with contaminated secretions

Various products secreted by streptococci, which aid in their pathogenicity include *streptolysins O* and *S*, *deoxyribonucleases*, *hyaluronidase* and *erythrogenic toxins*.

Effects of streptococcal products on the host	
<i>Erythrogenic toxins</i> —	3 types: Pyrogenic, cytotoxic, suppression of reticuloendothelial activity, immunosuppression and inducing susceptibility to endotoxin
<i>Streptolysin O</i>	Lysis of erythrocytes, cytotoxic action on neutrophils, platelets and cardiac tissue
<i>Streptokinase</i>	Fibrinolysis
<i>Deoxyribonucleases</i>	Hydrolyse nucleic acids and nucleoproteins. These are antigenic
<i>Hyaluronidase</i>	Spreading factor, helps the organism to spread in tissues
<i>Nicotinamide adenine dinucleotidase (NADase)</i>	Antigenic

Streptococcal Pharyngitis

The incubation period is 2-4 days. This presents with abrupt onset of sore throat, dysphagia, headache, malaise, anorexia, and fever. The posterior pharyngeal wall is red and edematous. The tonsils are enlarged, red and covered with yellowish exudate, which can be easily removed with a swab. Anterior cervical lymph nodes are enlarged and tender. The disease runs a short course, lasting for about a week. Thirty to forty percent of tonsillitis and pharyngitis are streptococcal, the rest is viral or caused by mycoplasma.

Scarlet Fever

This is characterized by the occurrence of an erythematous rash on the second day of illness. The primary lesion is in the throat. Erythrogenic toxin of the streptococcus is responsible for the rash. The rash is seen over the neck

and trunk, the palms and soles are generally spared. The rash blanches on pressure. The rash subsides with extensive desquamation after 4-5 days.

Scarlet fever has to be differentiated from other exanthems, drug rashes, allergic dermatitis and infectious mononucleosis.

Diagnosis is established by isolating group A streptococci from the exudate obtained from the tonsillar crypts.

Treatment: Streptococcal lesions respond promptly to penicillin. A single intramuscular injection of benzathine penicillin G 600,000 units for children less than 25 kg and 1.2 million units for all others is enough to clear the infection. Phenoxymethyl penicillin (penicillin V) 250 mg orally four times daily for 7-10 days is also equally effective. Erythromycin 250 mg 6 hourly for 7-10 days is a suitable alternative for subjects allergic to penicillin. If suppuration develops, surgical drainage of the pus may be required.

Erysipelas

Erysipelas is an acute spreading infection of the skin and the subcutaneous tissue by streptococci. Face is commonly affected. The disease sets in abruptly with malaise, chills, headache and vomiting. The skin lesions are erythematous with clear advancing margins which may show vesicles. The part is tender and local lymph node enlargement may occur. If left untreated, the lesions rapidly spread. In immunocompromised individuals (e.g. diabetics) septicemia may develop.

Streptococcal Impetigo

This is inflammation of the skin characterized by isolated pustules which become crusted. Sites of predilection are around the mouth and nostrils – If left untreated they may ulcerate to produce shallow ulcers with crusts or scabs which may lead to pigmentation and scarring.

This stage is called ecthyma.

Cellulitis

This is spreading inflammation of the subcutaneous tissue due to entry of the organism through the abrasions of the skin. There is pain, tenderness, erythema, fever, and often regional lymphadenopathy.

Lymphangitis

Acute lymphangitis may follow local trauma. This condition presents in the form of linear red streaks radiating from the site of entry to the draining lymph nodes.

Streptococcal Bacteremia

Irrespective of the focus of entry and primary lesion, streptococcal bacteremia gives rise to metastatic foci of

Diseases Caused by Infections

infection such as suppurative arthritis, osteomyelitis, peritonitis, endocarditis, meningitis, or visceral abscesses.

The toxic shock syndrome may be produced by streptococci.

Necrotizing Fasciitis—

Syn: Streptococcal gangrene

This is a progressing destructive lesion of the subcutaneous tissue leading to necrosis of fascia and adipose tissue, but often sparing the skin. The organisms enter through trivial wounds, but within 24 hours the part is hot, swollen, tender and edematous. The edema and violaceous hue spread in all directions. Within 48 hours bullae develop, which go on to gangrene within 4-5 days. The gangrenous area gets demarcated. General symptoms include severe prostration, toxemia, mental clouding and delirium. If the diagnosis is missed, mortality is high.

Differential diagnosis includes infection by *Cl. septicum*, *Cl. perfringens*, and *Staph. aureus*. Treatment consists of the administration of benzyl penicillin and gentamicin in usual doses and aggressive fasciotomy and surgical debridement. In severe cases with toxemia and rapid progression clindamycin should be employed. This drug effectively arrests the growth and toxin-production of streptococci.

Streptococcal Myositis

This is an uncommon lesion. Infection reaches the muscles by the bloodstream. Onset is with severe pain and swelling of muscles. Muscle compartment syndromes may develop. If unrecognized, mortality is over 80%. Streptococcal myositis has to be differentiated from spontaneous gas gangrene. Presence of superficial crepitus favours the diagnosis of gas gangrene. Treatment includes the administration of broad spectrum antibiotics and early surgical debridement.

Pneumonia and Empyema

Streptococcal pneumonia usually follows a viral infection, and it manifests as bronchopneumonia. In many cases empyema develops as a complication.

Most of the strains of streptococci are sensitive to penicillin. Benzyl penicillin G (crystalline penicillin) given IM or IV in a dose of 600,000 units to 1 million units 6 h for 5-10 days generally clears the infection. Some strains have developed resistance to penicillin. Such infections have to be treated with broad spectrum bactericidal antibiotics.

Streptococcal Toxic Shock Syndrome

Infection by group A streptococcus may lead to vascular collapse and organ failure. M-protein which is a constituent of the cell wall is the virulence factor, which

plays the major role in the pathogenesis of toxic shock syndrome. It forms large aggregates with fibrinogen, in blood and tissues. These activate polymorphonuclear leucocytes intravascularly and this leads to the production of toxic shock syndrome.

OTHER PATHOGENIC STRAINS OF STREPTOCOCCI

Group B Streptococcus—*Syn: Str. agalactiae*

This is a major pathogen found in the female genital tract, rectum and also throat. Chorioamnionitis, septic abortion and puerperal sepsis may occur during pregnancy. Urinary tract infection may occur in both sexes. Hematogenous spread may result in endocarditis, pneumonia, empyema, meningitis and peritonitis. Immunocompromised hosts and elderly subjects are more susceptible.

Neonatal infections are caused by Group B streptococcus. The lesions include neonatal sepsis and meningitis. Early infection of the newborn leads to septicemia. Infection a few days after birth usually leads to purulent meningitis.

Streptococcus viridans

This is a heterogenous group consisting of *Str. mutans*, *Str. sanguis* and *Str. mitis*. They produce either alpha hemolysis or no hemolysis in culture. They are normal inhabitants of the oral cavity. Viridans streptococci account for more than 40% cases of infective endocarditis. *Str. mutans* which colonizes dental plaques is an important cause of dental caries.

Organisms closely related to streptococci are *Str. pneumoniae* and peptostreptococci.

Enterococci

These are gram positive cocci originally classified with streptococci. The name indicated its abundance in the gut. The most common species is *Streptococcus faecalis*, followed behind by *Streptococcus faecium*. In the mid 1980s, nucleic acid studies indicated that enterococci were not closely related to streptococci and therefore these are classified as a separate genus and the nomenclature of the species is *E. faecalis*, *E. faecium*, *E. durans* and others.

They colonize the intestines and vagina. They are pathogenic and the lesions include urinary tract infections, biliary tract infections, septicemia, peritonitis, infective endocarditis and abdominal suppuration. They are best known as antibiotic resistant opportunistic pathogens especially in patients who have been treated with several antibiotics with prolonged hospitalization.

Treatment: Enterococci are notorious for developing multidrug resistance. Many strains are resistant to vancomycin, aminoglycosides and beta-lactam antibiotics. Teicoplanin which is a glycopeptide is active against

vancomycin resistant strains. The fluoroquinolones, especially the newer preparations such as moxifloxacin, clinafloxacin, gatifloxacin and sitafloxacin offer the advantage of greater potency over ciprofloxacin. Chloramphenicol may be effective against some strains. The newer drug quinupristin/dalfopristin which is a streptogramin related drug is effective against vancomycin resistant strains. Linezolid which is a new oxazolidinone antibiotic is active against vancomycin resistant enterococci.

Acute Rheumatic Fever

Rheumatic fever is not an uncommon disorder seen in the pediatric age group in India. It is clinically characterized by fever, polyarthritis, carditis, chorea, skin manifestations and pleurisy. The underlying cause is hypersensitivity reaction to group A streptococci. Rheumatic fever follows 2-3 weeks after an attack of streptococcal pharyngitis. Rheumatic valvular disease accounts for a major proportion of cardiac morbidity occurring below 40 years of age in India.

Epidemiology

Though rheumatic fever is worldwide in distribution, it is more common in the developing countries. Group A hemolytic streptococci may occur as commensals in the throat in a small proportion of people. Sometimes, these streptococci become virulent and produce outbreaks of upper respiratory tract infections, especially in children living in closed communities like schools and dormitories. Rheumatic fever occurs only in humans. Repeated infection by streptococci increases the chance of developing rheumatic fever. Spread of group A streptococcus occurs rapidly from person to person by contact.

WHO estimates that 15.6 million people have rheumatic heart disease (RDH) globally. In India 0.5 million develop acute rheumatic fever annually, out of which 300,000 may develop heart disease. Annual incidence is 54/100,000 population (Padmavathy.S.Ind Heart J 2001 53: 35-37). RHD is the result of cumulative damage produced by repeated attacks of rheumatic fever. Prevalence of RHD increases with age, maximum is in the age group 25-34 years. In India both rheumatic fever and RHD are seen at much younger age groups compared to other countries.

Since overcrowding and poor living conditions predispose the spread of streptococcal infection, rheumatic fever is more common in the poorer socioeconomic groups. The risk of developing rheumatic fever after an attack of streptococcal tonsillitis is 0.3 to 3%. The most vulnerable age group is 5-15 years, though any age may be affected. In India the mean age of affection is 6 years. Both sexes

are affected and a familial predisposition is noticed in many cases. Rarely skin infection by streptococcus may lead to acute rheumatic fever, otherwise it may increase the susceptibility to it. After several decades of freedom from rheumatic fever, small outbreaks have been reported from many developed countries in the recent past.

Pathogenesis

In 80% of cases the disease follows streptococcal tonsillitis. In 20-30% cases the episode of tonsillitis may go unnoticed. Over 80% of subjects with rheumatic fever show rise in antistreptococcal antibodies within two months. Extrapharyngeal streptococcus infection does not generally lead to rheumatic fever. The M-protein of streptococci contain epitopes that cross-react with cardiac tissues and other tissues such as synovium and brain. The antigens contained in streptococcus show similarity to several tissue antigens in the human body, especially myocardial sarcolemma. Antibodies produced against streptococcal antigens cross-react with tissue antigens resulting in a type II antigen antibody reaction and consequent inflammation. Lesions are most evident in the connective tissue.

The M serotypes 3, 5, 6, 14, 18, 19 and 24 have strong association with cardiac disease. Throat infection is more commonly caused by serotypes 12, 1, 25, 4 and 3. ASO titre is more elevated in infections of the throat than in skin infections. Strains of streptococci leading to rheumatic fever increase more of streptolysin O than streptolysin S. Strains giving rise to skin infections give rise to greater elevation of ADNase B titres (Table 37.1). Rheumatic fever represents an autoimmune reaction triggered by pharyngeal infection by the appropriate strain of group A streptococcus and amplified by recurrent infection by the same or related group A streptococci.

Pathology

The pathological process consists of an exudative stage which is seen in the acute phase and a proliferative stage which is a more prolonged process. In the exudative stage, fibrinoid necrosis of the connective tissue is seen. There is edema of the collagen fibers which later undergo fragmentation. Immune response affects myosin in muscle

TABLE 37.1			
Comparison to the streptococcal lesion in acute rheumatic fever (ARF) and glomerulonephritis (GN)			
	ARF	GN	
1. Site of lesion	Mostly throat	Throat or skin	
2. Prior sensitization	Essential	Not necessary	
3. Serotypes of streptococci	3,5,6,14,18,19	12,44,2,52,55,57,4	
4. Immune response	Marked	Moderate	

leading to myocarditis - In the valves which lack myosin, the attack is against laminin which is present in the basement membrane and around the endothelium.

The hallmark of the proliferative phase is the formation of **Aschoff's bodies**. These are small granulomas consisting of a central zone of fibrinoid necrosis surrounded by round cells, epithelioid cells, *Aschoff's giant cells* and fibroblasts. This histological appearance is similar in all tissues showing rheumatic lesions.

Heart: All the layers are involved to produce endocarditis, myocarditis and pericarditis (pancarditis). Endocarditis affects the valvular or mural endocardium. When the valvular endocardium heals, it results in scarring and deformity of the valves. Scarring alter mural endocarditis may be seen as the **MacCallum's patch** in the posterior wall of the left atrium. Affection of the myocardium may be mild or severe. Lesion in the pericardium is a fibrinous inflammation. The pericardium shows a 'bread and butter' appearance microscopically. Pericardial effusion may develop. Adhesive pericarditis may follow rarely.

Joints: Rheumatic lesions involve large synovial joints producing acute synovitis. Effusions develop which clear up completely without any residual deformity.

Other organs: Rheumatic granulomas found in the subcutaneous tissues, are seen as subcutaneous nodules. Respiratory involvement manifests as a pneumonia with or without evidence of pleurisy. The basal ganglia of the brain are affected. The lesions take the form of aseptic focal encephalitis which clears completely. Autoantibodies to caudate and subthalamic nuclei are detectable in patients with rheumatic chorea. These antibodies can be absorbed by group A streptococcal membranes. These also cross-react with the sarcolemmal membranes of the heart. In India, the occurrence of cutaneous and neurological lesions is distinctly less when compared to the descriptions from the west.

CLINICAL FEATURES

In some cases prodromal symptoms include epistaxis (bleeding from the nose), *erythema nodosum*, and vague discomfort. Rheumatic fever starts abruptly as a remittent or intermittent pyrexia with characteristic sweating. In many cases other manifestations may not develop for considerable periods, so that the diagnosis may be unsuspected in them. In 20-25% of cases the fever is accompanied by polyarthritis and carditis. *Sometimes these are mild and go unrecognized, especially in children.*

Arthritis: Acute arthritis affecting the major joints is the characteristic involvement. The joints show signs of acute inflammation and exquisite pain which make the subject immobile. Knees and ankles are most often affected

followed by hips, elbows, wrists, and shoulders. Small joints of the hands and feet and axial joints are affected only rarely. The arthritis is migratory and fleeting and leaves behind no residual changes. Sometimes the manifestation may be subacute with arthralgia, pain and tenderness over the neighbouring tendons and muscles. This may be mistaken for growing pains in children.

Jaccoud's arthritis: Jaccoud's arthropathy may affect the hand in up to 50% of cases. It is characterized by reducible, non-erosive joint deformities with preservation of hand function. The pathogenesis of this condition is probably extra-articular secondary to inflammation and shortening of the tendons. The condition clears up with treatment.

Carditis: There may be clinical features of endocarditis, myocarditis, and pericarditis in varying combinations. Tachycardia out of proportion to fever, arrhythmias, gallop rhythm, and congestive cardiac failure should suggest the presence of myocarditis. Mild cardiomegaly may be evident in the skiagrams. Arrhythmias include frequent ectopics, paroxysmal tachycardias, atrial fibrillation, and heart blocks.

Presence of endocarditis is evidenced by the appearance of murmurs or change in the quality of the already existing murmurs. Mitral, aortic, tricuspid, and pulmonary valves are affected in the order of frequency. Acute valvulitis may lead to mitral and aortic regurgitation. Sometimes a low pitched mid-diastolic murmur may be heard in the mitral area due to acute mitral valvulitis (*Carey-Coombs murmur*). It is transient and disappears as the valvulitis subsides. As the valvulitis heals, fibrosis occurs and this distorts the valve apparatus resulting in stenotic and regurgitant lesions.

Pericarditis is clinically manifested as chest pain, presence of pericardial rub, or a small pericardial effusion.

A prospective study conducted at Kottayam Medical College revealed that echocardiographic studies including Doppler are of great value in detecting acute rheumatic valvulitis. Combination of arthritis and carditis occurred in 56.6% of cases of rheumatic fever. Carditis without arthritis occurred in 19.4%. Acute aortic regurgitation occurred in about 50% but most of them (43%) cleared-up on follow up. Sequelae included mitral regurgitation, mitral stenosis, a few cases of aortic regurgitation and occasionally tricuspid regurgitation. Pericardial involvement is also easily detected by echocardiography. (See also Section 13, Chapter 119).

Rheumatic chorea (*Syn: Sydenham's chorea, St. Vitus dance, minor chorea*)

Chorea generally occurs 1-6 months after the onset of rheumatic fever. Since chorea sets in much later than the other manifestations of rheumatic fever, in many cases it may be the only abnormality encountered. Chorea is more common in females and that too in children. It is

characterized by involuntary movements which are quasi-purposive non-repetitive, rapid and jerky and these involve mainly the distal joints. Upper limbs are mostly involved, but lower limbs, face and tongue may also be involved to a lesser extent. These movements may be mistaken for tantrums or fidgety behaviour. Emotional disturbances are frequent and these aggravate the chorea. The limbs are hypotonic and when the hands are held outstretched they assume characteristic postures (choreic hand). The movements disappear during sleep.

Diagnosis of chorea is clinical and there is no pathognomonic investigation. The cerebrospinal fluid is normal. Sydenham's chorea is almost always rheumatic in nature. For chorea and indolent carditis evidence of streptococcal infection need not be stressed upon for diagnosis (WHO Expert consultation-Geneva Oct-Nov 2001-WHO publication 2004).

Chorea is self-limiting and it completely disappears within weeks or months without leaving any neurological sequel. Subjects developing chorea have a higher incidence of cardiac involvement. Except during pregnancy, rheumatic chorea is rare in adults. Rarely chorea may be caused by systemic lupus erythematosus.

Treatment of chorea: Salicylates and steroids have no effect on chorea. The patient is put to bed in a quiet room. Involuntary movements can be controlled by diazepam, chlorpromazine, or phenobarbitone, given in the usual doses. Haloperidol is very effective in controlling the chorea if given in a dose of 0.25 mg 6 h. Rarely intravenous immunoglobulin (IV Ig) may be required in an intractable case (See also Section 19, Chapter 191).

Skin manifestations

Subcutaneous nodules: They are firm, nontender, pea-sized nodules seen over the extensor aspects of the forearm, elbows, ankles, scalp and scapulae. These last for 1-2 weeks and disappear. The risk of carditis is high in those who develop rheumatic nodules.

Erythema marginatum: These are erythematous non-pruritic annular lesions with serpiginous borders, usually seen over the anterior aspects of the chest and abdomen and over the thighs. They spread peripherally like ripples with central clearing. The lesions blanch with pressure. In coloured races this lesion is difficult to identify, unless carefully examined in good light. This rash falls in the category of toxic erythema.

Other rheumatic manifestations: Pleurisy and pneumonitis are not generally evident clinically, these are made out more often by investigations.

Course and progress: Rheumatic fever tends to subside spontaneously over a period of weeks or months. The arthritis subsides but the cardiac lesion progresses. Recurrence of streptococcal infection results in

exacerbation of the rheumatic process, and hence relapses invariably occur. The course of the disease extends over several months or even a few years with remission and relapses. The risk of developing fresh cardiac lesions and worsening of the existing lesions is increased with successive relapses. Mortality in the acute phase is due to sudden cardiac failure, fatal arrhythmias or heart block. In India the course of the disease is accelerated when compared to the west, so that established valvular disease is seen even as early as 6-7 years of age.

Diagnosis: Clinically rheumatic fever should be considered in all cases of prolonged fever in India. Rapid pulse, arthritis, skin manifestations, and carditis suggest the diagnosis.

Streptococcal infection may be demonstrable either by throat swab culture or by serological methods. Moderate neutrophil leukocytosis occurs in many cases.

Serodiagnosis: Several antibodies to streptococcal antigens have been identified.

1. Anti-streptolysin O titer (ASO)
2. Anti-streptokinase (ASK)
3. Anti-deoxyribonucleotidase B (AntiDNase B)
4. Anti-nicotinamide-adenine dinucleotidase (Anti-NADase)
5. Anti-hyaluronidase (AH)
6. Anti-streptozyme test (ASTZ)

Anti-streptolysin O titer has been widely accepted as one of the more easily available diagnostic tests and any value above 250 Todd units in adults and 333 Todd units in children is suggestive. However, the diagnostic levels vary in different places and it is related to the prevalence of antibody levels in the local population. Antistreptolysin O titer does not correlate with the clinical severity. Anti-streptozyme test is a highly sensitive hemagglutination test.

Acute phase reactants: These are laboratory tests which are helpful in the acute phase of the illness. Values of ESR and C reactive proteins are elevated.

The presence of carditis is suggested by the presence of electrocardiographic abnormalities which may show sinus tachycardia, ectopic beats, or first and second degree heart blocks. The voltage of QRS complexes is low; ST elevation and T inversion are seen in the presence of pericarditis. It should be remembered that in many cases with carditis, ECG may not show any abnormalities and hence a negative ECG does not rule out cardiac involvement.

The American Heart Association has accepted the **modified "Jones' criteria"** (1965) for diagnosis which are relevant in Indian conditions as well. The major criteria denote the more specific lesions whereas the minor criteria are nonspecific. For the diagnosis of rheumatic fever two major or one major and two minor criteria should be present. In any case there should be evidence of previous streptococcal infection. In Indian subjects polyarthralgia

TABLE 37.2

Jones' criteria (revised)*

Major manifestations	Minor manifestations
Carditis	Previous rheumatic fever or history of rheumatic heart disease
Polyarthrititis	Fever
Chorea	Acute phase reactants
Erythema marginatum	Prolongation of PR interval in the ECG
Subcutaneous nodules and evidence of preceding streptococcal infection, i.e., ASO titer	
*Duckett Jones	

is also taken as a major criterion if supported by the evidence of streptococcal infection (Table 37.2).

Differential Diagnosis

Infective endocarditis may present with fever and heart lesions. Presence of clubbing, hepatosplenomegaly, absence of arthritis, and development of embolic complications help to distinguish this condition. Henoch-Schönlein purpura may resemble rheumatic fever when purpura is insignificant. Acute leukemia may present with arthralgia and arthritis and produce difficulty in diagnosis before the blood picture becomes diagnostic. Presence of severe pallor, bleeding tendencies, non-migratory arthritis, hepatosplenomegaly, and fundal hemorrhages should alert the physician about the possibility of leukemia. Septic arthritis is usually monoarticular and the source of primary infection may be evident. Gonococcal arthritis, Reiter's syndrome, systemic lupus erythematosus, polyarteritis nodosa, allergic arthritis and serum sickness have to be excluded in atypical cases. Acute or subacute rheumatoid arthritis may cause genuine diagnostic difficulty especially in children.

Chronic rheumatic heart disease has to be differentiated from congenital heart diseases and other acquired heart diseases.

TREATMENT

Treatment may be divided into: (i) management of the acute stage, (ii) eradication of the streptococcal infection, and (iii) prevention of recurrences (secondary prevention).

Acute Phase

Strict bed rest should be instituted since it is absolutely essential to limit the carditis and reduce the incidence of chronic heart disease. It is to be continued till ESR comes down to normal.

Anti-inflammatory agents: The drug of choice is aspirin which has a dramatic effect. The antirheumatic dose of

aspirin is 90-100 mg/kg/day, given in four divided doses after food. Since in this high dose the drug may produce gastric irritation, antacids such as aluminium hydroxide or magnesium trisilicate may be given simultaneously. The dose of aspirin is reduced when fever subsides and it should be continued in a small dose for 10 days after disappearance of all the symptoms. Adverse side effects of aspirin include nausea, dizziness, tinnitus, deafness, vomiting, hyperventilation, hemorrhagic tendency, and psychosis. Idiosyncrasy to aspirin ingestion may lead on to asthma, and nasal polyposis. Aspirin sensitivity can be allayed by desensitization using incremental doses under supervision.

Alternatively corticosteroids may be given. Corticosteroids and salicylates are equally effective in the management of rheumatic fever. Corticosteroids are preferable in those with carditis, since it controls the cardiac lesion, whereas aspirin may not. The common preparation is prednisolone in a dose of 40-50 mg daily given orally. Withdrawal of steroids may result in exacerbation and hence it should be tapered off under the cover of aspirin.

Streptococcal infection is controlled by giving procaine penicillin intramuscularly in a dose of 500,000 units/day for 7-10 days. Erythromycin and cephelexin are suitable alternative drugs.

Secondary prophylaxis: Since rheumatic recurrence is invariably precipitated by streptococcal reinfection, benzathine penicillin 1.2 mega units is given once every three weeks to prevent streptococcal reinfection and rheumatic recurrence. As an alternative, oral penicillin 200,000 units twice daily may be given. Penicillin-sensitive individuals may be treated with erythromycin 250 mg/day. It is desirable to continue rheumatic prophylaxis life long but the chance of recurrence comes down with increasing age and the passage of time after the acute attack. It is mandatory to continue penicillin prophylaxis at least till the age of 25 years or for 5 years after the initial attack, whichever is later.

Primary prevention has been achieved very effectively in most of the developed countries by early diagnosis and prompt treatment of streptococcal infections. Sporadic cases occur when this policy is slackened.

Primary prevention by early prompt treatment of acute streptococcal pharyngitis and tonsillitis and secondary prophylaxis by prolonged antibiotic therapy have served to bring down the incidence of rheumatic fever and heart disease.

Attempts to produce anti-streptococcal vaccine are also going on.

Poststreptococcal Glomerulonephritis (GN)

This may follow either cutaneous or pharyngeal lesion by group A streptococcus. Ten to fifteen percent of children

getting recurrent skin infections may develop glomerulonephritis. Serotypes 12,44,2,52,55,57 and 4 are more often nephritogenic. Latent period for the development of acute GN is 10 days after pharyngitis and 3 weeks after pyoderma. Streptococcal infection supervening on scabies is a common cause for acute glomerulonephritis in India.

This described in section 16, ch. 170.

Staphylococcal Infections

General Considerations

Staphylococci are the most ubiquitous organisms affecting man. Staphylococci are gram-positive cocci 1 µm in diameter, capable of aerobic and anaerobic metabolism. They produce lesions by direct invasion. Many strains are toxigenic and several syndromes result from toxic effects. Incubation period for local lesions is 2-3 days.

Staph. aureus is coagulase positive. *Staph. epidermidis* and *Staph. saprophyticus* are coagulase negative. All are pathogenic, the most common type is *Staph. aureus*.

Epidemiology: Healthy people carry staphylococci in the nose and to a lesser extent in the perineum. The organism is spread by direct contact, through fomites, dust, or by airborne droplets. Large number of organisms are shed from superficial lesions and from the respiratory tract. Though, initially, staphylococci were sensitive to sulphonamides and penicillin, many strains have developed resistance to several antibiotics in common use. Penicillin is inactivated by penicillinase (betalactamase) and this is the basis of penicillin resistance. Resistance can be transferred from one strain to another by transduction through the mechanism of plasmids. At present most hospital strains of staphylococci are resistant to several antibacterial agents. Methicillin resistant staphylococci are resistant to several other beta lactam antibiotics. Therefore resistance to methicillin is tested to identify such strains.

Pathogenesis: Staphylococci invade hair follicles and sebaceous glands. Incidence of infection is higher in diabetics and obese subjects. Subjects recovering from influenza and measles are more susceptible to staphylococcal infection. The organism multiplies in the lesions and leads to suppurative inflammation.

Lesions produced by staphylococci

Staph. aureus: Pyogenic lesions such as boils, carbuncles, wound infection, abscesses, impetigo, mastitis, osteomyelitis, pneumonia, septicemia and pyemia.

Coagulase negative staphylococci: Infection of cardiac and vascular prostheses, endocarditis, ventriculitis (cerebral), peritonitis in continuous ambulatory peritoneal dialysis, septicemia, cystitis.

Toxin-mediated lesions: Food poisoning, toxic shock syndrome, scalded skin syndrome, pemphigus neonatorum.

Toxins of staphylococci: *Staphylococcus aureus* elaborates toxins like hemolysins, leucocidins, enterotoxin, hyaluronidase, fibrinolysin, nuclease, lipase and protease. In addition, nontoxic substances like coagulase, which facilitate invasion, are also produced.

Toxins produced by strains of *Staph. aureus* and the syndromes produced

Enterotoxin A-E	Gastroenteritis
Epidermolytic toxin A and B	Blisters of skin, pemphigus neonatorum, scalded-skin syndrome
Toxin-1	Toxic shock syndrome

Superficial Lesions

Furuncle: A furuncle is an acute necrotic infection of a hair follicle. It presents as a small follicular inflammatory nodule, soon becoming pustular and then necrotic. It heals after discharge of the necrotic core to leave a violaceous macule and ultimately a permanent scar.

Carbuncle: It is a large furuncle or an aggregate of interconnected furuncles accompanied by intense inflammatory changes in the surrounding and underlying connective tissue. Sites of predilection are the back of the neck, the hips and thighs. It starts as a hard red lump, at first smooth and acutely tender. It slowly increases in diameter to reach 3 to 10 cm. Suppuration begins after 5 to 7 days and pus is discharged from multiple follicular orifices. Constitutional symptoms are usually severe. Carbuncles are particularly common in diabetics and those with lowered general resistance.

Impetigo: Bullous impetigo is purely staphylococcal. It usually occurs in newborns and infants. Face is more often affected although lesions may occur in the palms and soles. The lesions consist of multiple pustules.

Ecthyma

Both staphylococci and streptococci can cause ecthyma. The lesion is characterized by small bullae or pustules on an erythematous base, soon developing into a hard crust. Irregular ulceration is evident when the crust is removed. The sites of predilection are the buttocks, thighs, and legs.

Sycosis Barbae

This is seen in males after puberty and the lesions are seen on the beard region. The lesion starts as an edematous, red, follicular papule or pustule, centered by a hair. The individual papules remain discrete.

Follicular Impetigo of Bockhart

This is staphylococcal infection of the hair follicle seen commonly in childhood. It occurs mainly in the scalp or scalp margins.

The Scalded Skin Syndrome

(Syn: pemphigus neonatorum, Ritter's disease, toxic epidermal necrolysis)

This is a generalized exfoliative dermatitis caused by *Staph. aureus*. It is characterized by generalized painful erythema and large bullae which can be easily disrupted by finger pressure. Newborns are commonly affected.

Staphylococcal Pneumonia

Staphylococcal pneumonia occurs as a complication of influenza, measles or other viral infections. It starts with high fever, chills, dyspnea, cyanosis, cough, and pleural pain, sputum may be bloody or purulent. Scattered fine to coarse rales and rhonchi may be heard over the involved areas. Typical consolidation is rare. Primary staphylococcal pneumonia may occur in infants and young children and this causes pneumothorax, pneumatoceles, or empyema. Hematogenous secondary staphylococcal pneumonia is frequent in drug addicts who also develop endocarditis. Staphylococcal pneumonia carries a higher mortality, especially in the old and debilitated patients.

Osteomyelitis

Majority of cases of primary osteomyelitis are due to staphylococcus.

Staphylococcal Bacteremia

The primary source consists of local staphylococcal infections, urinary catheters, foreign bodies, or infected intravenous shunts. The onset is marked by high fever, tachycardia, cyanosis and vascular collapse. Pyemic abscesses may form in the skin, bone, kidneys, brain, or lungs. Fulminant sepsis may lead to death within 24 hours.

Other staphylococcal lesions include endocarditis, pericarditis, arthritis, polymyositis, parotitis, and urinary tract infection.

Staphylococcal Food Poisoning

Staphylococcal food poisoning occurs as a result of ingestion of preformed enterotoxin in food contaminated by *Staph. aureus*. Canned food, processed meat, milk, cheese and others account for the majority of cases. Symptoms start within 6-8 hours and the patients present with varying grades of gastroenteritis or dysenteric symptoms. There is mild fever.

Staphylococcal enterocolitis is due to direct invasion of the bowel mucosa, sometimes seen in surgical patients. Gram staining of feces reveals the organisms.

Tropical Pyomyositis

This is more commonly described from Africa, but cases occur in India too. Large abscesses develop in the muscles of the limbs or trunk in apparently healthy adults. The spread of the organism is probably hematogenous. In

addition to systemic therapy surgical evacuation of pus is also necessary.

Diagnosis of Staphylococcal Infections

Clinical diagnosis should be confirmed by culturing the organism from the exudates. Phage typing is employed for identifying the strains in epidemics and tracing the carriers.

Treatment

Superficial skin infections respond to proper cleaning and application of topical ointments containing chlorhexidine or cetrimide. In systemic infections or when the lesions are deep, systemic antibiotics are required. Benzyl penicillin is the most effective antibiotic if the organisms are sensitive.

Infections acquired from the community may be sensitive to benzyl penicillin in usual dosage. Up to 90% of hospital acquired infections may be resistant to penicillin and other beta-lactam antibiotics due to the production of penicillinase. *Methicillin*, *cloxacillin*, *fluocloxacillin*, *cephalosporin*, *clavulanic acid* and *sulbactam* resist penicillinase and, therefore, these may be effective.

Hence it is ideal to get culture and sensitivity results where circumstances permit. Pending the result *cloxacillin* or *flucloxacillin* may be started in a dose of 250-500 mg orally six hourly. If the organism is penicillin sensitive, the most effective drug is benzyl penicillin. *Procaine penicillin* in a dose of 600,000 units IM daily for 6-10 days clears the infection. Resistant cases may require other antibiotics such as *gentamicin*, *clindamycin*, *fusidic acid* or *erythromycin*. *Vancomycin* is usually effective in multidrug resistant cases and it is the drug of choice. *Rifampicin* in dose of 400-600 mg daily orally acts synergistically with vancomycin.

Quinupristin/dalfopristin which is a streptogramin antimicrobial agent recently licenced in the UK and USA for the treatment of gram-positive organisms, especially methicillin resistant *Staphylococcus aureus*, coagulase negative *Staphylococcus aureus* with intermediate glycopeptide resistance (i.e. to teloplanin), vancomycin resistant *Enterococcus faecium* and penicillin resistant and macrolide resistant *pneumococci*. It is inactive against *enterococcus faecalis*. It can be given as IV infusion, preferably through central venous catheter over a period of 60 minutes. Adverse side effects include rashes, gastrointestinal upsets and irritation at the site of injection.

Staph. epidermidis cystitis responds to *cotrimoxazole* or *norfloxacin*.

PREVENTION

Patients with open staphylococcal lesions should be isolated. Surgeons and hospital staff should be periodically

checked for carrier state and positive cases are treated by local application of neomycin and chlorhexidine. Topical application of antiseptics such as hexachlorophene are found useful in preventing staphylococcal infection in selected cases. The importance of proper hand washing by the attending staff cannot be overemphasized.

Multidrug resistant *Staphylococcus aureus* (MRSA) is found to colonize the nose, wounds and other parts in 30-40% of patients undergoing prolonged hospitalization. During an outbreak of MRSA infection in hospitals, application of mupirocin ointment to the nose helps to eradicate the nasal carrier state. The whole genome sequence of methicillin resistant *Staph. aureus* has been unravelled by Japanese workers (Kuruda M *et al*, The Lancet 2001: 357, 1255-40). About 70 genes have been identified to contribute to drug resistance.

Toxic Shock Syndrome

This syndrome described first in 1978 consists of sudden development of shock associated with high fever, headache, sore throat, diarrhea, and erythroderma. It was noted in young girls using certain brands of vaginal tampons during menstruation. This syndrome is caused by a diffusible toxin produced by staphylococci (phage type 1) which grows in such tampons. Blood cultures are negative. Mortality is high in untreated cases. This syndrome can develop even when the source of infection is different.

Treatment: Emergency measures to combat septic shock should be instituted. Betalactamase-resistant antibiotics should be used in full dosage from the onset. Corticosteroids have helped to reduce toxemia in some cases. Further use of such tampons should be avoided. Strong clinical suspicion is absolutely necessary to save life in such situations.

Pneumococcal Infections

Syn: *Diplococcus pneumoniae*,
Streptococcus pneumoniae

General Considerations

Pneumococci are found in the upper respiratory tract of about half of the population. On the basis of capsular precipitation reactions using type specific antisera, about 84 serotypes have been identified. All are pathogenic to man but the most commonly encountered types are 1, 2, 3, 4, 7, 8 and 12. These are gram-positive nonmotile encapsulated ovoid or lanceolate organisms 1 µm in length occurring in pairs. Most strains are facultative anaerobes, some are strictly anaerobes.

Pneumococcal polysaccharide plays the major role in virulence and it protects the organism to some extent from phagocytosis. The capsule is the most important determinant of virulence. It is important for immunization.

Though capsular polysaccharides have similar physico-chemical properties, some strains are more pathogenic and only some strains are frequently associated with bacteremic illness. The capsule by itself is not toxic. Invasiveness is related to the size of the capsule and more importantly to its chemical composition. Route of entry in the respiratory tract by droplet infection. The normal respiratory tract offers adequate resistance to invasion by pneumococcus. Patients with underlying lung diseases such as bronchiectasis, carcinoma, or chronic obstructive airway disease are predisposed to develop pneumonia. Aspiration of infected material, respiratory irritants, pulmonary edema and trauma to the chest reduce the local resistance and favour the growth of pneumococci. Respiratory viral infections predispose to infection by *S. pneumoniae*. Large droplet size and close contact favour infection.

Alcohol intoxication and anesthesia impair leucocyte migration. The mucinous secretions of the respiratory tract protect the pneumococci and these multiply and lead to further outpouring of proteinaceous fluid.

The normal defence mechanisms consist of the migration of polymorphonuclear leucocytes and phagocytosis. These are enhanced by the presence of antibodies. Breakdown of these defence mechanisms result in bacteremia and the development of metastatic lesions in the meninges, joints, peritoneum, or the endocardium. Recovery from infection starts with the formation of type specific antibodies in the circulation and this is clinically marked by a fall in temperature by crisis. Treatment with antimicrobials reduces the bacterial population and enhances the host defence mechanism which is still important in the elimination of bacteria. Necrosis of lung parenchyma is uncommon.

Spread of pneumococci from the nasopharynx to the adjacent structures results in the development of otitis media, mastoiditis, paranasal sinusitis, or conjunctivitis.

Pneumococcal Pneumonia

Syn: *Lobar pneumonia*

Pneumonia is the most common pneumococcal lesion in adults. In adults commonly the pneumonia is segmental or lobar in distribution, but in children and the aged the lesion may be bronchopneumonic.

Pathology: Invasion of the lung by pneumococci leads to the formation of an inflammatory exudate in several alveoli and this depends upon the virulence of the organism. Segmental boundaries are not preserved and the bronchi which are relatively uninvolved, remain patent.

The inflammatory exudates contain a large number of neutrophils and red cells. In the initial stages the alveoli are filled with red blood cells and fibrin, and the pulmonary capillaries are widely dilated (*red hepatisation*). In the next stage neutrophil leucocytes predominate. They phagocytose the bacteria. The capillaries become less congested (*grey*)

hepatisation). It is uncommon for the inflammatory process to proceed to necrosis. As resolution starts, the inflammatory exudate liquefies and it is absorbed through lymphatics and removed by the alveolar macrophages. It takes considerable periods of time for complete recovery.

Clinical features: Pneumonia is often preceded by coryza or other upper respiratory tract infections. Incidence of pneumonia is higher in males. The onset is sudden with fever and chills in the majority of cases. There is marked tachycardia and tachypnea. The alae nasi are seen to move when the patient breathes. Severe pleuritic pain and cough with expectoration of pinkish or rusty mucoid sputum follows. The respiration becomes rapid and shallow and may be associated with grunting. Respiratory embarrassment results in cyanosis. The patient becomes very ill and toxic. In the untreated case fever persists continuously for 7-11 days after which it comes down by crisis. It is common to get a crop of labial herpes simplex during the fever.

Physical examination reveals rapid pulse fever and signs of consolidation over the affected lobe of the lung. As resolution starts, coarse creptitations develop. If pleurisy occurs, pleural friction rub may be elicitable. In uncomplicated cases, once the temperature comes down, the patient feels well and recovery starts. However, the pulmonary lesions resolve completely only after a few weeks.

Early institution of specific therapy can prevent the development of consolidation and the general symptoms, but if consolidation has been established, resolution takes time, depending on the body's natural defences. The response to penicillin therapy is dramatic. With the widespread use of antibiotics from the start of fever, the classic picture of lobar pneumonia is seldom seen at present.

Laboratory findings: Sputum is rusty in colour. Pneumococci can be demonstrated by gram staining. Blood culture is positive in 20-25% of cases in the early stage of the disease. There is marked leukocytosis ranging from 12,000 to 25,000 cells/cmm and neutrophils from 85 to 90% of the total. Absence of leukocytosis or even leukopenia may sometimes be observed in patients with overwhelming infection and bacteremia. The prognosis in such cases is very poor. Skiagram of the chest shows a homogeneous opacity corresponding to the lobe or segment involved (Fig. 37.1).

Bacterial organisms in respiratory infections			
	<i>S. pneumoniae</i>	<i>H. influenzae</i>	<i>M. catarrhalis</i>
Acute sinusitis	42	29	22
Acute otitis media	42	38	17
Acute exacerbation of chronic bronchitis	15	32	13
Community acquired Pneumonia	20-75	3-10	—

Complications: Local complications include atelectasis, lung abscess, and delayed resolution.

Fig. 37.1: Skiagram chest lobar pneumonia – right (pneumococcal) See well demarcated homogenous opacity right mid zone

Spread of inflammation to adjacent structures leads to pleural effusion, empyema, pericarditis, and peritonitis.

Hematogenous spread results in septicemia, meningitis and acute endocarditis. Gastrointestinal complications include paralytic ileus, gastric dilatation, impairment of liver function, and jaundice.

Prognosis: In the vast majority of cases the lesion subsides and recovery is complete. Adverse prognostic signs include leucopenia, bacteremia, multilobar involvement, extra-pulmonary involvement, circulatory collapse, presence of pre-existing systemic diseases, and occurrence of the disease at the two extremes of life (below 3 years and above 55 years). Infection with type 3 pneumococcus has a higher mortality rate (Tables 37.3 and 37.4).

EXTRA-PULMONARY PNEUMOCOCCAL LESIONS

Pneumococcal meningitis: Pneumococcal meningitis may develop primarily or this may be a complication of pneumococcal pneumonia, otitis media, mastoiditis, or sinusitis. This is a serious illness associated with 20-30% mortality and up to 50% residual morbidity in survivors, if not treated in time.

Over 75% of community acquired meningitis is caused by *S. pneumoniae* and *N. meningitides*.

Early lumbar puncture on clinical suspicion and the promptness with which early specific antimicrobial treatment is started are the most important prognostic factors for recovery.

Pneumococcal peritonitis: This is a rare infection. It is more frequent in girls, patients with nephrotic syndrome, cirrhosis of liver, and abdominal malignancies.

TREATMENT OF PNEUMOCOCCAL INFECTIONS

Pneumococci are generally susceptible to penicillin, but resistant strains are being reported. It is advisable to send

the sputum for sensitivity tests before starting specific therapy. Benzyl penicillin is the drug of choice for pneumococcal infections.

Pneumonia: Crystalline penicillin is given intramuscularly in a dose of 0.5 mega units/8 h till the temperature comes down to normal and then procaine penicillin in a dose of 0.5 to 1 mega unit daily is substituted and continued till the patient is well on the road to recovery. In the ordinary case the antibiotic has to be administered for a total duration of 7-10 days. When resolution is delayed, the cause should be detected by investigations.

An alternative to penicillin is ampicillin 250 mg 6 h for 7-10 days.

The abnormal physical findings in the chest clear in 2-3 weeks. The skiagram may show abnormalities for up to 2 weeks after the temperature comes down to normal. Delay in resolution is due to bronchial obstruction or other underlying lung diseases.

Multiple-drug-resistant pneumococci respond to vancomycin 2 g/day in divided doses or cephalexin or ceftazidime. Levofloxacin is also effective.

Symptomatic treatment includes analgesics (aspirin) for chest pain, oxygen inhalation, non-narcotic sedatives (diazepam), and expectorants for clearing the respiratory passages. Medicated steam inhalations containing tincture benzoin or eucalyptus oil provide symptomatic relief and assist expectoration. It is important to ensure adequate convalescence (at least 2 weeks) after lobar pneumonia and this helps in reducing the sequelae.

Note: See section 14, ch. 134.

Since *S. pneumoniae* has acquired resistance to penicillin, other antibiotics may have to be used. These include vancomycin and third generation cephalosporins.

Susceptibility Rates of Respiratory Pathogens to Antimicrobials

Percentage susceptibility to various antibiotics using NCCLS (National Committee for Clinical Laboratory Standards) breakpoints (Table 37.5).

Prevention

Specific prophylaxis is by vaccinations. Pneumococcal vaccine contains a mixture of 23 polysaccharide serotypes giving protection against 90% of the infecting strains. The vaccine has to be given by SC or IM injection. A single dose gives protection about 3 to 5 years or longer. Vaccination may have to be repeated after 5 years if exposed to the risk of infection. Mass vaccination of children in a community produces herd immunity in the population, in

% susceptible using NCCLS breakpoints

Diseases Caused by Infections

addition to the individual benefits. This phenomenon is being studied further. It has been observed that individuals immunized against pneumococcus may be predisposed to colonization of the nasopharynx by *Staph. aureus*.

Indications for vaccination: Asplenia, nephrotic syndrome, sickle cell disease, lymphomas and other immunodeficiency states. In children below 2 years of age and in immunocompromised individuals vaccination is not effective. They have to be given orally phenoxymethyl penicillin on a long-term basis. Protein conjugate pneumococcal vaccine may be given to children > 2 years for protection. Multiple doses may have to be given.

General Measures to Increase Resistance

Studies from Dhaka, Bangladesh have shown that malnutrition predisposes to pneumonia. Oral supplementation of 70 mg of zinc acetate in 10 mL of syrupy base once a week was associated with substantial protection against pneumonia and suppurative otitis media. Mortality from pneumonia was also reduced.

(W. Abdulla et al. The Lancet. 2005. 366-999-1004).

Meningococcal Infections

GENERAL CONSIDERATIONS

Neisseria meningitidis (meningococcus) is pathogenic exclusively to man. The clinical syndromes include meningitis, meningococcal septicemia, and rarely lesions in the joints, ears, eyes, adrenal glands, lungs and heart.

Meningococci are gram-negative diplococci. Based on the capsular polysaccharide antigens, these are divisible into three main serogroups A, B, and C. Group A commonly produces epidemics and Group C, localized outbreaks of meningitis. Other serogroups W₁₃₅ and Y are also pathogenic.

Epidemiology: The organisms are found in the nasopharynx of 5-10% of humans who act as carriers. Before the onset of epidemics carrier rate among the local population goes up above 20% and during an epidemic 90% of subjects may carry the organisms. Outbreaks usually occur in close-knit communities such as inmates of jails, ships, army camps, or dormitories. Sporadic cases may also occur. In India a clear seasonal prevalence is not seen. The organism commonly spreads through droplet infection and to some extent through fomites. In the majority of cases the infection is asymptomatic. In some, the only manifestation is an upper respiratory tract catarrh.

PATHOGENESIS AND PATHOLOGY

The major lesions are cerebrospinal meningitis and meningococcal septicemia. Bacteremia precedes the meningitis. The organism may reach the central nervous

system directly along the perineural sheath of the olfactory nerves or through the bloodstream. Bacteremia leads to endothelial damage and the organisms enter the CSF. Serogroups B and C account for the majority of cases in the west. Serogroups W₁₃₅ and Y account for a smaller proportion. Group C produces more serious disease.

Once the CSF is reached further multiplication is rapid since the humoral defences are absent. Cytokines promote inflammatory processes and increase vascular permeability. Leukocytes adhere to endothelium. Vasogenic cerebral edema occurs which itself may lead to brain herniation. In the central nervous system meningococci produce suppurative lesions of the pia arachnoid. Inflammatory lesions are seen on the surfaces of the brain and spinal cord and the ependymal lining of the ventricles. The whole of CSF becomes turbid and purulent. The base of the brain and the surface of the cerebral hemispheres show thick pus. This exudate may block the foramina leading to internal hydrocephalus and also compress the cranial nerves emerging from the base of the brain. Meningococci may invade the underlying cerebral cortex as well and cause encephalitis.

Histologically the lesions show perivascular cuffing with polymorphs. Thrombosis of small blood vessels may occur. In severe cases, subdural effusions containing blood or exudate may occur.

Clinical pattern of meningococcal infections		
Site of infection	Clinical syndrome	Outcome
Blood and CSF	Septicemia and meningitis with rash	Fatal in 14-50%
	Septicemia and meningitis without rash	Fatal in 2-6%
Blood	Fulminant septicemia Waterhouse-Friderichsen syndrome	Fatal
Blood	Septicemia purpuric rash	Fatal 14-50%
Blood	Chronic septicemia	Recovery with treatment
Metastatic lesions	Arthritis, osteomyelitis, pericarditis, endocarditis, local lesions, pneumonia	Recover with treatment
Eye	Purulent conjunctivitis	Clears with treatment

Meningococcal septicemia (meningococcemia) is characterized by hemorrhagic manifestations. The organisms can be demonstrated in the small blood vessels from all organs. Vascular damage occurs as an allergic

phenomenon (*Schwartzman phenomenon*) caused by the endotoxin of meningococci. In fulminant meningococemia, hemorrhage occurs into the adrenal glands leading to adrenal failure and profound shock. Generalized hemorrhagic tendency may develop due to disseminated intravascular coagulation. Metastatic lesions occur in the joints, ears, eyes, and lungs.

MENINGOCOCCAL MENINGITIS

Syn: Cerebrospinal fever

Infection of the leptomeninges by *N meningitidis* leads to meningococcal meningitis. This may occur in epidemic and sporadic forms. The most common age group is from 6 months of life to adolescence. Incubation period varies from 3-5 days and there may be a preceding upper respiratory tract infection. Onset is acute with fever and other constitutional features like severe headache, neck rigidity, vomiting, and photophobia. Fever is usually high grade, intermittent, and associated with rigor and chills. The pulse is slow. Herpes labialis may develop. The patient is irritable and prefers to lie curled in bed. Drowsiness, confusion, delirium, and coma supervene. Convulsions are common at the onset, especially in children. In children, early signs such as leg pain, coldness of the extremities and abnormal skin colour may develop even before the classic signs of meningitis. Recognition of the disease at this stage and institution of specific therapy are more beneficial.

In a large proportion features of meningococcal septicemia are seen. These include maculopapular and purpuric skin rashes appearing over the axilla, flanks, wrists, and buttocks, and ecchymosis and peripheral gangrene (Fig. 37.2). Signs of meningeal irritation are evident from an early stage. These include neck rigidity, Kernig's sign, and Brudzinski's signs. There is pain over the hamstrings when the knee is extended passively with the hip flexed to 90°, and the extension is restricted (*Kernig's sign*). *Brudzinski's leg sign* is the flexion of the opposite knee when Kernig's sign is elicited on one side. Brudzinski's neck sign is flexion of both legs when the neck is passively flexed. In severe cases, especially in

children, the spasm of neck muscles may be so severe as to produce head retraction and opisthotonus.

Rise in intracranial tension may lead to papilledema. In a small proportion of cases blindness, deafness, and hemiplegia may be found in the acute phase. Some of the patients recover within a month. A toxic encephalopathy may develop in some patients and this is probably due to diffusion of toxins or bacterial invasion.

It is characterized by the development of deep coma within a few days of onset. This condition is associated with a mortality up to 50%. The development of subdural effusion, internal hydrocephalus, or brain abscess should be suspected from the development of localizing signs and progressive deterioration, despite adequate therapy. Most of the untreated patients die in a stage of deep coma within days or weeks, but a few may proceed to a chronic phase characterized by progressive emaciation, opisthotonus, paralysis, bedsores, and hydrocephalus.

Meningococemia

Meningococemia may be fulminant or chronic. The fulminant form is characterized by abrupt onset, severe constitutional disturbances, peripheral vascular collapse, shock, and sometimes myocarditis. The skin rashes are extensive and may even ulcerate. Though in many cases there is associated meningitis, the signs of meningeal irritation may be absent due to shock. In some cases the illness may progress rapidly so that toxemia and shock may occur within hours. These features are collectively called *Waterhouse-Friderichsen syndrome*. This syndrome is caused by hemorrhage into the adrenal glands resulting in acute adrenal failure. Toxic vasculitis aggravates the hypotension. Complications include endocarditis, allergic polyarthritis, pneumonia and osteomyelitis.

Chronic meningococemia is characterized by intermittent fever lasting for several weeks, maculopapular rashes, erythema nodosum, arthralgia or arthritis, and splenomegaly in 20%. If left untreated, the infection may either subside or progress to meningitis.

Other rare meningococcal lesions include *pneumonia*, *genitourinary infection*, *endocarditis*, *osteomyelitis* and *purulent conjunctivitis*. In acute meningococcal infections polymorphonuclear leucocytosis with total counts going up to 12,000 to 40,000/cu mm is common. In chronic meningococemia the leucocyte count may be normal.

Diagnosis

Clinically meningitis is diagnosed when there is fever, severe headache, and signs of meningeal irritation. This has to be distinguished from meningism which is seen in toxic febrile states where the signs of meningeal irritation are present but the CSF is normal. Meningitis has to be distinguished from encephalitis, subarachnoid

Fig. 37.2: Boy meningococemia. Note: blotchy ecchymosis

hemorrhage, and other causes of coma. Meningococcal meningitis has to be distinguished from other causes of purulent meningitis. At the slightest suspicion of meningitis lumbar puncture should be done and the CSF should be examined to establish the diagnosis. **Since early diagnosis and institution of specific antibacterial treatment is the most important single factor in determining the outcome, lumbar puncture should not be delayed.**

Differential diagnosis includes other bacterial meningitis, mainly caused by *H. influenzae* and pneumococci.

Laboratory diagnosis: Diagnosis of meningitis is confirmed by examination of CSF. Lumbar puncture should be done at the earliest if there are no contra indications. Conditions which resemble meningitis include subdural empyema, brain abscess, or necrotic temporal lobe in *Herpes simplex* encephalitis. In patients with onset of seizures, signs of raised intracranial tension and moderate or severe impairment of consciousness, CT or MRI should be done to assess the intracranial pathology before performing LP. Repetition of Lumbar puncture is indicated when the progress with treatment is not satisfactory.

CSF findings confirm the diagnosis of meningitis. These include:

1. Rise in pressure	Opening pressure may exceed even 400 mm CSF
2. Physical appearance	Turbid or purulent
3. Pleocytosis	Leucocyte count is usually 500-10000/cmm or even more. Over 95% are neutrophils. Rarely lymphocytes may be the predominant cells. In 5-10% of cases cell count may be only mildly elevated or be normal. This is associated with poor prognosis.
4. Demonstration of organism	Gram staining of CSF shows meningococci in 60-90% of cases. PCR of CSF can detect the organism early.
5. CSF glucose	It is less than 40% of the level of blood glucose estimated simultaneously
6. Culture of organism	Positive in a variable proportion. Organisms disappear rapidly on starting specific therapy.
7. Detection of meningococcal antigen in CSF	Counterimmunoelectrophoresis

In patients with persistent elevation of intracranial tension lumbar puncture and release of CSF may lead to trans-tentorial herniation of the temporal lobe of the brain and coning of the brainstem which can be fatal if unrecognized. In such cases LP should be done with

precaution to monitor the patient and institute life saving measures if coning occurs. Coning of the brain stem leads to drowsiness, coma and slowing of respiration and death. Emergency management consists of intravenous administration of 200 mL of 20% mannitol, elevation of the foot end of the bed and release of supra tentorial pressure by surgical means. If in any case the LP is likely to be delayed and the clinical suspicion is strong, antibiotic therapy should be started straight away, empirically.

Identification of the infecting agent:

1. Meningococci may be seen in gram stained CSF preparations. This is the most rapid method for diagnosis.
2. The organism can be cultured from CSF, blood or material taken from skin rashes.
3. Meningococcal antigen can be identified in CSF by counterimmunoelectrophoresis.
4. Sera of convalescent patients show antibodies to meningococci and these can be demonstrated by complement fixation test, passive hemagglutination, or by radioactive antigen binding tests. These tests are helpful in retrospective diagnosis.
5. Carrier state is diagnosed by isolating the organisms from material collected from the nasopharynx using a West's postnasal swab. The swab has to be transported to the laboratory in a special medium (Sturt's medium).

Treatment

As early as possible, specific treatment should be started. Penicillin G is the antibiotic of choice and should be administered intravenously in a dose of 24 million units daily in divided doses. In children the dose is 16 million units/m². Dexamethasone 10 mg IV should be started with the first dose of antibiotic and repeated 6 h for 4 days. Further doses should be determined, based on the patient's progress. Addition of glucocorticoids early in treatment favours prompt recovery and prevents complications considerably.

Treatment should be continued for several days. Ampicillin in a dose of 200-400 mg/kg body weight daily is also equally effective. Since penicillin and ampicillin enter the CSF through the inflamed meninges, intrathecal administration is not necessary. In penicillin-allergic patients, chloramphenicol in a dose of 4-6 g daily in divided doses can be used intravenously. The third generation cephalosporins, especially cefotaxime is quite effective when given in doses of 6-8 g/day. The exact dose can be calculated from the weight of the patient. 150-200 mg/kg IV daily in 6 hourly doses to a total of up to 12 g. An alternative is ceftriaxone in a daily dose of 75-100 mg/kg (up to 5 g) given in two divided doses.

The administration of antibiotics is continued at high doses till the CSF becomes clear and cell count comes

down. Thereafter the drug is continued at a lower dose till all symptoms subside and the CSF returns to normal. Return of the CSF sugar level to normal indicates full recovery.

Supportive treatment consists of the maintenance of nutrition, fluid and electrolyte balance, treatment of shock and the management of convulsions. Adrenal crisis should be managed with large doses of hydrocortisone.

Course and prognosis: The disease was invariably fatal before the advent of specific antimicrobial therapy. At present the mortality is reduced to 10%. *Prognosis for full recovery and avoidance of complications depends directly on the early institution of specific antimicrobial therapy with glucocorticoids and therefore it is of utmost importance to make the diagnosis and start treatment without delay.* Other poor prognostic factors include extremes of age, presence of rash, tachycardia (>120 /minute), diastolic BP < 60 mm Hg, total leucocyte count < 1000 / cmm and platelet count below 180,000 / cmm. Long-term sequelae include cranial nerve palsies, seizure

disorders, various forms of paralysis and cognitive impairment.

Prevention

During epidemics it should be the aim to reduce the carrier state among the susceptible population. Rifampicin is given in a dose of 10 mg/kg once in 12 hours for 2 days for adults and children above 1 year. For children below 1 year the dose is 5 mg/kg bw 12 hourly for 2 days.

Alternate drugs include ciprofloxacin 500 mg oral or ofloxacin 400 mg oral single dose daily for four days. For pregnant women ceftriaxone 250 mg in single dose daily for a few days is the drug of choice.

Vaccination: Vaccines containing pure group specific capsular polysaccharides of meningococci A, C, Y and W135 groups are available. The vaccine is given subcutaneously. Immunity lasts for three years. At present this vaccine is available for persons going for Haj pilgrimage.

Diphtheria

General Considerations

Definition: Diphtheria is an acute infectious disease caused by *Corynebacterium diphtheriae*, clinically characterized by a membranous inflammation at the site of infection and deleterious effects on several tissues particularly on the myocardium and nervous system due to the exotoxin.

C. diphtheriae are gram-positive rods $3 \times 0.3 \mu\text{m}$ in size, pleomorphic, non-motile, non-sporing, non-capsulate, generally aerobic and facultatively anaerobic. Based on the colony morphology on tellurite medium, biochemical reactions and hemolytic property, *C. diphtheriae* is classified into three main types—gravis, intermedius and mitis. Virulent strains produce an exotoxin which is responsible for producing remote effects. Around 90-95% of the gravis and intermedius strains are toxigenic while only 80-85% of mitis strains are so. The toxin is a labile protein of molecular weight 62,000 and it is inactive when released by the bacterium. Action of proteases present in infected tissue is necessary for its activation. Treatment with 0.2-0.4% formalin converts the toxin into toxoid. The toxoid is not harmful to the tissues, still it possesses antigenicity and hence is used for immunization.

Epidemiology: The disease has been almost wiped out from developed countries, but in India it is still prevalent. Diphtheria is more common in children, though all ages may be affected. The organism is harboured by carriers and cases. The disease is spread by droplets, contaminated vessels shared by children, or by direct inoculation into skin abrasions or eyes. Unimmunized children in a partially immunized community are highly susceptible. Relaxation of immunization schedule has led to resurgence of outbreaks of diphtheria in some Asian countries. Untreated cases are infective for more than two weeks. Antibiotic therapy reduces the communicability to 2-3 days. During outbreaks susceptible individuals can be identified by the Schick intradermal test, but this method is seldom used in practice.

Pathogenesis and Pathology

The organisms gain entry through the respiratory passage, eyes, middle ear, genitalia, and skin. Incubation period is 3-4 days but it may vary from 2-7 days. The exotoxin causes tissue necrosis, which favours further growth of the organism and toxin production. The epithelium degenerates and a serofibrinous exudate develops which contains inflammatory cells and fibrin. This forms a bluish white membrane over the involved area. The membrane is adherent and when removed forcibly it leaves a raw bleeding surface. Site of predilection for the primary lesions is the respiratory tract. Other sites of infection are the nose, ears, conjunctiva, genitalia, and skin. Around the membrane there may be necrosis, ulceration or hemorrhage. Sometimes, the membrane may not be evident, but the pharynx may show hyperemia and edema.

Regional lymph nodes are markedly enlarged. The toxin is absorbed from the primary site and it causes damage to the myocardium, kidneys, adrenal glands, and the cranial and peripheral nerves. Myocardium shows

cloudy swelling, fatty change, minute hemorrhages and round cell infiltration. This may lead to cardiomegaly and conduction disturbances. Kidneys show cloudy swelling of the tubular epithelium and interstitial nephritis. The adrenal glands are enlarged with hemorrhages in the cortex. Liver cells show degenerative changes with scattered areas of focal necrosis.

Peripheral nerves may show degeneration of the myelin sheaths and axis cylinders, motor fibers being more affected. The posterior column of the spinal cord may be involved. Rarely cerebral hemorrhage, meningitis, and encephalitis have been described. Respiratory obstruction by the membrane or toxic myocarditis may lead to death.

Clinical Features

These depend on the primary site of involvement, duration of the illness, systemic effects of the toxin, and resistance of the host. The disease starts with sore throat, low grade fever, headache, malaise, vague aches and pains and catarrhal symptoms. As the disease progresses, tachycardia, nausea, vomiting, pallor and weakness follow.

Pharyngeal diphtheria: It is the most common form and the membrane is present over the tonsils and pharynx. Gross cervical lymphadenopathy (described as bull neck) is evident and respiratory obstruction may develop, especially in children. In severe cases circulatory collapse occurs. Local effects of the toxin lead to paralysis of the palate and pharynx. The term “malignant diphtheria” is given to the condition characterized by marked edema of the submandibular areas and anterior part of neck. There is moderate leukocytosis (14,000-16,000/cu mm) with polymorphs forming 60-80%.

Laryngeal diphtheria: This forms 25% of the cases. It produces respiratory obstruction early, which may be fatal. The clinical features include barking cough, hoarseness, dyspnea, stridor and cyanosis. Infants with laryngeal diphtheria may refuse to suck the breasts due to choking.

Nasal diphtheria: It occurs in 2-3% of cases. The membrane is limited to the septum or turbinates and it is usually unilateral. The condition may present with a foul smelling serosanguinous nasal discharge or frank epistaxis.

Cutaneous diphtheria: *Corynebacterium diphtheriae* cannot penetrate the intact skin and it gains entry through wounds, burns, or abrasions. It causes ulceration. The typical ulcer is usually punched out and 0.5 cm or more in size. Sometimes, it may resemble a nonspecific ulcer. In the early stage the ulcer is covered by a greyish yellow or brownish membrane. There may be coexistent pharyngeal diphtheria in 20% of cases.

Other sites of lesion are the conjunctiva, vulva, vagina, uterine cervix, bladder, urethra, penis, middle ear, buccal mucous membrane and esophagus.

Complications: Mechanical obstruction of airway by the spreading membrane is a dreaded complication. The other complications are due to the systemic effects of the toxin. The incidence and severity of toxic manifestations increase in proportion to the extent of the membrane.

Toxic complications are most pronounced in the heart and motor nerves. Though 60% of patients have pathological lesions in the heart, only 10 to 12% manifest clinically. Myocarditis should be suspected if there is variation in the intensity of heart sounds, systolic murmurs, conduction defects, atrial fibrillation, ventricular ectopic beats, or ventricular tachycardia. Sudden death may occur due to ventricular fibrillation. Congestive failure and cardiac dilatation are less common. In infants and young children vomiting may be an early symptom of cardiac involvement. Though electrocardiographic changes are nonspecific, the presence of abnormalities strongly suggests myocarditis.

Toxic peripheral neuritis develops 2-6 weeks after the primary lesion. Third, sixth, seventh, ninth, and tenth cranial nerves are commonly affected. Palatal and pharyngeal paralysis may occur as early as the third day. External ophthalmoplegia and paralysis of accommodation are frequent. The autonomic neuropathy leads to paralysis of accommodation with preservation of light reflex. This pattern distinguishes diphtheritic paralysis from other conditions like botulism. Autonomic neuropathy involves the heart, vasomotor tone, urinary bladder and bowel. Motor weakness may involve the limbs or respiratory muscles. Ascending polyneuritic type of lesions may follow 2-3 months after the acute attack of diphtheria. Though there are pathological lesions demonstrable in the adrenals, most cases do not manifest clinically.

Diagnosis

The diagnosis of diphtheria is essentially clinical. Confirmation of the diagnosis depends on the demonstration of the organism in stained smears made from the membrane and by culture using Loeffler's medium. Fluorescent antitoxin staining provides a method for rapid diagnosis. Toxigenicity can be assessed by guinea pig inoculation, passive agar gel diffusion (Elek plate method), or counter immunoelectrophoresis.

Differential diagnosis: Acute follicular tonsillitis with exudate over the tonsils may resemble diphtheria. In follicular tonsillitis the exudate is confined to the tonsils, it is yellowish and can be wiped off without being adherent. The fever is high in acute tonsillitis whereas it is only mild in diphtheria. Regional lymphadenopathy is more marked in diphtheria than in acute tonsillitis.

Agranulocytosis and acute leukemia may lead to necrotic ulceration of the tonsils. In these there is no true membrane. The tonsils are red, enlarged, and necrotic or

hemorrhagic. Hematological examination establishes the diagnosis. In all cases of reasonable clinical suspicion, the antitoxin should be given without delay.

Treatment

The aims of treatment are to neutralize the formed toxins and eradicate the organisms from the primary site to prevent further production of toxin. The formed toxin is neutralized by the administration of diphtheria antitoxin (**anti-diphtheritic serum-ADS**) in adequate quantities. It can be given intramuscularly or intravenously. The dose can be roughly estimated from the extent of the membrane.

Only one tonsil involved	20,000 units
Both tonsils	40,000 units
Laryngeal and pharyngeal forms	80,000 units
Severe cases	120,000 units

The anti-diphtheritic serum is prepared in horses and so sensitivity to horse serum has to be tested by appropriate intradermal test using 0.1 mL of 1/100 solution. One centimeter erythema developing within 20 min indicates allergy. In allergic cases ADS should be administered only after desensitization or after taking appropriate measures to combat anaphylactic shock. Usually one dose of ADS is sufficient.

Corynebacterium diphtheriae is sensitive to penicillin and erythromycin. Procaine penicillin 600,000 units IM bd or erythromycin 40 mg/kg body weight in four divided doses, for 6 to 7 days is adequate to eliminate the organisms. Since there is the possibility of developing carrier state and spread of the infection, the child should be allowed to mix with other children only after ensuring that three repeated throat cultures are negative. General measures of treatment include rest in bed for two weeks and soft liquid feeds. Tetracycline, rifampicin and clindamycin are also effective against *C. diphtheriae*.

Since an attack of diphtheria may not lead to solid immunity, all cases should be followed up with regular vaccination with diphtheria toxoid, during convalescence.

Treatment of complications: Myocarditis is managed with strict bed rest, use of antiarrhythmic drugs, and supportive measures. Corticosteroids (betamethasone 8 mg four times daily) have been employed with beneficial results in some. Artificial pacing may be required if heart block develops.

Neuritis is usually self-limiting and does not respond to any specific treatment. Supportive care and physiotherapy are indicated. Nasogastric tube may be required to aid feeding, if there is palatal and pharyngeal paralysis.

Respiratory obstruction due to the presence of the membrane is an emergency indication for tracheostomy and maintenance of the airway. Respiratory paralysis is managed by artificial ventilation.

6

Prevention

Prevention includes general active immunization and management of contacts. Active immunization is done with diphtheria, pertussis, tetanus (DPT) vaccine which is also known as triple antigen. The first dose should be given at two months and thereafter two more doses at four week intervals. Booster doses must be given at the second and fifth years. The DPT vaccine gives substantial immunity, but rarely the disease may occur even in immunized children. *Hemophilus influenzae* type b (Hib) vaccine can be combined with DPT vaccination for primary vaccination.

Immediate contacts should be given 2000 units of ADS. Throat swab culture should be done to identify the carrier state. Carriers should be given treatment. Penicillin or erythromycin is used to eradicate the infection. An alternative is rifampicin in a dose of 600 mg daily orally for 7 days.

A booster dose of DPT is required in previously immunized persons on fresh exposure.

Non-diphtheria corynebacteria: At times, corynebacteria other than C-diphtheriae may cause lesions as given in Table 38.1.

Whooping Cough

Syn: Pertussis

Introduction

The term pertussis, which means intensive cough, is an acute respiratory infection, seen more commonly in young children. The disease is also more serious in them. The term “whooping cough” is derived from the occurrence of progressive repetitive paroxysms of cough followed by inspiratory whoop. Natural pertussis infection and vaccination do not produce life-long immunity. The immunity wanes over a few decades. Since there is almost

complete coverage of DPT vaccination in children, adolescents and adults may become susceptible to infection increasingly. It is therefore possible that adults develop pertussis infection.

Pertussis is caused by *Bordetella pertussis* which is highly infective. *Bordetella parapertussis* and *B. bronchi-septica* are members of the same genus, rarely causing disease in man. Maximum incidence is seen in children below five years and the mortality is highest for children below 1 year of age. The organisms are spread by droplet infection and the route of entry is the respiratory tract. The infectious period is the catarrhal prodrome and for three weeks after the onset of illness. *Bordetella* are small gram-negative coccobacilli, exclusively pathogenic to humans. The genome of *B.pertussis* has been sequenced.

Pathology

The mucosal lining of the respiratory tract shows inflammation. Peribronchial lymphoid hyperplasia occurs initially and this is followed by necrosis of the midzonal and basilar layers of the bronchial epithelium. This leads to the accumulation of tenacious mucus, atelectasis and eventually bronchiectasis.

Clinical Manifestations

The incubation period is usually 7-14 days but may be prolonged to 20 days. Three stages can be distinguished—*catarrhal*, *paroxysmal* and *convalescent*—each lasting up to 2 weeks so that the course of the disease extends to 6-8 weeks.

The **catarrhal stage** manifests with rhinorrhea, mild fever, and cough. During this stage, clinical recognition of the disease is difficult. This is the most infective stage.

In the **paroxysmal stage** cough starts, increases in severity, and becomes repetitive and explosive. Each paroxysm is followed by a whoop produced by a sudden massive inspiratory effort through a narrowed glottis. During the paroxysms of cough the infant develops facial congestion, distension of neck and scalp veins, lacrimation, cyanosis, and clouding of consciousness. The paroxysm ends with the onset of vomiting. The whoop may not be distinctly made out in younger infants, but they may become asphyxiated and develop anoxic convulsions. Physical examination may reveal periorbital edema. In the uncomplicated cases lung signs are usually absent. Pertussis occurring in adults causes prolonged cough. With increasing age the manifestations also become more severe.

Convalescence is marked by the decrease in frequency and severity of the paroxysms. Vomiting subsides and the patient’s appetite improves. At this stage the child is very susceptible to develop superinfections by other respiratory pathogens and this may lead to recurrence of the paroxysms of cough. When this occurs it may last for several months.

Complications

Complications are common to develop

A. Respiratory:

Otitis media, especially in infants

Bronchitis

Bronchopneumonia

Atelectasis (segmental or lobar)

Interstitial or subcutaneous emphysema or pneumothorax due to rupture of alveoli.

Bronchiectasis

Flare-up of tuberculosis.

Sudden death of the infant may occur

B. Central nervous system:

Convulsions may occur due to anoxia, encephalopathy or rarely intracranial hemorrhage.

C. Gastrointestinal:

Severe vomiting with dehydration, tetany, ulceration of the frenum of the tongue (due to biting during a paroxysm), prolapse rectum, hernia.

D. Hemorrhages:

Epistaxis

Subconjunctival hemorrhage

Hemoptysis, hematemesis

E. Malnutrition:

Severe emaciation occurs in most of the affected children. In poor communities it is the starting point for marasmus and kwashiorkor.

Diagnosis

The disease has to be suspected clinically, particularly in an unimmunized child with known contact with the disease. Total leucocyte count is elevated to 20,000 to 50,000/cmm with absolute lymphocytosis. A leukemoid reaction may sometimes occur. Chest X-ray may show perihilar infiltrates or segmental collapse. Bacteriological diagnosis is established by culturing the organism obtained from nasopharyngeal swabs. Fluorescent antibody staining of pharyngeal specimens provides a rapid and specific diagnosis. PCR using nasopharyngeal aspirate reveals the organisms. In cases with duration above two weeks IgG antitoxic antibody can be demonstrated in serum.

Differential diagnosis: Whooping cough has to be differentiated from other conditions in childhood causing spasmodic cough. These are acute bronchitis, bronchopneumonia, aspiration of foreign bodies; extrinsic compression of the trachea and bronchi by tuberculous glands or other masses, obstructive airway disease, cystic fibrosis, and congenital malformations of the upper respiratory tract. Infections with *B. parapertussis*, *B. bronchiseptica* and adenovirus types 1, 2, 3 and 5 closely resemble whooping cough and cannot be clinically differentiated. Respiratory syncytial virus infection is becoming more widespread, accounting for a high proportion of respiratory morbidity

in children. This has to be borne in mind. Postnasal drip caused by dripping of exudate from the nasopharynx may lead to spasmodic cough when the child lies in bed. This may mimic whooping cough.

Treatment

Supportive care is important to maintain nutrition, prevent aspiration into the respiratory tract and maintain the airway. The airway is cleared by suction of the exudates. Anoxic convulsions are managed by administration of oxygen and anti-convulsants. Small, frequent feeds are tolerated if given soon after a paroxysm of cough. Intravenous fluids may be required if the child is dehydrated. In general, administration of antibiotics does not shorten the paroxysmal stage, once it is established. Erythromycin 50 mg/kg/day given for 5-7 days will reduce the period of communicability. It may even abort or prevent the progress of the disease if given in the catarrhal stage. Ampicillin, chloramphenicol and cotrimoxazole may also be used as alternative drugs. Azithromycin 250-500 mg po, od for 7-10 days is effective in controlling the infection if started early. Clarithromycin is a suitable alternative.

Antibodies are not transferred transplacentally in the case of whooping cough. In most patients, a single attack confers life-long immunity.

Prevention

Active immunization is achieved by the administration of the pertussis vaccine, usually given in combination with diphtheria and tetanus toxoids (DPT). The vaccine contains killed *B. pertussis*. The initial dose is given at 2 months, with 2 more doses at 4 week intervals. The first booster is given 1 year later and the next one at school entry. Adverse reactions may develop after vaccination. These are local reactions, fever developing within 12 to 24 hours of injection and rarely post-vaccination encephalitis. The reported risk of encephalitis is 1 in 10^5 to 10^6 vaccinations. At present the benefits of vaccination far outweigh the risks and, hence vaccination should be recommended for all infants. Contraindication to vaccination is severe adverse reaction to a previous dose. If a child has missed pertussis vaccination at the ideal period, it is better to start the course as early as possible. Conventional pertussis vaccine produced in India contains products of whole organisms. It is cheap, but it is likely to cause more adverse reactions. With whole cell vaccines the immunity begins to diminish after 3-5 years and possibly vanishes by 10-12 years.

(Scott A Halperin. N Eng J Med 2007;356:110-113).

Acellular vaccines containing up to five specific antigens of *B. pertussis* are available in other countries. They produce less of adverse reactions, but are more

costly. Adults exposed to risk of infection, such as doctors and nurses can also be protected by vaccination.

Haemophilus Influenzae Infections

General Considerations

Haemophilus are pleomorphic gram-negative rods, which are generally aerobic, but can be facultatively anaerobic. *H. influenzae* is an exclusively human parasite, residing principally in the upper respiratory tract.

Haemophilus influenzae exists in coccobacillary form in cultures but shows bacillary morphology in cerebrospinal fluid of patients with meningitis. It is mainly aerobic but can also grow anaerobically. Culture yields capsulated and non-capsulated colonies. The capsulated forms are more virulent. The organisms have been classified into six types designated a to f based on the capsular polysaccharide. The polysaccharide capsule-polyribosyl ribitol phosphate (PRP) is an important determinant of virulence and the major target for specific immunity. Type b is responsible for most of the serious infections. Around 60-80% of children below three years harbor the organism in the upper respiratory tract. Maternal antibodies confer passive immunity to the child upto the age of two months. Children aged two months to three years are more susceptible to infection. Natural immunity develops due to subclinical infections after the age of three years.

Pathogenesis and Pathology

Haemophilus influenzae may act as the primary pathogen to cause meningitis in children, laryngoepiglottitis, otitis media, pneumonia, arthritis, endocarditis, and pericarditis. It acts as a secondary pathogen in bronchitis, bronchiectasis and sinusitis in adults. Secondary infection is caused by noncapsulated strains.

CLINICAL SYNDROMES

***Haemophilus influenzae* meningitis** follows an acute course and is fatal in 90% of cases, if left untreated. Laryngoepiglottitis causes considerable edema and airway obstruction. Emergency tracheostomy may be necessary to save life. Infection of the lung and pleura lead to lobar pneumonia with empysema.

***Haemophilus influenzae* frequently causes pharyngitis** in children. In adults during prolonged antibiotic therapy superinfection by *H. influenzae* may develop. The

mucosa is red and may be covered by a soft yellow exudate. The local pain and discomfort are out of proportion to the appearance of the lesion. Systemic complications such as septicemia with arthritis, endocarditis, and pericarditis may occur, especially in children.

Secondary infection by *H. influenzae* causes bronchopneumonia, exacerbation of chronic bronchitis and other suppurative pulmonary lesions.

Laboratory Diagnosis

The organism can be identified by Gram stain and can be cultured from materials such as CSF, sputum, pus, etc. Since the organism is highly susceptible to low temperatures, refrigeration during transit should be avoided. The capsulated strain shows Quellung phenomenon when added to type B antiserum.

Treatment

The common antibiotics such as chloramphenicol, ampicillin, and cotrimoxazole are effective. Resistant strains have emerged. Tetracycline or chloramphenicol can be used for treating exacerbations of chronic bronchitis and emphysema. In milder nonfatal infections these drugs can be tried. Meningitis and epiglottitis are rapidly fatal if untreated. Ampicillin does not cross the blood brain barrier in adequate concentration. Third generation cephalosporins are the drugs of choice. For children cephalexin 200 mg/kg bw in divided doses IV has to be administered. For adults the daily dosage may reach up to 12 g. Ceftriaxone in a dose of 100-150 mg/kg bw/day is an effective alternative.

Active Prophylaxis

In many parts of the world a purified capsular polysaccharide vaccine is used. Vaccines have been developed through covalent linkage of the PRP to carrier protein. Four different types of vaccines are available. Hib polysaccharide tetanus protein conjugate vaccine (PRP-T) contains tetanus toxoid as the carrier protein. This can be given along with DTP vaccination in the second, third and fourth months. A booster dose may be required after two years. Routine vaccination has almost eliminated the infection in many countries.

In household contacts, children below the age of five years run the risk of acquiring infection. Rifampicin in a dose of 20 mg/kg daily given orally for 4 days eradicates the carriage of *H. influenzae*.

39

Salmonella Infections

S. Bhasi, K.V. Krishna Das

Chapter Summary

General Considerations	209
Typhoid Fever	209
Pathogenesis	210
Pathology	210
Clinical Feature	210
Diagnosis	211
Management	212
Antimicrobial Resistance	213
Paratyphoid Fever	214
Prevention of <i>Salmonella</i> Infections	214
Non-typhoid <i>Salmonella</i> Infections	215

General Considerations

Salmonella are members of enterobacteriaceae. They are gram-negative motile rods, commonly found in the intestinal tract of humans, several animals and many arthropods. More than 2000 serotypes have been identified.

Clinical syndromes caused by *Salmonella* include:

1. Typhoid fever and paratyphoid fevers caused by *S. typhi*, *S. paratyphi A*, *B* and *C* – collectively known as enteric fevers.
2. Gastroenteritis (*Salmonella* food poisoning)
3. Bacteremia with or without metastatic infection
4. Asymptomatic carrier state.

Typhoid Fever

Typhoid fever is an acute febrile systemic infection caused by *Salmonella typhi* with initial lesion in the bowel, bacteremia and subsequent affection of many tissues.

Etiology

Salmonella typhi is an exclusive pathogen of humans. 3 antigens have been demonstrated

1. Somatic antigen (called 'O' antigen) – a lipopolysaccharide cell wall antigen

Fig. 39.1: Schema of the antigens on salmonellae
O – somatic antigen H-flagellar antigen VI- virulence antigens

2. Flagellar antigen (called 'H' antigen) – formed from the structural proteins making up the flagella
3. The polysaccharide envelope VI antigen which confers virulence by masking the 'O' antigen from immunological attack (Fig. 39.1).

Epidemiology

The global incidence is around 15 to 30 million cases annually with half million deaths. The disease remains a serious public health problem in developing countries. The incidence in India is about 100 to 1000 cases per 100000 persons per year and enteric fevers continue to be a major infection throughout the country.

The organisms are excreted in feces and urine of cases of typhoid fever in the acute phase and upto 9 weeks during convalescence. Healthy carriers pass the organism in feces and urine without themselves suffering from the disease for indefinite periods. Disease is spread by fecal-oral route, infection getting in by contaminated water sources, milk, ice creams, processed meat, shell fish, food contaminated by infective food handlers and flies. The bacilli remain viable in water or food for considerable periods.

Pathogenesis

Several factors determine the establishment of infection. They are

1. *Size of the infective dose.* The average infective dose in immunocompetent subjects is 10^7 organisms. Higher infective doses are required to transmit paratyphoid.
2. Normal gastric acid rapidly kills the bacilli. Susceptibility is increased by diluting gastric acid by the ingestion of large quantities of fluids with and before meals, antacids, acid suppressant drugs, vagotomy and prior infection with *H.pylori*.
3. Virulence of the infecting strain – multi drug resistant organisms and isolates from fatal cases might vary in their virulence. Highly virulent strains are more invasive.
4. Immune status of the host and the status of bacteria in the upper part of the duodenum and jejunum.

Bacilli enter the epithelial lining of the distal ileum and reach the submucosa where they are phagocytosed by macrophages and polymorphs and reach mesenteric lymph nodes. There, they multiply and enter the blood stream via thoracic duct to produce transient bacteremia. This primary bacteremia results in the organisms reaching the liver, gallbladder, spleen, bone marrow, lymph nodes and other parts of the reticuloendothelial system where further intracellular multiplication occurs inside mononuclear cells throughout the 7 to 14 day incubation period. A second bacteremia follows accompanied by symptoms as the infection spreads throughout liver, gallbladder, spleen, Peyer's patches and bone marrow.

The organism produces endotoxins, which stimulate release of cytokines from macrophages and neutrophils responsible for inflammatory changes in various organs and production of constitutional symptoms and fever.

Pathology

Inflammatory changes mainly occur in the liver, spleen, lymph node, bone marrow and Peyer's patches consisting of mononuclear cell infiltration, hyperplasia and focal necrosis. Focal collections of mononuclear leukocytes are called **typhoid nodules**. The liver is enlarged and shows cloudy swelling. The Peyer's patches in the terminal ileum becomes swollen and surface undergoes necrosis with formation of ulcers. Blood vessels here may be eroded leading to intestinal hemorrhage. Ulceration may extend to the muscularis mucosa and serosa and may result in intestinal perforation. The rectus abdominis muscle may show Zenker's degeneration.

Clinical Features

The usual incubation period is 7-14 days (range from 3-60 days) Typhoid predominantly affects children and

young adults especially in endemic areas because of acquired immunity. It affects both sexes equally. The clinical manifestations are very variable ranging from fever with little other morbidity to marked toxemia and associated complications involving many systems. In a classical case onset is slow with fever, headache, lethargy, anorexia and malaise. The fever is continuous or remittent; it rises in a step ladder pattern in the first week. Chills and rigor do not occur if antipyretics are not used. Abdominal symptoms such as vague discomfort, pain, constipation in the first week, and diarrhea in the second and third weeks occur commonly in the majority of cases. Diarrhea is more common in children. Epistaxis may occur occasionally. Nonproductive cough may be prominent in a few and this may be mistaken for a primary respiratory disease.

Physical examination *in the first week* reveals relative bradycardia (slow pulse fever) and mild tenderness in the right iliac fossa. Erythematous 2-3 mm diameter maculopapular lesions called '*rose spots*' may appear over the upper abdomen and chest by the 5th or 6th day and fade off after varying periods. They are best made out in fair skinned people. They are rare in the local population. They fade after 2-3 days. They are caused by local vasodilatation; probably due to bacterial emboli. *In the second week* temperature reaches around 40°C and remains so for a few days. The tongue is coated in the center. Spleen is palpable 2-4 cm and soft in about 70% of cases. Abdomen is moderately distended (tumidity) with vague tenderness especially over the right iliac fossa. Palpation may also reveal gurgling due to distended ileal loops. Mild scattered wheeze in the chest is not uncommon. Malena or streaks of blood in feces may be present in a few. This should not be mistaken for typhoid hemorrhage in which bleeding is more pronounced.

Patients with advanced disease and toxemia may show "typhoid facies" (**typhoid state**). – a thin flushed face with staring apathetic expression. Typhoid encephalopathy may develop in severe cases in the second to fourth week and may present as muttering delirium, tremulousness of the fingers and wrist (**subsultus tendinum**), picking movement of the hands- example picking at the bed clothes (**carphology**) and a staring unarousable stupor – unconscious but eyes open (**coma vigil**) In uncomplicated untreated cases fever lasts for about 4 weeks and subsides by lysis.

Typhoid in children – It is a milder illness with diarrhea, vomiting and jaundice more commonly.

Neonatal typhoid may occur due to vertical transmission from infected mother during late pregnancy. It is rare but could be life threatening if it occurs.

Uncommon presentations

1. Gastroenteritis – acute presentation with vomiting and diarrhea. More common in children especially in paratyphoid

2. Acute bronchitis—fever cough and bilateral wheeze.
3. Acute abdominal pain mimicking acute appendicitis.
4. Jaundice from beginning – seen in about 1-5% cases. This may mimic viral hepatitis, leptospirosis or malaria
5. Lobar pneumonia caused by *S. typhi* (pneumotyphoid) may occur in 1-2%, *S. typhi* may be isolated from sputum culture. The chest lesion may resemble pneumococcal pneumonia.
6. Acute right upper abdominal pain may be mistaken for acute cholecystitis
7. Acute glomerulonephritis (nephrotyphoid) is seen in upto 3% cases – more common in children,
8. Fever with joint pain may resemble rheumatic fever. This occurs rarely.

Complications may develop quite frequently. These may be general or may be confined to the various organ systems. General complications include dehydration, typhoid state, coma vigil, convulsions in children, delirium and septic shock. Systemic complication are listed below:

Gastrointestinal system: Perforation of ileum with peritonitis, intestinal hemorrhage, paralytic ileus, cholecystitis

Respiratory: Pneumonia

Neuropsychiatric: Typhoid encephalopathy, typhoid meningitis, transverse myelitis, peripheral neuropathy

Hematological: Disseminated intravascular coagulation (DIC), thrombocytopenia

Genitourinary: Glomerulonephritis, pyelonephritis, urinary retention

Cardiovascular: Myocarditis, endocarditis, deep vein thrombosis, thrombophlebitis

Miscellaneous: Focal sepsis, abscess in liver, spleen, breast, typhoid osteomyelitis, parotitis, arthritis, bone abscess (Brodie's abscess)

Relapse

Intestinal hemorrhage occurs during the second or more commonly, the third week of illness. Mild bleeding manifesting as occult blood or malena is seen in about 20% of cases. Severe bleeding from the ulcerated Peyer's patches occurs in about 2% of cases. Unexplained tachycardia, fall in BP, sudden drop in temperature and pallor indicate the onset of intestinal hemorrhage. Patient passes fresh blood and clotted blood with feces in large quantities. If not treated, hypovolemic shock sets in and death follows.

Intestinal perforation occurs in 1-3 % of cases. Terminal 50 cm of the ileum is the site of perforation. The onset of perforation may be heralded by abdominal pain, tenderness and rigidity and features of shock including sudden fall of temperature. Signs of perforation such as abdominal rigidity tenderness and absence of peristaltic

sounds develop from the right iliac fossa and later become generalized. Due to escape of gas into the peritoneal cavity the liver dullness may be obliterated. The temperature may fall. Signs of free fluid in the peritoneal cavity and general peritonitis develop later. Severely ill patients may present without classical features and may show only restlessness, tachycardia and hypotension,

Presence of gas under the diaphragm can be demonstrated by X-ray chest taken in the erect position. Ultrasonography helps to confirm the diagnosis. Secondary infection of the peritoneal cavity leads to increasing toxemia. In untreated cases mortality exceeds 80%. With prompt treatment mortality can be reduced to less than 10%. In those who survive peritonitis may become localized to form an abscess palpable as a mass in the right iliac fossa.

Relapse In 5-10% cases one to three weeks after recovery, fever and other symptoms return. Blood culture often becomes positive again. Relapse rate is lower in those treated with fluoroquinolones and ceftriaxone, compared to those treated with chloramphenicol, cotrimoxazole, ampicillin or amoxicillin. Relapses are generally milder than the initial illness. They respond to the same antimicrobials. Usually only one relapse occurs but rarely several relapses may occur in succession, extending the febrile episode to even a few months.

Chronic carriers are those who continue to excrete *Salmonella* in feces or urine for more than one year. Fecal carriage is more frequent in women above 40 years and those with gallbladder disease. Urinary carriage may be seen more commonly in people with nephrolithiasis or schistosomiasis. Chronic carriers act as source of infection to others especially if they are working as cooks or food handlers.

Immunity: Infection confers partial immunity, which is unrelated to titer of antibodies against O, H, or Vi antigen.

Diagnosis

Clinical: Typhoid fever has to be considered in the differential diagnosis of all prolonged febrile illnesses seen in tropical countries. These include hepatic amebiasis, tuberculosis, infective endocarditis, brucellosis, leptospirosis, typhus, viral hepatitis, malaria, lymphoma, infectious mononucleosis, and prolonged viral fever.

Clinical clues to suspect typhoid

- Fever more than 5-7 days especially in children and young adults
- Gastrointestinal symptoms- vague abdominal pain altered bowel habits ± melena or hematochezia
- Relative bradycardia
- Palpable soft spleen
- Palpable liver ± tenderness

- Central coating of the tongue
- Perforation or peritonitis
- Major GI bleed
- Severe toxemia
- Myocarditis
- And peripheral circulatory failure

Laboratory Diagnosis

A. Isolation of *Salmonella typhi*

1. **Blood culture is the** mainstay of definite diagnosis. Blood is taken directly into 10 times its volume of culture media and incubated. Blood clot treated with streptokinase can also be used. Blood culture is usually positive in 72 hours. Sometimes incubation for up to 7 days may be needed. Positivity of blood cultures progressively diminishes from 90% to 75%, 60% and 25% or less respectively from the first week to the fourth week of the illness. Culture becomes negative soon after starting specific antibiotics.
2. **Bone marrow culture:** This gives the highest positivity. It is especially useful when blood culture is negative. It may remain positive even after starting antimicrobials. 1 to 2 mL of bone marrow aspirate is sufficient.
3. **Bile culture:** Culture of bile aspirated from the duodenum also yields better results.
4. **Feces culture:** This gives higher yield in the third week up to 75 %. Specificity is limited because of the positive results in carriers.
5. **Skin snip from rose spots:** This is not commonly done. It is reported to be positive in 75% of cases, and it may remain positive even for a few days after starting antibiotics.
6. **Urine culture:** This is positive in only 25 to 35% of cases, since bacteriuria may be intermittent. Specificity is limited since carrier state is known to exist. Both in the case of feces and urine culture positive results associated with rise in antibody titre is diagnostic.

B. Widal test: This identifies the agglutinating antibodies against the O and H antigens for *S. typhi* and *S. paratyphi* A and B.

It is a time honoured test in vogue for over eight decades introduced by Fernand Widal (French physician, 1862-1929) for the diagnosis of enteric fevers.

Antibody generally appears by the end of first week, steadily increases upto 3rd or 4th week and then gradually declines after varying periods, often months. Patients in endemic areas who are exposed to *Salmonella* antigen earlier (clinical/subclinical infection or TAB vaccination) may give a rapid and stronger antibody response.

The O antigen is shared by other *Salmonella* and other members of enterobacteriaceae, this sharing being only

partial. Both O and H antibodies increase but the O antibody rises earlier than H antibody. The O antibodies are more specific than H antibody and therefore they are diagnostically more important. The antibodies fall rapidly, reaching low values after 6-12 months. A four fold rise in antibody titre in paired samples collected 5 – 7 days apart is a fairly reliable evidence for diagnosis. The result of a single acute sample should be interpreted taking into account the locally prevalent-widal titer in the general population. Titers of 1/200 or more are suggestive. In the general population of south India 10% show H antibody titre upto 1 : 100 dilution and 2% upto 1: 200 dilution. Prevalence of O antibody in the general population is much less.

O antigen of paratyphoid A and B show cross reaction with that of *S. typhi* and hence O antibody titer is not commonly taken into consideration in the diagnosis of paratyphoid fevers. Widal test is simple and cheap compared to blood culture, but fraught with pitfalls.

The Widal test has a few disadvantages. These include delay or blunting of the antibody response, rise of only the O or H antibody, pre-existing high titers of antibody, false positive response and anamnestic reaction.

Anamnestic reaction: This is the rise in antibody levels in patients who have been exposed to antigen in the past, often by TAB vaccination, when they get any non-specific febrile illness. Hence information about previous vaccination is necessary to assess the diagnostic reliability. This rise in titer involves antibodies of all the *Salmonellae* and it is transient. More over a four-fold rise in titer may not occur on repeating the test.

Early antibiotic treatment may blunt the antibody response. False positive Widal may occur in malaria, rheumatoid arthritis, chronic liver disease and others.

Other Serological Tests

Many other tests for detection of antibodies, *S. typhi* antigen and *Salmonella* DNA in the body fluids have been described. These include passive hemagglutination, counter immunoelectrophoresis, latex agglutination and PCR.

Other laboratory findings include mild normocytic normochromic anemia mild thrombocytopenia and leukopenia with relative lymphocytosis. Leukocytosis may occur when typhoid is complicated by perforation, peritonitis, secondary sepsis or major bleed. The ESR is generally not elevated in uncomplicated typhoid. Mild to moderate elevation of transaminases (ALT and AST) is common.

MANAGEMENT

1. Supportive
2. Symptomatic

- 3. Specific – antimicrobial
- 4. Prevention

General Supportive Care

Rest in bed, proper nursing care, measures to avoid bed sores and maintenance of oral hygiene are to be instituted. A nutritious diet helps in recovery. The diet must be easily digestible and of low residue type. At least 1200-1500 Calories should be supplied as diet. Fluid and electrolyte balance have to be looked after. Generally 2-3 L of fluid should be given orally if patient tolerates. If not I V fluids are indicated. In places where IV fluids cannot be given and the patients cannot accept oral fluids due to vomiting, about 1-1.5L of saline can be given in 3-4 hours as a rectal drip through a urinary catheter introduced high up into the rectum, if the patient can tolerate.

Symptomatic Treatment

Paracetamol is useful for treating fever and headache in doses of 0.5 g 6.h. Tepid sponging, ice caps and physical methods of cooling may be given to lower the temperature when indicated and to give comfort and relief.

Abdominal discomfort and bloated feeling can be reduced by dietary adjustment-low residue easily digestible articles of food given in small quantities at 2-3 hours intervals. Antacid and anti-flatulent drugs such as magnesium hydroxide (250 mg) and activated dimethicone 50 mg given 6 h are effective. Constipation can be relived by drugs like milk of magnesia 11.25 mL as emulsion or sodium picosulphate 10 mg as tablets or syrup. Diarrhea can be controlled by avoiding milk and fatty foods in the diet and an opiod such as codeine phosphate 10-20 mg orally.

Specific Antimicrobial Drugs

The initial choice of antimicrobial drugs depends on the sensitivity pattern of *S.typhi* and *S. paratyphi* isolates in the local area. The following drugs are commonly used.

Fluoroquinolones- ciprofloxacin and ofloxacin

Cephalosporins-ceftriaxone (IM/IV), cefixime(oral) chloramphenicol, ampicillin / amoxicillin, cotrimoxazole in the usual doses. Except in resistant cases all these drugs produce fall in temperature to normal in 3-5 days, reduction of toxemia and cure in more than 90% of cases within 7-10 days (Table 39.1).

Antimicrobial Resistance of Salmonellae

This is mediated by plasmids. Chloramphenicol resistance was initially described in 1972 from Kozhikode by Jayaram Panicker et al. Several reports from Calcutta, Chandigarh and many parts of India and other countries of the world followed soon. The late 1980s witnessed widespread emergence of multidrug resistant *Salmonellae*, particularly *S. typhi*, resistant to chloramphenicol, cotrimoxazole and amoxicillin/ampicillin. This phenomenon continued till the 1990s. Fluoroquinolones, particularly ciprofloxacin and ofloxacin, and ceftriaxone became the drugs of first choice for typhoid. With the drastic reduction in the usage of chloramphenicol, resistance to this drug fell to less than 20% by 2000. Resistance to quinolones started appearing in the mid '90s at many centers in India and abroad and reached upto 50%. Ciprofloxacin- resistant cases may still be sensitive to ofloxacin. Resistance to nalidixic acid is a standard criterion used to assess the drug sensitivity of Salmonella. Resistance to nalidixic acid warrants the use of higher doses of quinolones. Cephalosporin resistance has also been reported but it is not widespread.

S.Typhi and paratyphi isolates can be classified into

- 1. Sensitive to 1st line antimicrobials like chloramphenicol, cotrimoxazole, and amoxycillin/ampicillin
- 2. Multi drug resistant but quinolone sensitive
- 3. Multi drug resistant including quinolone resistance

Fluoroquinolones -ciprofloxacin and ofloxacin- are very effective drugs for treatment of quinolone- sensitive typhoid fever with low relapse rate and chronic carrier

Commonly used antimicrobials in typhoid				
Antibiotics	Dose mg/kg/day	No of doses	Route	Duration days
Chloramphenicol	50 - 75	4	Oral/IV	14
Cotrimoxazole	6.5-10 trimethoprim	2	Oral/	14
Amoxicillin	75-100	3	Oral/IM/IV	14
Ciprofloxacin	1.5 g/day oral/400 mg IV bd	2/2	Oral/IV	7-14
Ofloxacin	800 mg/day	2	Oral/	7-14
Ceftriaxone	60 mg/kg	-2	IV/IM	7-14
Cefotaxime	80 mg/kg	3	IV	7-14
Cefixime	20mg/kg	2	Oral	7-14
Azithromycin	8-10mg/kg	1	Oral/IV	7

state (< 2 %). Chloramphenicol, which used to be the traditional first line drug of choice is less effective in this regard. Ceftriaxone and azithromycin (oral or parenteral) are useful for treating MDR typhoid including quinolone resistance.

Unless there are definite contraindications the drugs and fluids can be given orally. Indications for parenteral administration include severe toxemia, vomiting, and complications such as perforation and peritonitis, hemorrhage, paralytic ileus, meningitis, encephalopathy and toxic shock.

Drugs should be started in full dosage and administered regularly. If the organisms are sensitive, temperature starts coming down in 48-72 hours after starting the drug. Failure to achieve fall of temperature may be due to drug resistance of the organism or other coexisting complications. The drugs have to be continued at full dose for 5-7 days after the temperature has touched normal and remained so. Premature withdrawal of antibiotic therapy predisposes to relapse especially when bacteriostatic drugs like chloramphenicol are used. Toxicity of the drug should be look for.

Role of Glucocorticoids in Typhoid

Short course of oral or parenteral corticosteroids for 3-5 days has been found to be beneficial in patients with severe toxemia who are acutely ill or have encephalopathy and hypotension. Different regimens have been tried, eg. hydrocortisone 300 mg IV daily in divided doses for 3 days or prednisolone 30-40 mg (1 mg/kg bw) for 3-5 days or other preparations in equipotent dosage.

Prognosis. With early diagnosis and proper treatment, prognosis is good with full recovery in the vast majority. In uncomplicated cases, the mortality is 1-2%. Complications such as toxemia, hemorrhage, perforation and meningitis increase the mortality. Septic shock and multi-organ failure are serious with higher mortality.

TREATMENT OF COMPLICATIONS

Intestinal perforation: If the perforation is recent (within 12 hours) and the general condition satisfactory, emergency surgical closure with broad spectrum antibiotic coverage is indicated. If perforation is more than several hours old and the general condition poor, conservative treatment with IV broad spectrum antimicrobial combinations, IV fluids and other supportive measures should be instituted. With proper care the vast majority of these patients can be saved.

Intestinal hemorrhage: Blood loss has to be corrected with blood transfusion if there are signs of hypovolemia such as increasing pulse rate and fall in blood pressure, with continuance of active bleeding. In a severe case rapid quantitative replacement of several units of fresh blood may be required.

Treatment of chronic carriers: Most chronic carriers without gallstone disease can be cured by prolonged course of antimicrobials. Useful regimens are

1. Cotrimoxazole – 6.5 to 10 mg/kg of trimethoprim in two divided doses for 2 months
2. Ciprofloxacin 750 mg twice daily for 4 weeks
3. Amoxycillin/ampicillin 100 mg/kg with probenecid in 4 divided doses for 3 months

For patients with gallstone disease cholecystectomy is indicated in addition.

Treatment of Relapse

Usually relapse also responds to the same antibiotics which are effective for the primary disease. Hence the same medication should be continued, preferably for a longer period, with bacteriological monitoring.

PARATYPHOID FEVER

These are produced by *Salmonella paratyphi* A, B and C. Incubation period is shorter. The illness generally resembles typhoid in clinical pattern but toxemia and complications are less in the majority of cases. The duration of illness is shorter and mortality is less. At present more severe cases are being reported from south Asian countries. There is also disproportionate increase in paratyphoid fever. Gastroenteritis like presentation is more common, especially in children with *Paratyphi* A infection. In some cases paratyphoid may equal typhoid in severity and complications. Diagnosis is confirmed by isolating the organism and serological tests. Treatment is on lines similar to that of typhoid.

Prevention of Salmonella Infections

Personal hygiene, environmental sanitation and eradication of carriers help to prevent salmonella infection. Vaccination is indicated for persons travelling into endemic areas and for contacts and neighbors around index cases.

Vaccines

1. TAB vaccine: This is the most time-tested vaccine. It is a parenteral, killed, whole cell typhoid-paratyphoid A and B vaccine. It is effective, but largely discontinued in many countries because of side effects. In adults 2 doses of 0.5 mL given IM 1-2 weeks apart followed by booster doses every year is the recommended schedule. Adverse side effects include local pain and fever.
2. Vi polysaccharide vaccine – This can be used above the age of 2 years. A single IM or SC injection of 25 mcg gives 70-80% protection for 3 years. Revaccination is recommended every three years.
3. Ty 21a vaccine – This is a Swiss, live attenuated oral vaccine recommended for persons above 6 years of

age. Three doses are to be given on alternate days. Moderate protection occurs for three years.

None of the vaccines produces absolute protection and typhoid can occur if the infecting dose is very high.

A new Vi conjugate vaccine has been developed recently and preliminary data shows efficacy.

Disinfection of water sources with bleaching powder, boiling drinking water, anti-house fly measures and regular washing of hands before eating help to prevent spread of infection and contain the outbreak of typhoid.

Non-typhoid *Salmonella* Infections

These are produced by *Salmonella enteritidis* and *Salmonella typhimurium*. They lead to enterocolitis, bacteremia and localized infections.

Epidemiology : Infection is spread through food and water. Many animals such as chicken, ducks, cattle, sheep, horses, dogs, cats and rodents harbor these organisms as commensals in the intestines. Chicken and duck eggs constitute the largest reservoir of infection. Fish and mussels grown in contaminated water may act as sources for localized outbreaks. Humans develop convalescent or healthy carrier state and excrete the organisms for long periods.

Pathology: After gaining entry through food or drinks the organisms multiply in the small intestine and colon to produce inflammation of the lamina propria of the villi of both the small and large intestines. The lymphoid follicles are enlarged and become swollen. Diarrhea is produced by the production of enterotoxin and direct epithelial invasion. Organisms enter the blood stream to produce bacteremia and metastatic lesions. Conditions like sickle cell anemia and other hemoglobinopathies predispose to

the development of recurrent *Salmonella* infections. Osteomyelitis is common in them.

Clinical Features

Enterocolitis: This is also known as *Salmonella* food poisoning. Lesions occur both in the large and small intestines. Incubation period is usually 8-24 hours but can go up to 3 days. Patients present with fever, abdominal pain and diarrhea. Diarrhea is produced by production of enterotoxin and direct epithelial invasion. The nature of stool varies from profuse watery, to frank dysentery. In healthy young adults *Salmonella* gastroenteritis is usually a benign self-limiting illness, but in young children and elderly, severe dehydration may develop. Spontaneous resolution usually occurs in three to four days. Bacteremia occurs in 1-2%, more commonly in elderly and immunocompromised subjects. Microscopy of the feces shows cellular exudates and organisms can be cultured from feces.

Treatment Mainstay is replacement of fluid and electrolytes. Antibiotics do not alter the outcome. In severe cases ciprofloxacin may be useful.

Salmonella Bacteremia

This is characterized by prolonged or intermittent fever associated with rigor and chills and positive blood culture. Gastrointestinal symptoms may or may not precede bacteremia. Diagnosis is established by positive blood culture. Localized lesions develop in 25% of cases. This includes bronchopneumonia, lung abscess, pleurisy, empyema, pericarditis, endocarditis, nephritis, arthritis, osteomyelitis and meningitis. WBC count is usually normal but may be elevated when localized suppuration develops. Treatment is with systemic antibiotics on lines similar to that of typhoid.

Shigella Infections

GENERAL CONSIDERATIONS

Bacillary dysentery is caused by organisms belonging to the genus *Shigella*. Clinically dysentery is characterized by diarrhea with blood and mucus in the stool. Fever and abdominal pain may be present in the majority. *Shigella* dysentery is common in the tropics where environmental sanitation is poor and food hygiene is low.

Shigella are gram -ve non-motile, non-capsulated bacilli belonging to the family enterobacteriaceae. They are classified into 4 species on the basis of antigenic and biochemical features.

1. ***Shigella dysenteriae*** – Types 1 and 11 (*S. shigae* and *S. schimittii*) Type 1 is responsible for the most severe form of dysentery. They account for 8–25% of cases in India.
2. ***Shigella flexneri*** – Most common pathogen responsible for dysentery in developing countries – accounts for 50–85% of cases in India.
3. ***Shigella sonnei*** – Typically causes mild watery diarrhea – commonest cause in the west, responsible for 2–24% cases in India.
4. ***Shigella boydii*** – Least common isolate, usually produces mild disease.

S. shigae is very virulent pathogen, the infective dose can be as low as 10 to 100 organisms.

Epidemiology

Man is the main host. Infection is transmitted by fecal – oral route. Contaminated water supply, low personal hygiene, overcrowding, inadequate sewage facilities and proliferation of house flies contribute to the spread of disease. Apart from contamination of food and water, disease can be acquired through fomites, lavatory seats, door handles and others. During clinical illness and for upto 6 weeks after recovery organisms are excreted in the feces. These may survive for several months in food and water. *Shigellae* are relatively resistant to gastric acid.

PATHOGENESIS AND PATHOLOGY

Reaching the colon, organisms adhere to the mucosal surface and penetrate the epithelial cell lining where they

multiply intracellularly. Maximum involvement is usually in the rectosigmoid region. The entire colon may be affected. Mucosa is inflamed. Shallow ulcers are formed due to necrosis of mucosa. Biopsy specimen shows ulcers and crypt abscess. In severe cases necrosis of the mucosa may occur. The necrosed mucosa may be passed as intestinal casts.

Shigella dysenteriae type 1 produces a powerful exotoxin with enterotoxic and cytotoxic effects which are responsible for the colonic lesions and general toxemia. The toxin may act on the small intestine and lead to secretory diarrhea. Shiga toxin can also cause hemolytic uremic syndrome (HUS) as a complication. *Escherichia coli* 0157:H7 can also produce Shiga toxin and lead on to HUS. This toxin is known as *verotoxin*. HUS is more often caused by *E. coli* than *S. shigae*.

CLINICAL MANIFESTATIONS

Incubation period varies from 1–7 days and in severe cases, it may be as short as few hours. The illness usually starts with fever, colicky abdominal pain and diarrhea with blood and mucus in feces. The stool passed early in the illness contains fecal material, but subsequently it changes into mucus and blood with only small parts of fecal matter. Urgency and tenesmus are marked. Abdominal tenderness is usually prominent in the lower quadrant. The number of stools may exceed 28–30 times per day. In ordinary cases, the symptoms subside within a week. Some cases may be mild and ambulatory.

Fulminant dysentery is characterized by toxemia, electrolyte loss with hyponatremia, prostration and severe bloody diarrhea. In this type mortality may be high especially in children.

Complications

1. General – dehydration, electrolyte imbalance, circulatory failure
2. Renal failure – either due to hypotension or rarely hemolytic uremic syndrome, especially in children
3. Sepsis and septic shock – either primarily due to *Shigella dysenteriae* or due to polymicrobial bacteremia due to other coliforms.
4. Portal pyemia and multiple abscesses in the liver may occur rarely.
5. Intestinal perforation, paralytic ileus and intussusception may occur rarely.
6. Post dysentery complications – 1-3 weeks after resolution of the dysentery, arthritis or full fledged Reiter's syndrome with arthritis, conjunctivitis and urethritis may develop. Presence of HLA B-27 predisposes to this complication.

Diagnosis

Clinically the disease should be suspected when dysentery occurs with fever and signs of toxemia. Diagnosis of

TABLE 40.1

Differentiating features between bacillary and amebic dysentery		
Clinical features	Bacillary dysentery	Amebic dysentery
Onset	Sudden	Slow
Incubation period	Few days	Weeks to months
Number of stools/ day	Over 20	Below 15
Nature of feces blood+feces	Mucus and blood	Mucus,
Reaction of feces	Alkaline	Acid
Clinical course	Acute	Subacute
Microscopy of feces	Cellular exudate	RBCs and <i>E. histolytica</i>
Culture of feces	Shigella	Special methods for isolating ameba
Note: With the improvement in sanitation and the economic progress, amebic dysentery has become uncommon.		

dysentery is confirmed by observing blood and mucus in feces macroscopically and further by microscopy.

1. Microscopic examination of feces reveals large number of erythrocytes, pus cells and macrophages, collectively called *cellular exudates*.
2. *Shigella* can be isolated by culture of rectal swab or fresh feces transported to the laboratory in special medium.
3. Blood count usually reveals neutrophil leukocytosis
4. Sigmoidoscopy reveals superficial ulcers all along the rectal mucosa with intervening areas also showing hyperemia.

Differential Diagnosis

The common conditions to be differentiated include amebic dysentery, fulminant ulcerative colitis, staphylococcal food poisoning, or salmonellosis *Campylobacter jejuni* infection, viral enteritis cholera, necrotizing enterocolitis, antibiotic induced diarrheas rectal carcinoma and other ulcerating lesions. Sometimes amebic dysentery and bacillary dysentery may coexist (Table 40.1).

Enteritis caused by *Vitrio cholerae* and other forms of gastroenteritis show watery stools without blood and mucus.

Surgical conditions such as diverticulitis and carcinoma should be excluded if the clinical picture is atypical and response to treatment is unsatisfactory.

TREATMENT

1. *General and supportive measure include* correction of fluid and electrolyte losses. Potassium loss may be severe since the mucus is rich in potassium. Majority need oral fluids and electrolytes including potassium. Severe cases should be hospitalized. They may need

- intravenous fluids. Diet should be of high calories and low residue, frequently given, and in small quantities.
2. Antidiarrheal agents that reduce intestinal motility such as diphenoxylate or loperamide should be avoided as they may retard intestinal clearance of the organism. Abdominal pain may require antispasmodics such as hyoscine butyl bromide 10 mg oral or 20 mg IM or IV or dextropropoxyphene HCl 65mg with paracetamol 500 mg oral 8 h.
 3. *Antimicrobial therapy* Mild cases, especially produced by *S.sonnei* are self limiting and antibiotics are not needed. Severe cases, especially those produced by *S.dysenteriae* benefit from early treatment with 3-5 days course of antimicrobials which decrease the duration of symptoms by 50% and improve the outcome. Ciprofloxacin 500 mg twice daily is the drug of choice in adults. Ampicillin and cotrimoxazole were the preferred agents in the past. Azithromycin is also effective. Multidrug resistant strains are now common and hence local sensitivity patterns are also to be considered in selecting the drug.

Prevention

Personal and environmental hygiene is important. Hand washing with soap and water after defecation and before handling food helps to avoid spread of infection. Oral vaccines are in the process of development.

Escherichia coli Infections

GENERAL CONSIDERATIONS

Escherichia coli (*E.coli*) belongs to the group enterobacteriaceae and is found as a commensal in the intestine of normal man.

E.coli are aerobic gram-negative motile rods. Classification of strains of *E.coli* is based on three antigens—somatic(O) antigen, flagellar (H) antigen and capsular (K) antigen

Three main types are identified. These are

1. Commensal strains
2. Intestinal pathogenic strains(Enterovirulent *E.coli*) and
3. Extraintestinal pathogenic strains

Commensal strains are present as normal flora of intestinal tract – they generally lack virulence trait. Occasionally they produce infections in the urinary tract in the presence of urinary catheter, urinary obstruction, immunocompromised situations and the like.

CLINICAL FEATURES

Intestinal pathogenic strains These are not commonly present in the fecal flora of healthy humans. They may produce enteritis, enterocolitis or colitis. Five different types are described. These include:

1. **Enterotoxigenic *E. coli* (ETEC)** It is the major cause of endemic diarrhea in tropical and developing countries and also the common cause of traveller's diarrhea. Infections occur by taking contaminated food or fluids. Organism produces a heat labile or heat stable enterotoxin producing secretory diarrhea and vomiting. Incubation period is 1-2 days. Illness is usually mild and self limiting, improving in 3-4 days. Occasionally life threatening cholera- like illness may occur. Antibiotics limit the duration of illness.
2. **Enteroinvasive *E. coli* (EIEC)** – This may either produce watery diarrhea or an illness similar to Shigella dysentery due to invasion of colonic mucosa leading to inflammatory colitis. The disease is usually self limiting.
3. **Enteropathogenic *E. coli* (EPEC)** – which most commonly produces acute diarrheal disease in children. Organisms show characteristic affinity to attach to intestinal cell membrane producing effacement of microvilli (attachment and effacement lesion). This interferes with normal intestinal absorption. These cases present with mild or severe diarrhea with or without vomiting. Fever may be present.
4. **Enteraggregative *E. coli* (EAEC)** – This causes prolonged diarrhea in children and is also responsible for traveller's diarrhea. These strains have genetic codes for adhering to small bowel mucosa and produce a locally active enterotoxin, which causes diarrhea without blood in stools.
5. **Enterohemorrhagic *E. coli* (EHEC)** This strain particularly serotype 0157:H7 produces distinct enterotoxin called verocytotoxin similar to Shiga toxin produced by Shigella. EHEC produces hemorrhagic colitis. The reservoir of infection is herbivores such as cattle. The source of infection is contaminated meat products, milk, unwashed or uncooked contaminated vegetables and others. Small infective doses are sufficient to produce illness. Incubation period is 1-7 days. Initial watery diarrhea is followed by bloody diarrhea with abdominal pain. Fever and vomiting are not common.

Shiga toxin producing *E. coli*, also known as STEC, produce toxins similar to Shiga toxins 1 and 2. These have genes encoding 1 or 2 Shiga toxins. They are the more common causes of HUS. 10-15% of the affected persons may develop HUS, 5-7 days after the onset of symptoms. *E. coli* are common to produce traveller's diarrhea in new immigrants and traveller's.

EXTRAIESTINAL INFECTION BY *E. COLI*

E. coli producing infection outside the gastrointestinal tract are different from commensal and intestinal pathogens. They are more common in hospital settings.

The common infections are:

1. **Urinary tract infection (UTI)** *E. coli* is the single most common pathogen for all UTI syndromes
 2. **Abdominal and pelvic infections:** e.g. peritonitis due to fecal contamination, or spontaneous bacterial peritonitis, appendicitis, diverticulitis, cholangitis and cholecystitis. Rarely septic thrombophlebitis of the portal veins (pyelophlebitis) and pyogenic abscess in the liver may occur
 3. **Neonatal infections,** bacteremia and meningitis
 4. **Pneumonia:** *E. coli* is rare to cause community acquired pneumonia, However *E. coli* and other gram-negative bacilli are common etiological agents for hospital acquired pneumonia, especially in general postoperative and intensive care patients.
- Bacteremia and sepsis:** *E. coli* bacteremia may occur due to
- a. Infections in intravascular devices.
 - b. Primary infections at any other site, commonest being UTI followed by intra-abdominal infections-
 - c. Increased permeability of intestines in situations like chemotherapy-associated mucositis, enteritis, colitis and in neonates. Gut flora cross the natural mucosal barrier of the intestines and reach the peritoneum and bloodstream.
5. **Bone and soft tissue infections:** *E. coli* may cause infections and decubitus ulcers, cellulitis of the leg especially in diabetes, burn site infections and osteomyelitis.

Diagnosis

Culture of *E. coli* from appropriate samples will confirm the diagnosis.

TREATMENT

In the past, most strains of *E. coli* were sensitive to common antibiotics like ampicillin/amoxycillin, tetracyclines, cotrimoxazole and first generation cephalosporins. Now many isolates are resistant to these drugs. Other drugs which are effective include quinolones, third generation cephalosporins, aminoglycosides and extended spectrum penicillins like piperacillin and carbapenams. *E. coli* resistant to multiple drugs especially quinolones and cephalosporins are common in hospital acquired infections. Strains resistant to ampicillin/amoxycillin may still respond to ampicillin – sulbactam or amoxycillin-clavulanic acid.

Prevention

Infection rate can be reduced by restricting the use of indwelling catheters, proper care of the parts and isolates of infected patients. Drug resistance can be reduced by judicious use of antimicrobial agents. *E. coli* transfers its antibiotic resistance to other enteric bacteria like

Salmonella. Hence indiscriminate use of antibiotics without proper indication should be avoided.

Klebsiella pneumoniae Infections

Klebsiella are capsulated gram-negative bacilli found normally in the throat and intestines in healthy humans. The colonization rate ranges from 5 to 35 % in the colon and 1.5% in the oropharynx in the community. Colonization rate increases with wide antibiotic use and hospitalization.

The most frequent serotype found in humans is *Klebsiella pneumoniae* (Friedlander's bacillus) which is 1-2 mm long and 0.5 to 0.8 mm broad. Person to person spread is the predominant mode of transmission.

Lesions Produced by *K. pneumoniae*

1. ***K. pneumoniae* produces pneumonia** commonly in diabetics, alcoholics, persons having chronic lung disease and hospitalized patients (Fig. 40.1).
2. **Urinary tract infection** commonly in complicated UTI including those on indwelling catheters.
3. **Abdominal infections:** biliary tract infections, peritonitis
4. **Other infections** usually occur in devitalized tissues or immunocompromised individuals. Examples includes decubitus ulcers, cellulitis in diabetes, burn site infections, nosocomial sinusitis, meningitis associated with neurosurgery and others.
5. **Bacteremia:** usually spread from primary sites of infection or from intravascular catheters.

Diagnosis

Culture of the organism and determination of the antibiotics sensitivity from appropriate material confirms the diagnosis.

Fig. 40.1: *Klebsiella pneumoniae* left upper lobe

Treatment

Klebsiella are intrinsically resistant to ampicillin/ amoxycillin. Effective antibiotics are third and fourth generation cephalosporins, aminoglycosides, quinolones and carbapenam. Treatment with effective antibiotics has to be continued for 10-14 days.

Pseudomonas Infections

GENERAL CONSIDERATIONS

Pseudomonas aeruginosa is the most common human pathogen among the *Pseudomonas* species. They are opportunistic gram-negative bacilli. Most strains of *P. aeruginosa* produce a characteristic bluish green pigment called pyocyanin which helps in the identification of the organism. The organism has affinity for moist areas, and occasionally it colonises the skin, external ear, upper respiratory tract, perineum or colon of healthy human beings. The organism may contaminate medical devices like ventilators, endoscopes or pressure monitors. Health care workers in hospital may transmit the infection from patient to patient.

P. aeruginosa infection is rare in healthy individuals. Infections occur in immunocompromised persons who are predisposed. Most of the infections are acquired in hospitals especially from intensive care units. Prolonged use of broad spectrum antibiotics favour colonization by the organism and subsequent infection.

Conditions predisposing to infection are

1. Neutropenia – due to disease, chemotherapy or both
2. Mucosal damage – cancer chemotherapy
3. Cystic fibrosis with progressive respiratory tract changes
4. Respiratory assist devices directly inoculating the organism into the tracheo bronchial tree
5. Indwelling urinary catheters
6. Extensive burns
7. Prolonged broad spectrum antibiotic use
8. AIDS

The organisms enter through the breach in the skin or through urinary, respiratory or gastrointestinal tracts. In addition to infection at local site hematogenous spread may also occur.

CLINICAL FEATURES

1. Pneumonia commonly occurs in hospitalized patients especially in immunocompromised subjects, patient on ventilatory support and those receiving prolonged broad spectrum antibiotics. Organisms reach the lungs in aspirated material from the oropharynx or through the blood stream. The lungs show micro abscesses.
2. Bacteremia – This is common in patients with neutropenia especially those with hematological

malignancies. Bacteremia may be primary or it may result from infection elsewhere. Sepsis and septic shock may develop. Mortality is 50-70%. Meningitis may develop

3. Endocarditis – This may occur in IV drug users, patients after cardiac surgery or those who had suffered from burns.
4. Urinary tract infection – *P. aeruginosa* is a common pathogen of complicated UTI, often it results from urinary tract catheterization, instrumentation or obstruction
5. Skin lesions – Wounds, ulcers and burns may be secondarily infected. Bacteremia may lead to *ecthyma gangrenosum* which appears as indurated purple black areas about 1 cm in diameter with ulcerated centers. Maculo-papular and vesiculo-pustular rashes may occur.
6. Ear infection – It is a common pathogen producing external otitis. In elderly diabetic patients severe otitis may result
7. Other infections – *P. aeruginosa* may also produce osteomyelitis, eye infections, meningitis, *hemorrhagic colitis* and brain abscess.

TREATMENT

The antibiotics effective against

P aeruginosa are shown in Table 40.2.

Combinations such as beta lactam antibiotics with aminoglycosides or betalactams with fluoroquinolones are more effective in systemic infections.

Superficial infections respond to local dressing with polymyxin.

Prophylaxis

Since pseudomonas is a common cause of nosocomial infections , utmost care should be taken to prevent cross infection by proper hand washing and strict aseptic precautions. Indiscriminate use of prophylactic antibiotics is not beneficial.

Proteus Infections

The genus proteus includes 3 species pathogenic to man—*P.mirabilis*, *P.vulgaris*, *P.penneri*. They are gram negative rod- shaped bacilli. *Proteus mirabilis* causes 70-90% of proteus infections.

TABLE 40.2

Antibiotics effective against *P. aeruginosa*

Antibiotic class	Agent
Betalactam drugs	Piperacillin, piperacillin/ tazobactam
Cephalosporins	Ceftazidime, cefaperazone, cefipime
Carbapenams	Imipenam+cilastatin,meropenam
Monobactams	Aztreonam
Aminoglycosides	Tobramycin, gentamicin, amikacin
Fluoroquinolones	Ciprofloxacin, levofloxacin
Others	Polymixin B ,colistin

Common Lesions

1. **Urinary Tract Infection:** Normal urinary tract is seldom infected with *Proteus*, but 10-15 % of cases of complicated UTI in diabetes, urinary tract obstruction and in patients with indwelling catheters are caused by this organism. *Proteus* infection makes the urine alkaline by producing ammonia from urea. Alkalinization may lead to precipitation of organic and inorganic compounds leading to urinary stone formation.
2. **Other lesions:** These include pneumonia, sinusitis, biliary tract infections, intra-abdominal abscesses, surgical site infections, decubitus ulcers and diabetic foot infections. In the newborn, the umbilical stump may be colonized by proteus leading to bacteremia and meningitis.

Bacteremia – This may result from UTI or occasionally due to infection in intravascular devices.

Diagnosis

Culture of organisms from urine or appropriate specimen gives the diagnosis.

Treatment

Proteus mirabilis is usually sensitive to most of the antibiotics. Resistance to ampicillin and first generation cephalosporins are now common. Resistant strains respond to cotrimoxazole, fluoroquinolones, aminoglycosides and third generation cephalosporins in the usual dosage.

animal products even for several years (10-71 years on record). Boiling for 10 minutes or treatment with potassium permanganate, formaldehyde, glutaraldehyde and hypochlorite kills the spores. The organism grows well aerobically in ordinary laboratory media.

Epidemiology

Anthrax primarily affects animals, it is prevalent in all countries throughout the World, but only rarely seen in India. Animals get the infection by coming into contact with spores persisting in soil. Most of the human cases are zoonotic in origin. Human to human transmission has not been reported except in the respiratory form. Human infection is by:

1. Direct contact with infected animals and consuming contaminated meat – raw or poorly cooked.
2. Contact with anthrax spores containing animal products such as wool, hides, hair, skin, bone and inhalation of spore-containing aerosols which may travel long distances in wind. Contaminating the atmosphere with spores may be a method adopted by bioterrorists or for bio-warfare.

Mode of Entry and Virulence

The organisms enter the body:

1. Through abrasions in skin
2. Gastrointestinal tract – eg – eating infected meat
3. and Inhalation of spores

The aerosol should be 1-5 in size to reach the lungs. The infective dose is 8000 to 50000 spores by inhalation. Virulence of the bacterium is determined by two factors (1) γ -linked poly-D glutamic acid capsule and (2) a three component protein exotoxin-termed anthrax toxin complex comprising of protective antigen (PA), lethal factor (LF) and edema factor (EF). Individually these are nontoxic, but in combination they produce lesions. LF + PA form the lethal toxin.

Pathology

Primary foci of human anthrax occurs

1. Skin

Anthrax

GENERAL CONSIDERATIONS

Anthrax is a zoonotic disease, caused by *Bacillus anthracis*. Anthrax occurs primarily in herbivorous animals, especially cattle, goats, sheep and horses which form the reservoirs. Recent interest in anthrax has been the fear of using anthrax spores as biological weapons either in battle or by terrorists.

Etiology

Bacillus anthracis is a large aerobic gram +ve spore forming bacillus. The organism exist as bacillus in the tissues – spores are not produced in living tissue. Spores are produced outside the body under aerobic conditions. These are very resistant, they remain viable in soil and

Diseases Caused by Infections

2. Gastrointestinal tract
3. Oropharyngeal region and
4. Lungs.

Septicemia and meningitis may occur from any of these primary foci. Changes occur due to tissue invasion by the bacillus multiplying rapidly extracellularly and the effect of the exotoxin. The main pathological changes in the tissue are edema, necrosis and hemorrhage.

CLINICAL FEATURES

The disease may present as the cutaneous pulmonary, gastrointestinal, and the meningeal forms.

Cutaneous Anthrax (Malignant pustule)

This occurs as a result of direct contact with *Bacillus anthracis* and this is the common type. The lesion usually occurs on exposed areas and starts as a small papule after an incubation period of 1-2 days (usually 2-5 days). It vesiculates and contains serosanguineous fluid which is highly infectious. The papules are surrounded by erythema and induration. The vesicle turns into pustule, and ulcerates with a depressed black eschar. The lesion is usually painless. Lymphangitis and regional lymphadenitis commonly occur. Systemic symptoms are mild. With appropriate antibiotic therapy recovery occurs. Bacteremia can occur with clinical features of systemic infection.

Pulmonary Form (Inhalation anthrax/wool sorter's disease) – This occurs as an occupational hazard when spores from wool or hides are inhaled. The spores may also spread from person to person as droplet infection. They reach the mediastinal lymph nodes. The bacilli develop in a few days, but the incubation period can be as long as 60 days.

It is feared that as a part of bioterrorism or bio-warfare, dissemination of spores in the environment may lead to large outbreak of severe and fatal anthrax pneumonia.

Classically a biphasic illness occurs. After an average incubation period of 1–5 days (even up to 6 weeks) symptoms start with malaise, fever, myalgia and non-productive cough mimicking viral respiratory disease. In some, there is transient improvement after 2 – 4 days followed by second stage with severe dyspnea, fever, cyanosis and hemoptysis. About 50% develop meningitis. Edema of the chest wall and neck may occur. Bacteremia is common. X-ray of the chest may show mediastinal widening due to lymphadenopathy and pleural effusion, which is often hemorrhagic. Mortality is high and death usually occurs within 24 hours.

Gastrointestinal form of Anthrax – This develops 2–5 days following consumption of contaminated meat. Deposition of bacteria in oropharynx leads to *oropharyngeal anthrax* with ulcers and lymphadenopathy. Dysphagia is common. In the GIT, organisms are deposited in the

duodenum, terminal ileum and caecum. The patient presents with fever, abdominal pain, vomiting, bloody diarrhea, hematemesis, hemorrhagic ascites and mesenteric lymphadenitis. Disease may progress to toxemia, shock and death.

Meningeal Anthrax

Any form of primary anthrax may be complicated with meningitis. CSF is usually hemorrhagic containing bacilli. Mortality is high.

DIAGNOSIS

Clinical suspicion is absolutely necessary for early diagnosis. Occupational history will be helpful.

1. Gram staining of the vesicular fluid in cutaneous anthrax, ascitic fluid, oro-pharyngeal swab, sputum or CSF and demonstration of gram +ve rods arranged in long chains is suggestive.
 2. Blood culture is positive in cases with bacteremia, if done before starting antibiotics.
 3. The capsular and cell wall antigens and virulence factor genes can be detected by PCR.
 4. Antibodies against anthrax can be demonstrated by ELISA test and other methods.
- Neutrophil leukocytosis is common.

Differential Diagnosis

1. Cutaneous anthrax has to be differentiated from tularemia, lymphogranuloma venereum, cat scratch disease, rat bite fever, bubonic plague, glanders and typhus fever.
2. Pulmonary anthrax should be differentiated from other forms of pneumonia, especially hemorrhagic pneumonias
3. Anthrax meningitis may be mistaken for subarachnoid hemorrhage.

TREATMENT

Specific

Penicillin, amoxycillin, tetracycline, doxycycline, erythromycin and other macrolides, chloramphenicol and ciprofloxacin are all effective.

Drug of choice for cutaneous anthrax is benzyl penicillin – 200,000 units IM 6 h for 5–7 days. Higher doses are needed for meningitis. Penicillin resistant patients may be treated with ciprofloxacin 400 mg bd IV or 500mg bd orally for several days.

Anthrax pneumonia should be treated with ciprofloxacin 400 mg bd IV or 500 mg orally b.d. Amoxycillin 500 mg 8h for periods up to 60 days is an effective alternative *Current recommendation by Centre for Disease control USA, (CDC) is a combination of 2 or 3 antibiotics to be given for upto 8 weeks.*

Supportive Care – Ventilatory support may be required for pneumonia with respiratory distress. Vasopressors and volume repletion are necessary for those in shock.

PREVENTION

Personal protection for at-risk persons is by using protective clothing and masks, and by vaccination.

1. Vaccination is available for individuals at high-risk. The vaccine is an inactivated cell free vaccine. Three subcutaneous injections at 2 weeks intervals and additional 3 doses at 6, 12 and 18 months and annual booster doses give adequate protection.

An attack of anthrax generally produces permanent immunity.

2. Gastrointestinal anthrax can be prevented by public education to avoid consumption of contaminated meat.
3. Post exposure antibiotic prophylaxis should be given for those who are exposed to inhaled spores. Ciprofloxacin 500 mg/day oral is recommended for 60 days.
4. Control of anthrax in animals is by immunization.
5. Carcasses of animals that have died due to anthrax are to be buried or cremated to avoid sporulation and further contamination.

Procedure to be observed when anthrax spores are used for bioterrorism/warfare

1. Suspect anthrax and alert the public and health personnel
2. Early specific therapy
3. Burn all infected cattle carcasses
4. Disinfection of infective material with 5% formalin
5. Vaccination of susceptible population and animals. Protective clothing for those at risk
6. Ciprofloxacin prophylaxis for exposed individuals.

Plague

GENERAL CONSIDERATIONS

Plague used to occur in the form of epidemics up to the early part of the 20th century causing more deaths than many other diseases. Now it is a rare disease still capable of appearing as localized outbreaks. There was an outbreak of plague in Surat in India in 1994. Plague is one of the most virulent and potentially lethal bacterial diseases known.

Etiology

Yersinia pestis, the cause of plague is a gram negative aerobic cocco-bacillus. It shows bipolar staining. The organism remains viable for long periods in human

sputum and dried flea feces when protected from sunlight and heat.

Epidemiology

Plague is a zoonotic infection. The main animal reservoirs are rats, mongooses and rabbits. Among the rodent population plague is spread by transmission from one rodent to another by the bite of the rat flea *Xenopsylla cheopis* (sylvatic plague). The organisms multiply in the alimentary tract of the flea and they regurgitate into the mouth parts. These enter the new host when the flea bites to suck blood. Organisms are also passed in the feces of the flea.

Man is the accidental host. Human epidemics usually arise from infected domestic rodents. Man gets infection

1. When bitten by infected rat flea *Xenopsylla cheopis*. When the rat dies and its body heat is lost, the fleas jump to other warm blooded animals including man and sucks blood. Under suitable conditions the flea lives for 1-2 years and remains infective for long periods.
2. Handling of carcasses of infected animals – Direct inoculation into the skin predisposes to the development of septicemic plague
3. Inhalation of respiratory droplets released from infected animals or from dried flea feces
4. Man to man transmission in the setting of pneumonic plague by droplet infections. This risk is low and requires close contact.

Pathogenesis and Pathology

Organisms are transmitted through the skin by the bite of the infected rat flea. At the site of entry a papule or pustule may form. The bacilli reach the local lymph nodes which enlarge and suppurate. This constitutes the bubo. Bacilli proliferate and enter the blood stream to produce metastatic lesions in other lymph nodes, liver, kidneys, spleen, meninges, brain and lungs.

Organisms can directly reach the lung by inhalation of droplets of respiratory secretions of pneumonic cases. Organisms can also remain in the environment by getting released from dried flea feces. The lesion in the lung is pneumonic consolidation. Hemorrhagic manifestations develop due to endothelial damage and disseminated intravascular coagulation (DIC).

CLINICAL FEATURES

Initial manifestations include abrupt onset of high fever, tachycardia, malaise and backache. The patient is toxic and delirious. Three clinical types are classically described.

1. **Bubonic plague** is the most common type. The incubation period is 2-6 days. Symptoms start with fever and lymphadenopathy. Bubos are seen most

frequently in inguinal or axillary regions depending upon the flea bite. Bubo­es may slowly suppurate and discharge their contents. Death may occur due to peripheral circulatory failure.

- The term ***Pestis minor*** refers to mild cases seen during epidemics. This presents with only the buboes which suppurate and discharge pus in due course or may resolve without significant systemic manifestations.
- Septicemic plague**- primary septicemic plague resembles severe bubonic plague with sudden onset of chills, fever, tachycardia, headache, vomiting and delirium. Several organs may be affected. Death may occur within a few days before localizing lesions are evident. Hemorrhagic manifestations like petechiae, subcutaneous ecchymosis, epistaxis, hematemesi­s or malena may develop. Meningitis may occur.
- Pneumonic plague**: Two types of pneumonia occur in plague—primary and secondary. In the primary form the organism reaches the lung by inhalation and in the secondary form, through the blood stream.

The primary form is more fulminant and rapidly fatal. The onset is abrupt with high fever, tachycardia and dyspnea. In comparison to severity of symptoms and respiratory distress physical signs are less marked. Sputum may be scanty, blood stained or frothy

DIAGNOSIS

High index of suspicion is necessary for early diagnosis. Diagnosis is confirmed by:

- Demonstration of organisms by staining of smear of fluid aspirated from bubo, sputum or buffy coat in blood.
 - Culture of blood, sputum or aspirated materials
 - Animal inoculation studies
- Serological tests are also useful
- Neutrophili leukocytosis with shift to left is common

TREATMENT

Early effective antibiotic treatment is necessary to prevent deterioration and death. Streptomycin is the drug of choice. Alternate effective drugs are tetracycline, doxycycline, and chloramphenicol. In meningitis chloramphenicol is preferable. Gentamicin and cotrimoxazole also have been used successfully. Quinolones are also very effective. The duration of treatment is for 10 days (Table 41.1).

Supportive treatment for circulatory failure, DIC, hyperpyrexia, respiratory distress and fluid and electrolyte imbalance has to be instituted early. Bubos may require surgical drainage, at times.

Prognosis

Overall mortality of untreated plague is 50%. Untreated, primary septicemic and pneumonic plague are invariably

TABLE 41.1

Antimicrobial regimen for plague

Drug	Daily dose	Doses/day	Route
Streptomycin	2 g (30 mg/kg)	2	IM
Tetracycline	2 g (adult)	4	Oral /IV
Doxycycline	200 mg (adult)	1-2	Oral
Chloramphenicol	50 mg/kg	4	Oral/IV

fatal. Modern antibiotic therapy has improved the outcome considerably.

PREVENTION

Plague is a notifiable disease. Rats and fleas are to be controlled. In endemic areas avoid contact with susceptible animals or there products. Rodents found dead should be handed only after application of gammaxane or kerosene to kill the fleas. Patients with pneumonic plague are isolated and attendants must wear masks. Contacts should be protected by tetracycline 2 g daily orally in divided doses or doxycycline 200 mg daily for 7- 10 days.

A heat-killed vaccine is useful for population at risk. Plague vaccine is known as Haffkines vaccine in honour of W.M.Haffkine who was of Russian origin. While working in Grant Medical College Hospital, Mumbai he produced the vaccine and tested it on himself on the 10th of January 1897. The vaccine is not in general use, but can be used under special circumstances. An aerosol vaccine is also available for use in special circumstances.

Brucellosis

GENERAL CONSIDERATIONS

Syn. Undulant fever, Malta fever, abortus fever

Brucellosis is an infectious disease of animals which is transmitted to man by ingestion of contaminated articles of food such as unboiled goat’s milk and milk products and meat and also by handling tissues of infected animals.

Etiology

Brucellosis is produced by one of 4 species of *Brucella* commonly.

- Brucella melitensis* the most common type spread from goats, sheep and camels.
- Brucella abortus* : This spreads from dairy cattle. It produces abortion in cattle
- Brucella suis* – from pigs
- Brucella canis* – from dogs

Brucella organisms are small, non-capsulated non-motile gram negative aerobic rods or cocco-bacilli. They are facultative intracellular parasites.

Epidemiology

The disease is worldwide in distribution. The true incidence is not known, but it is definitely many times more than what is reported. Brucellosis is common in the Middle East, USSR, Mexico and S. America. It occurs less commonly in India, Europe, USA, and other countries. Brucellosis is an occupational disease in veterinarians and farm workers, workers in meat processing industries and slaughter houses, shepherds and laboratory workers. Exposure to the placenta and other products of conception of cattle, swine, sheep, dogs and other animals and contact with sick animals can cause infection.

Mode of Transmission

Infected animals pass the bacillus in their milk for long periods. The placenta, fetus, semen, vaginal discharge and urine of animals are also infective. Human infection occurs by

1. *Ingestion of untreated milk and its products, raw meat, liver or bone marrow.* Organisms enter through the mucous membrane of GIT.
2. *Penetration through the abrasion in skin coming in contact with infected material.* *Brucella* may also enter through the conjunctiva when infected material gets into the eye accidentally.
3. *Inhalation of aerosol particles,* - Close contact with infected animals can lead to droplet infection.
4. Transplacental transmission from mother to fetus may occur. *Brucella* has been isolated from human breast milk. Transmission through sexual contact has been recently reported in humans.

***B. melitensis* can be used as an agent in biological warfare or bioterrorism.**

Pathogenesis and Pathology

After entry the organisms pass through the local lymph nodes to reach bloodstream and localize in reticulo-endothelial system. *Brucellae* are unique in that they have no specific virulence factors like exotoxins or endotoxins. Organism which enter the tissue are phagocytosed by RE cells. 15-30% of the organisms survive in vacuoles within the phagocytes. They are periodically released into the circulation.

In the RE tissues including bone marrow, liver, lymph nodes and spleen, they multiply to produce granulomas made up of epithelioid cells, giant cells, lymphocytes and plasma cells. *Brucella* persists in the tissues through inhibition of apoptosis.

Exposure to infection elicits humoral and cell mediated immunity, which helps to clear the infection.

CLINICAL FEATURES

The incubation period is 1 to 3 weeks but may be as long as several months. The clinical syndromes produced by

different species are similar, but *B. melitensis* produces more aggressive disease often with acute presentation.

The onset is either sudden or gradual with fever, malaise weakness, sweating, chills, arthralgia and backache. The term undulant fever is derived from the characteristic pattern of the temperature. Fever shows wide fluctuation and it persists for long periods, up to several weeks or months.

Bones and joints are commonly affected. Migrating polyarthritis mainly involve major joints like knee, hips, sacroiliac joints shoulder and others. Septic monoarthritis is also known to occur in the knee, hip, shoulder and sacroiliac joints. Spondylitis with back pain is a very common and suggestive symptom. This may affect any vertebra, but the fourth lumbar vertebra is the common site of lesion. *Brucella* osteomyelitis is rare outside the vertebral column.

Cardiovascular lesions include myocarditis, endocarditis, pericarditis and thrombophlebitis.

Liver involvement leads to formation of granulomas. Sometimes suppuration may occur. Mild jaundice may be present in some. Cholecystitis may occur.

Splenomegaly is common

Central nervous system: Neurobrucellosis may take the form of meningo-encephalitis with lymphocytic pleocytosis in the CSF. Other lesions include myelitis, radiculopathy, cranial nerve palsies and vasculitis presenting as strokes.

Genitourinary system: Unilateral or bilateral epididymo-orchitis may occur. Acute nephritis has also been described.

Respiratory system: Pneumonitis, pleural effusion and pulmonary opacities in the skiagram may develop. The pleural fluid shows lymphocytic pleocytosis.

Other less common lesions: These include uveitis and pancytopenia.

The term *chronic brucellosis* is used to denote the chronic febrile illness associated with specific organ involvement.

Chronic brucellosis may present as pyrexia of unknown origin or chronic spondylitis.

DIAGNOSIS

Prolonged fever with arthritis or spondylitis with risk of exposure should suggest the possibility of brucellosis. Residence in endemic areas should be considered a strong point for making the diagnosis.

Confirmation is by isolation of *Brucella* from blood, bone marrow or other tissues such as joint fluid, CSF, or tissue aspirate. This is positive in about 50-70% cases. The organisms are slow -growing and take about 6 weeks. Culture by BACTEC technique yields positive cultures in 7-10 days.

Serology: IgM antibodies appear early followed by IgG and IgA. Serum agglutination tests are employed for diagnosis. A single titer $\geq 1:320$ is considered highly suggestive. A 4 fold rise when repeated after 2-4 weeks is practically diagnostic. Antibodies can be detected also by alternate methods such as complement fixation test, ELISA and Coomb's antiglobulin test.

PCR – This is more sensitive and quicker than blood culture. Mild anemia is common. Non-specific laboratory findings include anemia and leucopenia.

TREATMENT

Antimicrobial therapy - For adults with acute brucellosis without localizing lesions elsewhere like bone CNS, and others, treatment with a combination of two antimicrobials given for six weeks is ideal. Most commonly recommended regimens are

1. Streptomycin 1 g IM daily x 2-3 weeks with doxycycline 100 mg oral 12 hourly for 6 weeks. Relapse rate with this regimen is about 5%. Aminoglycosides show synergistic activity with tetracycline.
2. *Alternate regimen* is doxycycline 100 mg oral 12 h + rifampicin 600-900 mg oral daily for 6 weeks. The relapse rate is higher. Chronic brucellosis with established focal infection needs treatment for 3-6 months

PREVENTION

1. Control of infection in animals by active immunization.
2. Pasteurization of milk will prevent transmission from milk and milk products.
3. Human vaccine is in use in countries like Russia and China. It is given to people who are occupationally exposed to high risk of infection.

Cholera

GENERAL CONSIDERATIONS

Word meaning of cholera is “flow of bile”. Cholera is an acute infectious disease caused by *vibrio cholerae* occurring in outbreaks, characterized by watery diarrhea and effortless vomiting, often leading to severe dehydration and shock. *Vibrio cholerae* is a comma-shaped, flagellate, motile, gram-negative organism. It was discovered by Robert Koch in 1884. The somatic (O) antigen is of importance in the identification of the organism. Ninety two serogroups are identified based on the O antigen structure. Of these the strain producing epidemic cholera possesses O1 antigen and hence this vibrio is designated *Vibrio cholerae* O1. *Inaba*, *Ogawa* and *Hikojima* are the most important pathogenic subtypes. The others are collectively designated non-O1 *V. cholerae*. Among these some have been now identified to be

pathogenic. The Eltor biotype is a variant of *V. cholerae* O1, and it is characterized by its hemolytic activity and resistance to polymyxin. Many Eltor vibrios are non-hemolytic at present. Morphologically and antigenically Eltor resembles *V. cholerae*. Differentiation is by phage typing and other tests.

The classic disease is caused by *Vibrio cholerae*, but in the majority of outbreaks occurring in India and neighbouring countries in recent times, the main pathogen is the 'Eltor' biotype. Eltor biotype was first identified in Eltor village in Egypt in 1905, from Indonesian Haj Pilgrims. Cholera has been endemic in the banks of the Ganges and Brahmaputra in India and Bangladesh for several centuries. From these endemic foci the disease used to spread along routes of human communication to other parts during fairs, festivals, floods, and famines, causing outbreaks associated with high mortality. Between 1817 and 1923 the disease swept to other parts of the world including Europe and America as pandemics on at least six occasions. *Eltor vibrio* was identified as the cause of the cholera-like disease during 1937-38 in Celebes island of Indonesia. This was identified as a major pathogen causing diarrheal illness in India, Pakistan, Afghanistan, Iran, Iraq and southern parts of USSR in 1965-66. From this time *Eltor vibrios* are responsible almost exclusively for cases of cholera reported in this subcontinent.

A new strain named *V. cholerae* O 139 was found to produce toxin and this was identified as a cause of clinical cholera in 1992. It rapidly spread to several countries in South East Asia and by 1993 it almost replaced the O1 Eltor strain. By 1995-96 Eltor were considerably eliminated even though occasional cases did occur in India and Bangladesh. Recent outbreaks in Ambajogai region of Maharashtra documented the presence of O139 strain in about 25% of cholera like illness.

Etiology and Epidemiology

Man and environment form the natural reservoir. Spread occurs through the environment. Organisms are eliminated in feces of acute cases and carriers. Convalescent patients become temporary carriers passing the organisms in feces for 4-7 days after an attack. Rarely chronic carrier state may develop and organisms may be present in feces for years. Unlike the explosive outbreaks of classical cholera, Eltor epidemics follow a protracted pattern with a few cases occurring everyday for several weeks. The pathogenic vibrios can survive outside the human host in the environment for varying periods. Freezing infected water does not kill the vibrios. The main vehicles of infection are water, cooked food kept unhygienically exposed to flies, sea foods, fruits and vegetables. Apart from shell fish and plankton, there are no animal reservoirs. Biofilm, formation and conversion into a visible, but non culturable state due to nutrient deprivation, helps the organisms to persist within natural aquatic habitats for long periods.

Cholera is predominantly of the lower socioeconomic groups living in gross insanitary conditions. The organisms are killed in the presence of normal gastric acidity. In different places cholera outbreaks follow seasonal patterns.

Immunity

An attack of classic biotype of *Vibrio cholerae* usually protects against recurrent infection by either type. But, El Tor type cholera does not protect against further attacks. Persons with blood group 'O' are at an increased risk of developing El Tor cholera.

PATHOGENESIS

Vibrio cholerae are ingested in food or drinks and they multiply in jejunum and small intestine and produce an enterotoxin. This toxin causes the enterocytes (intestinal mucosal cells) to secrete large amount of isotonic fluid. The rate of secretion of the fluid exceeds the rate of absorption which also goes on. The result is watery diarrhea which leads to the loss of isotonic fluid. The fluid loss accounts for all the clinical manifestations. Virulence is determined by genetic factors which favour bacterial colonization and attachment to intestinal epithelium.

Cholera enterotoxin is a protein of mol. wt. 84,000, made up of two immunologically distinct regions—A (active) and B (binding). The B region is composed of five subunits of mol. wt. about 11,500. This region of the cholera toxin is responsible for binding to cell membrane receptors containing GM I ganglioside. The binding enables the 28,000 MW 'A' region to penetrate the mucosal cells. This toxin leads to the formation of adenylate cyclase which induces excessive production of cyclic-AMP (cAMP), which in turn is responsible for oversecretion of electrolytes and water by the enterocytes. The exact mechanism of action of cyclic-AMP, however, is not clear. The enterotoxin acts locally and does not invade the intestinal wall, as a result the feces does not show cellular exudates which are characteristic of inflammation. The feces is watery, turbid and often does not contain any visible fecal matter.

The pathophysiological changes result directly from the massive gastrointestinal loss of fluid isotonic with plasma. The feces are low in proteins and chloride, but relatively rich in sodium, potassium, and bicarbonate (sodium 126 ± 9 , potassium 19 ± 9 , bicarbonate 47 ± 10 and chloride 95 ± 9 mmol/liter). Excessive loss of fluid and electrolyte gives rise to hypovolemic shock and metabolic acidosis. Most of the fluid loss is from the small intestine.

CLINICAL FEATURES

Severity of cholera varies from a completely asymptomatic form to fulminant diarrhea and shock. In Eltor cholera

outbreaks the proportion of asymptomatic and mild cases is higher than the severe cases.

In most cases the incubation period varies from less than a day to 5 days. Mild cases of cholera may be asymptomatic and diagnosis has to be established by stool culture. In some only a mild diarrheal illness may be seen.

In moderate and severe cases the onset is abrupt with uncontrollable painless watery diarrhea and effortless vomiting. The excreta may contain fecal material at the onset but soon it assumes the characteristic 'rice-water' appearance due to the presence of flakes of mucus and large number of vibrios. Watery stools are passed in quick succession. In many patients vomiting supervenes either along with the diarrhea or may follow later. Nausea is absent. Vomitus consists of clear, watery fluid. Loss of fluid and electrolytes leads to dehydration, acidosis, and shock. Earliest indication of fluid deficit is thirst with dryness of the mouth and tongue. Decreased renal blood flow produces oliguria and renal shutdown. The patient may be unable to talk due to loss of voice. Painful muscular cramps develop due to hyponatremia.

Mental state remains clear. Restlessness is the forerunner of shock. When dehydration is severe, the eyes are sunken, skin is shrivelled, neck veins are collapsed, and signs of shock supervene. The rectal temperature is usually normal or raised even though the extremities may be cold. The abdomen is scaphoid and nontender. The illness seldom lasts for more than 3-5 days. Rarely large amounts of fluid may collect in the intestinal lumen and severe dehydration, shock, and death may result even before evacuation occurs. The term "*Cholera sicca*" is used to denote such cases.

DIAGNOSIS

Laboratory diagnosis is made by isolating the organisms from proper stool samples collected before the administration of antimicrobial agents. The specimen should be transported to the laboratory without delay. A suitable medium for transporting specimens is Venkatraman and Ramakrishnan (V-R) fluid or Carry and Blair medium. It is very important to make bacteriological diagnosis in all cases of diarrhea since undetected sporadic cases may be starting point of outbreaks. Moreover cholera being a notifiable disease, should be notified to the Public Health Authorities in order to take preventive measures. Vibrios can be identified in fresh microscopic preparation of feces by their characteristic movement.

Other laboratory findings: These are non-specific, but they help to assess the fluid and electrolyte status and to plan definitive management. These include:

elevation of PCV	dehydration
neutrophil leukocytosis	
fall in serum bicarbonate	lactic acidosis
increase in anion gap	
hyponatremia	
Hypokalemia	electrolytic loss

Differential Diagnosis

A clinically indistinguishable picture can be presented by about 25 intestinal pathogens such as enterotoxigenic *E. coli*, other vibrios, *Campylobacter jejuni*, rotavirus, and others. Bacterial and toxin type of food poisoning has to be looked for and excluded. Gastroenteritis may resemble cholera. In gastroenteritis vomiting precedes diarrhea, there is abdominal pain and stools may contain cellular exudates. Fever may be present.

Prognosis

During epidemics mortality may be as high as 30%. Malnutrition, intercurrent illness, and want of proper medical attention are adverse factors. Diarrhea is one of the most common causes of infantile and childhood mortality in developing countries. Adequate and early replacement of fluid and electrolytes reduces mortality considerably. Introduction of the oral rehydration solution (ORS), recommended widely by the WHO and adopted as the first line of treatment in diarrheal diseases, has brought down mortality to a great extent. Many complications can also be prevented by early rehydration.

Complications

Most frequent complication is hypovolemic shock which is fatal if untreated. Hypokalemia may lead to fatal cardiac arrhythmias, abdominal distension, and muscle paralysis. Injudicious administration of electrolyte solutions intravenously without correcting metabolic acidosis may result in acute pulmonary edema. Convulsions may develop in children due to cerebral venous thrombosis. Severe hypoglycemia may also contribute to this symptom. Severe shock leads to renal cortical necrosis and renal failure. Other complications include venous thrombosis, cataract, and prolapse of the rectum in children. Florid malnutrition may develop after diarrheal episodes in children from poor communities.

Diarrheal illnesses precipitate and aggravate malnutrition.

TREATMENT

All cases with moderate or severe diarrhea should be hospitalized and treated properly. Early replacement of gastrointestinal fluid and electrolyte losses, maintenance of nutrition, and institution of antimicrobial drugs form the mainstay of treatment. Fluid replacement is done to correct the existing deficit of water and electrolytes (rehydration therapy) and it is continued to replace losses due to continuing diarrhea (maintenance therapy) (Tables 42.1 and 42.2).

Rehydration therapy: In mild and moderate cases, rehydration can be achieved with oral rehydration salt (ORS) solution. The WHO recommended ORS formula contains:

TABLE 42.1

Assessment of dehydration and fluid deficit			
Signs and symptoms	Mild dehydration	Moderate dehydration	Severe dehydration
General appearance and condition—infants and young children	Thirst, alert, restless	Intense thirst, restless or lethargic but irritable when touched	Drowsy, flaccid, cold sweaty, cyanosis, may be comatose
Older children and adults	Thirst, alert, restless	Intense thirst, alert giddiness with postural hypotension	Usually conscious, apprehensive, cold, sweaty, cyanotic extremities wrinkled skin of fingers and toes, muscle cramps
Radial pulse	Normal rate and volume	Rapid and weak	Rapid, feeble, thready pulse
Respiration	Normal	Deep, may be rapid	Deep and rapid
Anterior fontanelle	Normal	Sunken	Very sunken
Systolic blood pressure	Normal	Normal to low	Less than 80 mm Hg, may be unrecordable
Skin elasticity	Pinch retracts immediately	Pinch retracts slowly	Pinch retracts very slowly (>2 seconds)
Eyes	Normal	Sunken	Deeply sunken
Tears	Present	Absent	Absent
Mucous membrane	Moist	Dry	Very dry
Urine flow	Normal	Reduced amount and dark	Almost stops, empty bladder
Percent body weight loss	4-5%	6-9%	10% or more
Estimated fluid deficit	40-50 mL/kg body wt	60-90 mL/kg body wt	100-110 mL/kg body wt

Note: Material for Tables are taken from the WHO and UNICEF statement 1983.

TABLE 42.2

Guidelines for rehydration therapy				
Severity	Age group	Nature of fluid	Volume of fluid	Duration
Mild	All	ORS solution	50 mL/kg	Within 4 hours
Moderate	All	ORS solution	100 mL/kg	Within 4 hours
		Intravenous ringer lactate	30 mL/kg	Within 1 hours
Severe	Infants	Intravenously Ringer lactate	40 mL/kg	Within next 2 hours
		Followed by oral ORS administration	40 mL/kg	Within next 3 hours
	Older children and adults	Intravenous Ringer lactate	110 mL/kg	Within 4 hours initially as fast as possible until the radial pulse is palpable

Note: In the management of severe cases all the measures described under mild and moderate dehydration have to be started before hospitalisation. Use the largest size needle available for IV drip. A common error is the use small needles for IV drip which will delay fluid administration.

Sodium (90 mmol/L)
Potassium (25 mmol/L)
Chloride (80 mmol/L)
Bicarbonate (30 mmol/L) and
Glucose (111 mmol/L)

Procedure to prepare ORS at home

Sodium chloride 3.5 g
Sodium bicarbonate 2.5 g
Potassium chloride 1.5 g

Glucose 20 g
Water 1 liter

It can be easily prepared in any household by dissolving sodium chloride 3.5 g, sodium bicarbonate 2.5 g, potassium chloride 1.5 g, and glucose 20 g, in one liter of drinking water. Rice based oral rehydration solutions have been devised. These are made by replacing the glucose with 80 g/L of rice powder and boiling the solution. In addition to the carbohydrate, the glycine

liberated by digestion of protein also assists the absorption of sodium and water across the intestinal mucosa.

Mothers are advised to give this fluid at frequent intervals to the children, thirst being the guideline for deciding the quantity and frequency. The efficacy of ORS has been widely tested and accepted. The glucose acts mainly as an agent to favour absorption of sodium. Glucose can be replaced by twice the quantity of sucrose or even other household starches, but they are less efficient. Severe dehydration, with or without hypovolemic shock, should be treated with intravenous fluids to achieve satisfactory rehydration. Ringer's lactate solution is the best commercially available preparation suitable for all age groups. This contains sodium lactate, sodium chloride, potassium chloride and calcium chloride. If Ringer lactate solution is not available, the next best is a solution containing sodium chloride 4 g potassium chloride 1 g, sodium acetate 6.5 g and glucose 10 g per liter. The volume and rate of fluid required depends on the severity.

One of the disturbing aspects which make ORS less acceptable to rural people is the fact that even though it stimulates absorption of electrolytes across the intestinal mucosa, often the stool volume is not reduced abruptly. This disadvantage is partly corrected by rice or cereal based ORS. Amylase resistant starch obtained from several types of cereals reaches the colon without being digested and absorbed in the small intestine. Bacterial action converts this starch into short chain fatty acids which promote the absorption of fluid and electrolytes from the colon and thereby reduce stool volume. 10 g of amylase resistant starch added to 200 mL of conventional ORS was found to be beneficial in studies conducted in Vellore S. India.

Fluid replacement should cover the losses in stools, vomitus, and sweat. In a severe case fluid balance should be checked hourly. Where facilities permit, replacement of electrolytes should be guided by laboratory estimations. As the dehydration is corrected, the child's mental state improves, the acidosis clears, blood pressure comes up and urine is passed. It is ideal to achieve a urine flow of 50-60 mL/h. An intravenous line should be maintained till the child is well on the road to recovery.

Maintenance therapy: Maintenance therapy is intended to replace continuing losses of fluid and electrolytes and this follows the initial intensive regimen. The principle is to match the input to the output. Oral rehydration solution can be relied upon for maintenance therapy in moderate cases without severe diarrhea. The volume of ORS should be 100 mL/kg body weight/day in mild cases. In moderate and severe cases, fluid should be given at the rate of 10-15 mg/kg body weight/h until diarrhea stops. Severe cases should be treated with intravenous fluids. IV: fluids can deliver only up to 4 mmols of potassium/L

whereas ORS contains up to 20 mmol/L. Hence ORS should be started as soon as the severe phase is tided over.

Antimicrobial drugs: Though cholera is a self-limiting disease, it is customary to use antibiotics when a case is diagnosed. Tetracycline, furazolidone, ciprofloxacin and erythromycin shorten the duration of the illness and stop excretion of vibrios in stools. Recent work (Dabashish Saha et al N Eng J med 2006: 354:2452-62) has shown that a single dose of azithromycin 1g given orally at the onset of illness reduces the duration of diarrhea (to 30 hours) and achieves elimination of bacteria in 78% of cases. These results are much better than those achieved with ciprofloxacin.

Dosage of drugs: all given orally

Tetracycline	2g od for 3 days or 500 mg 6h for 3 days
Doxycycline	100 mg b.d for 3 days
Ciprofloxacin	500 mg b.d for 3 days and
Erythromycin	40 mg/ kg daily, 6 h for 3 days
Azithromycin	1 g single dose

Dietetic management: Even during the diarrheal phase, food should be given in accordance with the patient's desire and tolerance. Starvation, in addition to the depletion of calories, also reduces the ability of the small intestine to absorb a variety of nutrients. Infants should be breastfed as they demand. Older children and adults should be given easily digestible food with adequate calories depending on customary practices and local availability. Fruit juices, bananas, coconut water, and cereals are usually well tolerated. Bananas and apple help to reduce diarrhea and form stools of normal consistency.

PREVENTION

Cholera is a notifiable disease. All suspected cases should be fully investigated bacteriologically and notified to the health authorities to prevent an outbreak. Health education of communities during outbreaks, chlorination of water supplies, control of flies, and provision of adequate treatment facilities at the affected areas help to limit the epidemic. Instruction on the use of ORS from the beginning of the diarrheal phase has proved to be of great value in reducing morbidity and mortality.

On a long-term basis, improvement in environmental sanitation, provision of protected water supply, arrangement for proper disposal of excreta, and improvement of food hygiene are absolutely essential to wipe out infective diarrheas. Chlorination of water effectively destroys the organism. Spraying the breeding places of flies with deltamethrin will suppress the fly population. Flyproofing of kitchen and food containers is very effective in arresting the spread of cholera.

Personal prophylaxis Vaccination is protective against cholera. The original vaccine was made from killed

suspension containing 8000 million organisms per mL composed of equal number of Ogawa and Inaba serotypes. Many newer vaccines employ equal numbers of classical cholera and eltor biotypes and the concentration has been raised to 12,000 million organisms per mL. This vaccine is antigenic. The course of immunization consists of 2 subcutaneous injections of 0.5 mL and 1 mL separated by an interval of four weeks. Several well-controlled field trials have shown that conventional cholera vaccines provide only low degree of protection, and that too only for 3-6 months. Improved vaccines with better antigenicity containing aluminium hydroxide and phosphate as adjuvants are under trial. Oral live vaccines are also under way. An attack of cholera confers temporary immunity of 6-12 months after which reinfections may occur.

Newer oral vaccines have been developed which are safe and effective. One type contains inactivated whole vibrio cholera O1 either given alone or in combination with the B subunit of cholera toxin, with a view to promote antitoxic activity as well. The other vaccine consists of attenuated strain of V. cholera O1 depleted of the virulence genes but retaining the protective antigens. This is given as a single dose orally. It also produces antibacterial and antitoxic immunity. Widespread administration of the killed vaccine also confers a herd immunity in the population. Since V. cholera forms a part of the normal flora and ecology of the surface water in many places it cannot be eradicated in toto.

Vaccination is to be given to special groups such as inmates of refugee camps and following natural disasters such as earthquakes and floods.

NON-CHOLERA VIBRIOS

Other vibrios that are at times pathogenic to humans are V. parahemolyticus, V. vulnificus, V. anginolyticus and a few others.

Infective agent	Pathogenicity
V. parahemolyticus	Explosive diarrhea
V. vulnificus	a. rapid onset fulminating septicemia. b. rapidly spreading cellulitis. c. acute diarrhea following consumption of shell fish.
V. anginolyticus	Wound infections, mainly opportunis

Acute Diarrheal Diseases of Children

Acute diarrheal diseases are the major killers of infants and young children, accounting for 30-50% of deaths below the age of 5 years. In India about 1.5 million children die annually from diarrheal diseases other than cholera. Disorders in which three or more watery stools

are passed daily with or without vomiting are included under this group.

Etiologic agents: The most well known pathogens are Shigella, Salmonella, enteropathogenic E. coli. Vibrio cholerae, Eltor vibrios, E. histolytica and G. lamblia and these account for only about 20% of the total, the remaining 80% being due to other agents which number about twenty. Diarrhea results either from enterotoxin or through invasive mechanisms. The clinical picture and management are the same as described under cholera.

Viruses account for the majority of diarrheal episodes in infants and young children in both developed and developing countries. These viruses include rotavirus, Norwalk and Norwalk-like agents, corona virus, adeno virus, calciviruses and others whose causative role is not yet clearly established. Viral gastroenteritis occurs globally in epidemic or endemic outbreaks.

- Epidemic gastroenteritis
- Endemic gastroenteritis
- Norwalk viruses
- Rotavirus, astrovirus and corona virus

Adenovirus and calcivirus cause both endemic and epidemic outbreaks.

ROTAVIRUS

Rotavirus affects mainly infants and young children aged 6 months to 2 years. In many places rotavirus has emerged as a major pathogen causing wide outbreaks. Three groups A, B and C are pathogenic to man and produces diarrhea in local or epidemic outbreaks.

Infection is by fecal-oral route Incubation period ranges from 1 to 7 days but usually it is less than 48 hours. The virus affects the enterocytes of the small intestine and the epithelium overlying the Peyer's patches. Destruction of the villi lead to disaccharidases deficiency and malabsorption of carbohydrates. Recovery of the villi takes 2-3 weeks.

Clinical Features

Vomiting occurs early and it precedes diarrhea. Diarrhea extends over 5-7 days but virus is shed for up to 10 days. Asymptomatic infections and mild disease may occur during outbreaks. Breast milk may have a protective role due to the presence of maternal IgA antibodies.

Diagnosis can be established by demonstrating the organism by electron microscopy or rotavirus antigen by ELISA test, in stool. This is not required in the ordinary case since specific antiviral therapy is not widely available. Rotavirus diarrhea responds to standard rehydration therapy as described under cholera. In developing countries rotavirus accounts for 20-30% of the diarrheal deaths. Nitazoxanide, in a dose of 7.5 mg/kg bw given orally for 3 days controlled rotavirus diarrhea in

hospitalized patients. This drug has been licenced in the USA for treating rotavirus infections.

Vaccination

Two rotavirus vaccines are currently available-Rotarix (Glaxo Smith Kline)

1. Monovalent vaccine made from human rotavirus strain and attenuated.
Dose: 2 oral doses 1st dose 6-14 weeks of age. 2nd dose 4 weeks later.
2. Pentavalent vaccine (Rota Teq. (Merck) made from bovine rotavirus strains and attenuated: dose 3 oral doses 1st dose 6-12 weeks of age 2nd and 3rd doses 4-10 weeks intervals.

Several other vaccines are being produced. The Millennium Development Group has suggested the inclusion of rotavirus vaccine in the routine childhood immunization schedule in order to prevent 5% of the deaths occurring in childhood and 4% of deaths due to diarrhea.

Ref. Roger I Glas et al Rotavirus vaccines. Current prospects and future challenges The Lancet 2006;368:323-32.

NORWALK AND NORWALK-LIKE AGENTS

Since 1972 these viruses have been identified as the cause of outbreaks of generally mild gastroenteritis occurring in school, community, and family settings. Norwalk agent was first isolated from Norwalk in Ohio State (USA). Virus particles resembling Norwalk agent morphologically, but serologically distinct are also identified as causing outbreaks of gastroenteritis. They cause illness in all age groups. Symptoms include vomiting, diarrhea, abdominal pain and myalgia which clear up in a day or two.

The viral antigen can be detected in feces by ELISA test. Treatment is symptomatic.

Management

General measures such as fluid replacement orally and if needed, parenterally should be instituted without delay. The condition is self limiting and the child recovers within a few days.

Probiotics

Since diarrheas lead to severe malnutrition, especially in children with subnormal nutritional status, food supplements-calories, proteins, vitamins, minerals and fluids should be started early. Probiotics help to resume normal bowel function, provide symptom relief and aid recovery. Probiotics are live microbes, many of them being normal intestinal flora. For example, lactobacillus, bifidobacterium, varieties of streptococci saccharomyces

boulardi and others. These help to restore normal microbial environment of the gut and antagonize pathogens. The main probiotic effect is the development, maturation and regulation of mucosa-associated immunological defences. Probiotics are also beneficial in suppressing atopy and food allergies.

Rarer Causes of Viral Diarrheas

Other viral pathogens include adenovirus, astrovirus, calcivirus and minirovirus. These produce diarrheas of varying severity.

CAMPYLOBACTER JEJUNI

Epidemiology: *Campylobacter jejuni* (previously known as vibrio fetus) is found in the intestines of birds, particularly in chicken, turkeys, wild birds, and also in dogs, cats, and calves. The organisms are spread by fecal-oral route. They are acquired from sick puppies, kitten, or infected cases. *Campylobacter jejuni* is ubiquitous and has been isolated as the pathogen in several outbreaks. Normal gastric acidity kills the organisms.

C. jejuni is a slender spirally shaped gram-negative bacillus, rapidly motile, non-sporing and microaerophilic.

Pathogenesis

Campylobacter jejuni invades tissues and produces diffuse bloody exudative enteritis and nonspecific colitis. No enterotoxin has been isolated. Bacteremia and metastatic lesions may complicate the primary lesion.

Clinical Features

Incubation period is 1-7 days. Main symptoms include watery or bloody diarrhea, abdominal pain, malaise, fever, vomiting and constitutional symptoms. The severity may vary. On an average there may be 8-10 bowel movements in a day. Recovery occurs within a week. *Campylobacter* infection cannot be clinically differentiated from other forms of dysenteries. Rarely a prolonged illness resembling typhoid and meningitis may develop.

Complications include reactive arthritis (1-2%) and possible induction of Guillain-Barré syndrome (GBS). Fourteen to thirty eight percent of patients with GBS give a history of recent campylobacter infection.

Treatment

Since the infection is self-limiting, fluid and electrolyte replacement forms the mainstay of therapy. The organisms respond to erythromycin given orally in a dose of 250 mg every 6 h. Resistant cases respond to tetracycline in a dose of 250-500 mg every 6 h. For bacteremia, gentamicin or chloramphenicol are given systemically.

Intestinal hemorrhage, toxic megacolon and hemolytic uremic syndrome may occur rarely. Mortality is very low.

Prevention

The organisms are destroyed by proper cooking and storage of animal foods, pasteurization of milk and provision of protected water supply. Chlorination of water kills the organisms.

CLOSTRIDIUM DIFFICILE: PSEUDOMEMBRANOUS COLITIS

Syn: Antibiotic associated diarrhea

Diarrhea occurs as a common side effect of therapy with many antibiotics. In many cases this is mild and non-specific. In the majority, symptoms subside on withdrawal of the drug.

Pseudomembranous colitis is a more serious and specific infection caused by *Clostridium difficile* which develops following the use of clindamycin and several antibiotics such as ampicillin, cephalosporins and others given for both aerobic and anaerobic sepsis. *Clostridium difficile* is a gram-positive anaerobic spore-forming bacillus that can cause pseudomembranous colitis and other disease manifestations. It produces two toxins A and B. Generally toxin A is enterotoxin and toxin B is a cytotoxin. In addition, about 6% of organisms produce a third toxin known as binary toxin CDT which is similar to the toxin of *C. perfringens*. The toxins account for its virulence. Transmission occurs primarily in health care institutions where exposure to antimicrobial drugs especially clindamycin, erythromycin, tetracycline and

chloramphenicol. The presence of spores favour transmission. Alteration in the intestinal microbial flora contributes to the pathogenicity- which is pseudomembraneous enterocolitis. With the widespread use of antibiotics, pseudomembranous colitis has come into prominence.

Pathologically the lesions consist of disruption of villous tips, infiltration by neutrophils, and the presence of yellow plaque-like lesions on the mucosa, especially in the colon. These are caused by the toxins derived from *Clostridium difficile* which overgrows and become pathogenic.

Clinical Features

A broad spectrum of diseases ranging from mild diarrhea to severe life-threatening illness may occur. The disease is clinically characterized by abdominal pain, fever, leucocytosis, watery diarrhea and rarely toxic megacolon. Sigmoidoscopy reveals erythema with ulceration of the mucosa and patchy adherent membranous plaques. If not diagnosed and treated early, the mortality may go up to 50-60%.

Clinical suspicion should lead to the diagnosis. The organism can be isolated from feces. Presence of toxins can be demonstrated in fecal samples by ELISA.

Drug treatment consists of metronidazole in a dose of 400 mg tid for 10 days. An alternative is vancomycin 250 mg qid for 10 days. On stopping therapy recurrence is common. In them addition of rifampicin to vancomycin helps to control the infection. Probiotics like *Saccharomyces bulardi* or Lactobacillus help to reconstitute the intestinal flora.

Tick-Borne Relapsing Fever 237

Lyme Borreliosis 238

Bartonellosis

Syn: Carrion's Disease, Oroya Fever, Verruga Peruana

The genus *Bartonella* consists of three main pathogens affecting man.

Bartonella bacilliformis Cause of Carrion's disease

Bartonella henselae Cause of cat-scratch disease and bacillary angiomatosis in patients with AIDS

Bartonella quintana Cause of trench fever, transmitted by body louse.

CARRION'S DISEASE

This name is given in memory of Daniel A. Carrion a Peruvian student who injected infective blood into himself during studies on the infectivity of *Bartonella bacilliformis*.

Carrion's disease is confined to the valleys of Andes mountains of South America and has not been reported from India. It is caused by *Bartonella bacilliformis*, which is seen inside the erythrocytes. The disease is transmitted by the sandfly *Phlebotomus verrucarum*.

Bartonella bacilliformis is a small gram-negative coccobacillus $0.3-1.5 \times 0.2-0.5 \mu\text{m}$. It is motile and strictly aerobic.

It presents different clinical pictures at different stages of evolution of the disease. After an incubation period of three weeks, the disease develops. It is characterized by two distinct clinical syndromes. The initial illness is characterized by constitutional symptoms like fever, rigors, nausea, diarrhea and headache. This is called Oroya fever and lasts for 3 to 4 weeks. Organisms can be demonstrated in blood smears stained by Giemsa's or Wright's stain. Death may occur at this stage due to severe anemia or superinfection by *Salmonella*.

The second stage, called *Verruga peruana*, is characterized by hemangiomatous tumors of skin and mucous membranes varying in size between 2-15 mm, some of which may ulcerate. Mortality is very low at this stage, since immunity develops.

Specific treatment is with chloramphenicol or tetracyclines in addition to supportive measures.

BACILLARY ANGIOMATOSIS

This is caused by *Bartonella henselae* which is seen in domestic cats. It may produce three clinical syndromes;

1. Chronic bacteremia
2. Bacillary peliosis hepatis and disseminated bacillary angiomatosis. Skin lesions occur as vascular nodules and may reach large sizes. Such lesions may be seen in internal organ such as liver, spleen, lymph nodes and bone marrow. Prolonged fever is common. Treatment is with antimicrobials such as erythromycin, doxycycline or ciprofloxacin given for 3 to 8 weeks.

CAT-SCRATCH DISEASE

This is also caused by *Bartonella henselae*. It is transmitted by bites, licks or scratches by the cat. Local lesion develops as a crusted papule. It is followed by fever and malaise and tender regional lymphadenopathy. The lesion is self limiting and usually benign. Rarely complications may occur, which include meningitis, myelitis, encephalitis hepatitis and osteomyelitis. Treatment is with erythromycin or doxycycline.

TRENCH FEVER

This is caused by *Bartonella Quintana* which is transmitted from person to person by the body louse. It is seen in persons huddled in trenches, refugee camps and similar situations. Treatment is with erythromycin or doxycycline.

Legionellosis

Legionellaceae are gram-negative rods whose natural habitat is water. Man is accidentally infected and human to human transmission is unusual. There are over 36 defined species, among which *L. pneumophila* is the most common human pathogen. Two main clinical syndromes are produced—*Legionnaires disease* and *Pontiac fever*. The former has a low attack rate among those exposed whereas the latter has a high attack rate.

LEGIONNAIRES DISEASE

The first description was given in 1976 following the outbreak of an unusual pneumonic illness among members attending the legion convention at Philadelphia. The organisms have been isolated from air-conditioning systems, water taps, soil, and other environment. It is acquired by inhalation, ingestion, or through the conjunctiva.

At present legionella has been found to be a common cause of community acquired pneumonia in several countries including India. Infection is by inhalation of aerosols containing the organisms or microaspiration of infected water. Legionella exist in water. They can infect and replicate within several protozoa found in the soil, including amoebae. By successive replication its virulence increases.

The incubation period is 2 to 10 days after which the patient presents with fever, anorexia, weight loss,

headache, myalgia and confusion. Severe cases progress to pneumonia and pleurisy.

Lesions: Pneumonia is the commonest presentation followed by gastrointestinal symptoms such as watery diarrhea. Cardiac lesions include myocarditis, pericarditis, post-cardiotomy syndrome and prosthetic valve endocarditis. Neurological manifestation are not uncommon these include confusion, frank encephalopathy, neuropathy, myositis, cranial nerve palsies and cerebellar disturbances. These have been described in Indian patients.

(Kulkarni KH et al. Focal neurological manifestation in legionellosis. J. Ass. Phys. Ind. 53, 2005 731-733).

PONTIAC FEVER

Pontiac fever also occurs in persons exposed to the infective environment. It is a brief febrile illness resembling influenza, caused by other species of legionella. Mortality is nil. Nosocomial legionella infections may lead to wound infection or prosthetic valve endocarditis, rarely.

Diagnosis

1. Culture of the organism from sputum.
 2. Direct fluorescent antibody staining is a quick and ready method, but less sensitive and more non-specific.
 3. Legionella urinary antigen detects legionella in urine.
- RIA assay and ELISA are available. Rapid serological tests are good for epidemiological investigations, but not for case management. Four-fold rise in antibody titre or an antibody titre of 128 or more is suggestive of infection. Sometimes a few weeks may be required for serology to become positive.

Legionella pneumophila responds to erythromycin and rifampicin if given early in the course of the disease.

Dose of erythromycin is 500 mg 6 h oral.

Alternate drugs include:

Roxithromycin	300 mg oral bd
Azithromycin	500 mg oral or IV daily
Ciprofloxacin	500 mg oral—8 h or 750 mg oral bd

In severe cases ciprofloxacin may have to be given IV initially, later to be changed to oral dosage.

The total duration of treatment has to be up to 21 days

The disease carries a mortality ranging from 10-20%.

Immunocompromized subjects suffer more.

Legionella in water tanks can be sterilized by heating to 70°-80°C or chlorination.

Yaws

GENERAL CONSIDERATIONS

Yaws and pinta are nonvenereal diseases caused by spirochetes which resemble *Treponema pallidum* mor-

phologically and serologically, but differ in pathogenesis and epidemiology. Primary infection is usually acquired in childhood. Transplacental transmission of infection does not occur usually. Pathologic lesions are confined to the skin and bones, the other viscera are not affected as in syphilis.

Yaws is widely prevalent in the tropics and subtropics. It is seen sporadically in all parts of India, though the disease is more prevalent in Africa. The causative organism is *Treponema pertenue*. The discharges from the primary and early secondary lesions teem with the organism. Transmission is much more efficient during the wet seasons. Portal of entry is abrasions of the skin. Overcrowding and poor personal hygiene favour transmission.

Three stages—primary, secondary and tertiary can be identified during the course of the disease. With the improvement in living conditions and advent of penicillin therapy the picture of yaws and its prevalence have changed considerably, though there are some suggestions that the disease is also showing signs of resurgence.

The pathological lesions in the early stages within five years of infection take the form of papillomas. Late yaws develops five or more years after the onset. These take the form of gummatous changes with widespread tissue destruction, mutilation and ulceration.

Clinical Features

The primary stage: This shows red maculopapular lesions which develop at the site of inoculation of the organism after three to six weeks. These enlarge and become multiple. They are painless but pruritic. Ordinarily they heal without scarring.

The secondary lesions develop in crops, weeks to months after the healing of the primary lesions. Though they resemble the primary lesions, they are more numerous and widely distributed over circumoral, axillary, perineal, and perianal regions. In the moist areas they assume the appearance of condylomas. Over the palms and soles the lesions become painful and walking may be restricted due to pain (**crab yaws**). Bones are affected in the secondary stage. Multiple long bones are involved. The shaft shows cortical rarefaction and sub periosteal inflammation and new bone formation. The affected part is thickened and painful. Nasal bones show thickening (**gondou**) and the tibial lesion may give rise to sabre tibia.

The tertiary stage develops 5-10 years later with gummatous and destructive lesions. The skin and bones are affected. Deep ulcers develop which show overhanging edges. Chronic destructive lesions in the bone may lead to discharging sinuses. Extensive destruction of the facial tissues with gross mutilation of the nose and mouth leads to the formation of a single open cavity (**gangosa**).

Diagnosis

Clinical suspicion should be strong to diagnose this condition since it occurs sporadically or in families and the condition is likely to be missed by the unwary physician.

Yaws has to be differentiated from other granulomatous lesions involving the skin and bones such as syphilis, tuberculosis, leprosy, and mucocutaneous leishmaniasis all of which may cause lesions similar to gondou. The diagnosis is confirmed by demonstrating the treponemes in the discharges from primary and secondary lesions by dark ground illumination. Serological findings resemble those of syphilis.

Treatment

Dramatic improvement occurs with a single dose of 1.2 mega units of benzathine penicillin given intramuscularly. An alternative regimen is to give tetracycline 1-2 g daily for 5 days. Early cases are cured, whereas, in late cases, mutilation may persist.

Pinta

Pinta, which is also a non-venereal treponemal disease prevalent in South and Central America, is caused by *Treponema carateum*. Transmission occurs by close physical contact and the organism enters through skin abrasions. Exudates from the early skin lesions are highly infective.

Clinical Features

The incubation period is 7-21 days. The primary lesions develop at the site of inoculation as erythematous, pruritic papules, which coalesce to form ulcers, which take a long time to heal. Scarring and depigmentation occur at these sites. The secondary stage develops three to twelve months after the primary stage. Morphologically these lesions resemble the primary lesions. They are smaller but more numerous and widely distributed. Lesions at different stages of development occur simultaneously. Constitutional symptoms may occur at this stage. When the skin lesions heal, atrophy, scarring and depigmentation result.

Diagnosis

The discharges from early skin lesions reveal spirochetes on dark ground illumination. In late lesions organisms may not be demonstrable. Serological tests for syphilis are positive in such cases.

Treatment

Single dose of 1.2 mega units of benzathine penicillin given intramuscularly is curative in most of the cases.

Relapsing Fevers

K.V. Krishna Das, K. Sreekanthan

BORRELIAL INFECTIONS

Borrelia are helical rods 8-30 μm long and 0.2-0.5 μm in diameter with 3-10 loose spirals, actively motile and stainable by aniline dyes. In man they cause relapsing fevers and Lyme borreliosis. Relapsing fevers are further classified into louse-borne and tick-borne varieties depending on the vector which transmits the disease viz. body louse or soft tick. Lyme disease is transmitted by hard tick (Figs 43.1 and 43.2).

LOUSE-BORNE RELAPSING FEVER

This disease is caused by *Borrelia recurrentis*. It affects only man. Epidemics used to follow wars, famines, or natural catastrophes such as floods or earthquakes. Overcrowding, malnutrition, and unhygienic surroundings start off epidemics in the tropics and temperate zones. Severe epidemics have occurred in north Africa, Middle East and Europe following World War II and the mortality was as high as 70%. The vector is the body louse

Fig. 43.1: Hard tick

Fig. 43.2: Soft tick

(*Pediculus humanus corporis*) which is infected by blood meal containing the organism from infected persons. The louse becomes infective in 5-15 days and the organisms are found in its body cavity. It remains infective for its whole lifespan (1 month). Lice leave their host when the temperature is high or when the temperature drops after death, to seek new hosts. Pruritus caused by their bites leads to scratching and the lice are crushed. Smearing of their infected body contents and excreta to the bite wound results in infection of the host. Lice do not transmit the infection transovarially to their progeny.

Pathology

In the early phase of infection bacteremia develops and borreliae can be demonstrated in blood films outside the cells. They invade most of the viscera, especially the spleen, liver, brain, meninges, kidneys, and the heart. Skin, mucous membranes, and serous surfaces show petechial hemorrhages. Consumption coagulopathy may occur resulting in thrombocytopenia. Renal involvement leads to proteinuria and hematuria. Macrophages in the liver, spleen, lymph nodes and bone marrow may show engulfed borreliae. After an attack of fever the spirochetes disappear from the blood to reappear again during relapse. Probably immunological factors are important in producing clearance of these organisms.

Clinical Features

The incubation period varies between 2-12 days, but is usually 7-10 days. Onset is abrupt with high fever, rapid pulse, headache, body pains, conjunctival congestion, epistaxis and sometimes a petechial rash. Herpes labialis may develop. The liver and spleen enlarge and become palpable. Jaundice, meningism, and intestinal hemorrhage may occur. In four to ten days the fever comes down by crisis, but in some cases it returns after 5-7 days. Two or three such relapses may occur in succession. The relapses are generally milder and less prolonged. In epidemics, the mortality used to be as high as 40% especially in children and the elderly. After recovery from the illness immunity lasts for 1-2 years.

Diagnosis

Examination of blood films stained with Giemsa's or Leishman's stain reveal the borreliae. Dark ground or phase contrast microscopy of fresh blood may show the motile organisms.

Treatment

The disease responds well to penicillin and tetracycline in the usual doses, the former is more slow in action. Drug therapy may lead to severe *Jarisch-Herxheimer* reaction with profound fall in temperature, shock and cardiac

failure within a few hours. This potential complication should be expected and supportive measures instituted promptly. Initial administration of procaine penicillin 500,000 units on the first day, followed subsequently by tetracycline 2-4 g/day has been recommended as a safer course.

Prevention

The disease can be prevented by undertaking delousing measures. Use of 10% DDT powder effectively kills the lice. Boiling the clothes and bed linen for 30 minutes destroys the lice and their eggs.

TICK-BORNE RELAPSING FEVER

The causative organism is *Borrelia duttonii* which is transmitted by several species of soft ticks (Argasidae). Several antigenic variants of the same species have been identified in different regions, e.g. *B. novyi*, *B. carteri*, etc. Endemicity in a region is determined by the vector population. In the Middle-East, Iran and Afghanistan, *Ornithodoros tholozoni* is the main vector. In these regions non-human animal reservoirs like rodents or bats exist. The ticks are infected from them and they transmit the infection to humans accidentally. In North India relapsing fever is caused by *B. carteri* spread by *O. tholozoni*, *O. crossi*, *O. lahorensis*, and the fowl tick *Argas persicus*. In Central and East Africa the infection is mainly confined to man and the vector is *O. moubata* which inhabits mud floors, crevices in dwelling places or camp sites. Ticks transmit infection transovarially to the progeny so that a large colony of infected ticks develops which acts as a reservoir of infection. The soft ticks live for 14-21 years and can subsist on blood meals taken at very long intervals. These ticks bite at night, and the bite is painless. They attack several animals and man is only incidentally affected. They insert their mouth parts into the skin and remain attached to the body for a few days taking their blood meal, after which they fall off. The site of attachment shows a pruritic erythematous lesion which develops into an eschar. Both the adults and the larval forms suck blood. The saliva, coxal fluid and excreta of ticks contain the organisms. *Borrelia* enter through the bite wound, abrasions on the skin, and also intact mucous membranes. Pathology resembles that of louse-borne relapsing fever, but neurological involvement is more frequent.

Clinical Features

Tick-borne relapsing fever resembles louse-borne relapsing fever, but the febrile bouts may be shorter, lasting only for 3-5 days, so also the apyrexial intervals. Number of relapses are more and may reach up to ten. Neurological complications occur during relapses. These

Diseases Caused by Infections

6

include facial palsy, optic atrophy, spastic paraplegia, and other focal paralysis. Mortality is lower than in louse-borne relapsing fever. Though substantial immunity occurs, it is not permanent.

Diagnosis

The clinical diagnosis is supported by the demonstration of the organisms in stained blood smears or by dark ground microscopy. Compared to the louse-borne disease, the organisms are less numerous. Other diagnostic methods such as animal inoculation studies using rats, mice and guinea pigs are available.

Treatment

The disease responds to tetracycline 1 g given daily for seven days and repeated after a week if necessary. Though *Jarisch-Herxheimer* reaction may develop, it is less pronounced. Doxycycline in a single dose of 200 mg is effective against the borrelia but allergic reactions are more frequent.

Prevention

Ticks can be destroyed by spraying with Lindane 1% (gamma BHC). Visitors to infected areas should be informed of the risk. They should wear protective clothing and use insect repellants. Ticks should be looked for and removed mechanically from the body before going to bed after the day's work.

Lyme Borreliosis

This is caused by the spirochete *Borrelia burgdorferi*, transmitted by hard ticks *Ixodes ricinus* and *Ixodes persulcatus* in Eurasia and *Ixodes dammini*, *I. pacificus* and *I. scapularis* in North America. The organisms are present in the saliva of the ticks. Tick bites are generally painless. Ticks inhabit woods. Various intermediate and small mammals including rodents act as reservoirs. Birds help to transfer infected ticks over great distances during their migratory flights. Maternal-fetal transmission of infection has been recorded.

Borrelia burgdorferi is 10-30 μ long and 0.2-0.25 μ wide. Unlike *T. pallidum*, it can be grown in artificial media, though with difficulty. Three different genospecies and seven serotypes have been identified. This fact possibly accounts for the different organotropism and virulence exhibited in various geographical areas.

Pathology

The disease affects mainly the skin, nervous system, heart and joints. The organisms have been isolated from various specimens such as blood, skin, CSF, eye, joint fluid and myocardium, indicating that the organisms get

disseminated widely. The organisms are present in the lesions extracellularly. Histologically the lesions show inflammatory infiltrate consisting mainly of lymphocytes, histiocytes and plasma cells. The total pathogenesis may be the sum total of direct invasion, stimulation of several inflammatory cytokines and autoimmune mechanisms.

Clinical Features

Incubation period ranges from weeks to months. Three clinical stages are seen. The first two stages are early manifestations, the third is late manifestation.

Stage I: Clinical lesion is erythema migrans which is a rash spreading centrifugally.

Stage II: (Early disseminated infection)

This develops a few weeks to months after infection. Several organs become affected, probably because of hematogenous spread. Lesions include:

Neurological Features (Lyme Neuroborreliosis)

These include meningoradiculitis, meningitis, cranial neuritis involving predominantly facial nerve, plexus neuritis, mononeuritis multiplex and rarely encephalitis, myelitis and cerebral vasculitis.

Meningoradiculitis also known as Bannawarth's syndrome—which is common, is characterized by CSF pleocytosis and severe radicular pain, especially worse at night. Other accompaniments of meningitis such as severe headache and signs of meningeal irritation are not present.

Cardiac manifestations include heart block, arrhythmias and heart failure. **Arthralgias and myofasciitis** can develop at this stage. Localized or generalized lymphadenopathy may occur. Ocular involvement presents as conjunctivitis, iridocyclitis, choroiditis, optic neuropathy with papilloedema and panophthalmitis. Rarely hepatitis and orchitis may occur.

Stage III: This develops months to years after infection. This is characterized by mono or oligoarticular arthritis affecting the large joints, particularly the knees.

Skin lesions develop in the extremities as bluish red edematous areas which go on to atrophy and wrinkles. These are called **acrodermatitis chronica atrophicans**.

Rarely progressive lyme encephalitis and encephalomyelitis characterized by spastic paresis and ataxia may develop. Several other rare manifestations have been described.

Diagnosis

This is based on endemicity, evidence of tick bite and the clinical picture. Only 0.5 to 1% of tick bites in affected regions transmit the infection. Material removed by biopsy from the margins of the erythema can be used to culture the organism and also demonstrate them by PCR.

Serological tests to demonstrate IgG antibodies by ELISA, indirect immunofluorescence assay (IFA) and Western blot are available in specialized laboratories. Both serum and CSF have to be tested to diagnose neuroborreliosis.

The cultivation of the organisms from body fluids is difficult and hence serological tests are used for diagnosis routinely.

Treatment

Stage I: Doxycycline, amoxycillin, cefuroxime and ceftriaxone are the most effective antibiotics.

Stage II: High dose intravenous crystalline penicillin as is given for meningitis leads to fast resolution of radicular pain. Corticosteroids given concurrently accelerate relief. Other alternatives are ceftriaxone and cefotaxime.

Stage III: Arthritis responds to doxycycline and amoxycillin. Resistant cases respond to ceftriaxone, cefotaxime or high dose intravenous penicillin.

TABLE 43.1

Dose of antimicrobials for lyme disease	
Doxycycline	2 × 100 mg/day × 14 days
Amoxycillin	3 × 500-1000 mg/day × 14 days
Cefuroxime	2 × 500 mg/day × 14 days
Ceftriaxone	IV 2 g/day × 21 days
Phenoxy methyl penicillin oral	3 × 1-1.5 million units/day × 14 days

Rarely, Jarisch-Herxheimer reaction may develop during treatment (Table 43.1).

Prevention

Tick bites can be avoided by wearing protective clothing impregnated with permethrin which is a tick repellent. Ticks transmit the disease only if they are attached to the body for several hours. So early removal of ticks with forceps without breaking their mouthparts considerably reduces the risk of infection.

44

Leptospirosis

R. Sajith Kumar, K.V. Krishna Das

Chapter Summary

- General Considerations 239
- Pathology 240
- Clinical Features 240
- Diagnosis 241
- Treatment 241
- Prevention 242

General Considerations

Leptospirosis is one of the most common zoonotic disease across the world, caused by pathogenic spiral bacteria belonging to the genus *Leptospira*, the family *Leptospiraceae*, and the order *Spirochetales*. These are finely coiled, thin, motile, obligate, slow-growing anaerobes. Their flagella allow them to burrow into

tissues. The genus *Leptospira* was originally thought to comprise only of 2 species, *L interrogans*, which is pathogenic, and *L biflexa*, which is saprophytic. Recent work has identified seven distinct species of pathogenic leptospira which appear as more than 250 serologic variants (serovars). The classic *L interrogans* species, is divided into 7 named and 5 unnamed species as follows:

L interrogans, *L weilii*, *L santarosai*, *L noguchi*, *L borgpetersenii*, *L inadai*, *L kirschner*, and *Leptospira* species 1, 2, 3, 4, and 5. They infect many types of mammals including rats, dogs, cats, cattle, pigs, squirrels, raccoons, mongooses, and bandicoots. Leptospires are passed in the urine of infected animals, even though many of them do not suffer from the disease. They remain viable and infective in fresh water for varying periods upto 16 days and in soil for upto 24 days. They infect humans by entering through intact mucosal surfaces of the conjunctiva, oro-nasal cavity, genitourinary tract and

others, or disrupted skin, when the person bathes, wades through contaminated puddles and fields or engages in under-water activities. The organisms are killed by even minor changes in the temperature, acidity, salinity, chlorine content and other physical and chemical changes.

Epidemiology

The disease was first recognized as an occupational disease of sewer workers in 1883. In 1886, Adolf Weil described the clinical manifestations in four men who had severe jaundice, fever, and hemorrhage with renal involvement. Inada et al identified the causal agent in Japan in 1916. Almost all published case series focussed on seasonal outbreaks associated with changes in local water levels, flood conditions and increased risk of exposure of the population to infection. In India most outbreaks follow flooding in monsoon seasons. Andamans, Tamil Nadu and Kerala have been witnessing many epidemics from the middle of the twentieth century. Workers employed in paddy, pineapple and sugarcane cultivation and people engaged in underwater occupations like sand mining, inland water fishing and cleaning of contaminated water logged areas are predisposed to get the infection. The disease is also more common among butchers, veterinary staff, and people who handle live cattle, dogs and other pets. Leptospirosis has been encountered in almost all major hospitals all over the country.

Only about 10% of all leptospirosis cases run the classic clinical picture and get diagnosed. The majority may get only a non-specific febrile illness or may be even subclinical. Still all develop antibodies and therefore a large porportion of the population in many endemic regions possess anti-leptospiral antibodies.

Using microagglutination techniques, the major serogroups prevalent in Kerala were grippotyphosa, australis, autumnalis, icterohemorrhagiae and leuisiana. A new serovar *Bharathy type Kolencherry* has also been identified in Kerala.

Pathology

Entry of leptospira through the skin or mucous membrane is followed by extensive proliferation of the organism in blood and many tissues. The resulting leptospiremia causes widespread distribution and further damage in many organs. Leptospiremia stage is followed by disappearance of the organisms from blood, but this is followed later by the appearance of leptospira in urine (leptospiruric phase). Most of the pathological manifestations are due to immunologically mediated injury, even though direct invasion by the organism may also cause damage. The true mechanism of injury is not very clear even though complex interactions involving

endotoxin, hemolysin, and lipase are thought to play major roles.

The pathologic findings in many organs include vasculitis of capillaries causing endothelial edema, necrosis, and lymphocytic infiltration and hemorrhage. Capillary vasculitis leads to loss of red blood cells and fluid through the vascular wall. This causes secondary tissue injury. Platelet count is reduced in a good proportion of patients. Bleeding tendencies such as petechiae and mucosal bleeding (sub-conjunctival bleeding in particular) occur. Bleeding may not always be directly proportional to thrombocytopenia or alterations in coagulation function since it is multifactorial in origin.

The liver shows vascular congestion and disorganization of the liver cell plates on histology. Hyperbilirubinemia occurs in leptospirosis. This is caused by hepatic injury, also contributed to by muscle damage and release of myoglobin, intra- and extravascular hemolysis and hemorrhages.

In the kidneys, the interstitium, renal tubules, and tubular lumen are affected causing interstitial nephritis and tubular necrosis. Renal failure is usually due to tubular damage, but hypovolemia resulting from dehydration and altered capillary permeability are also contributory.

In the lungs either focal or diffuse alveolar capillary injury is common. Interstitial and intra-alveolar edema and bleeding can occur. Fatal adult respiratory distress syndrome (ARDS) may occur without warning.

In the heart, epicardial and endocardial petechiae, interstitial edema and lymphocyte and plasma cell infiltration of the myocardium, myocarditis and coronary arteritis may develop.

Clinical Features

The incubation period is usually 7-12 days, with a range of 2-20 days. Approximately 90% of patients manifest mild anicteric form of the disease. 5-10% have the severe form with jaundice, classically known as *Weil's disease*. The natural course of leptospirosis falls into two distinct phases: leptospiremic and immune phases. During a brief period of 1-3 days between the 2 phases, the patient shows some improvement.

The leptospiremic phase resembles any viral fever with high temperatures, generalized myalgia, sore throat, cough, chest pain, hemoptysis, generalized rash and frontal headache. Conjunctival suffusion and prominent myalgia and tenderness over big muscles are very suggestive of leptospirosis. Many cases recover and the patient may becomes afebrile within a week.

The next phase, also called as immune or leptospiruric phase is associated with the appearance of antibodies in blood and elimination of leptospira in urine. Symptoms may persist for 6 days to more than 4 weeks, with a mean duration of 14 days.

There are two well defined patterns, icteric and non-icteric. The non-icteric illness is more common.

The Non-icteric Illness

The presenting feature is usually headache, attributable to aseptic meningitis, confusion, irritability and occasionally delirium. Calf muscle tenderness and subconjunctival hemorrhages appear early in classic *Weil's disease*. Cutaneous manifestations include hemorrhages and maculopapular eruptions on the trunk. *The involvement of kidneys leads to rapid development of oliguric renal failure, which may necessitate dialysis therapy.* Hyperkalemia and metabolic acidosis are common.

The Icteric Illness

The icteric illness is usually associated with deep jaundice, acalculous cholecystitis, pancreatitis, and GI bleeding. Bilirubin levels may exceed 30 mg/dL. Aspartate (AST) and alanine aminotransferase (ALT) are moderately elevated, the elevation being considerably less compared to the rise in bilirubin. This is in contrast to the picture in viral hepatitis in which the elevation of transaminases is much more prominent.

Cervical, axillary and mediastinal lymph nodes may be enlarged. *Different types of bleeding* can occur ranging from epistaxis and gingival oozing to hematuria, hemoptysis, and pulmonary hemorrhage. Subconjunctival hemorrhage is common. It is not related to platelet count or coagulation abnormalities. Uveitis and iridocyclitis may occur.

Pulmonary manifestations include cough, hemoptysis, and pneumonia. Chest X-ray may show multifocal infiltrates, as well as pleural effusions. *Respiratory symptoms* may progress to acute respiratory distress syndrome (ARDS), requiring intubation and mechanical ventilation. *Myocarditis and coronary arteritis* may occur. These present as first-degree A-V block in 30% of patients early in the disease. It resolves completely with recovery. Atrial fibrillation may occur, this carries a bad prognosis. ECG changes includes T-wave inversion in 18%, ST-segment elevation in 15%, and abnormalities of rhythm in 11%. Renal involvement to produce acute oliguric renal failure is also common.

It is known that clinical features of leptospirosis are not specific to the infecting organism since considerable overlap may occur in the disease manifestation caused by the different serovars. But some clinical manifestations are more frequently seen by infection by particular serotypes. These include:

Hepatorenal lesions	<i>L icterohemorrhagiae</i>
Pretibial skin lesion	<i>L autumnalis</i> (Fort Bragg fever)
Meningeal symptoms	<i>L canicola</i>

Diagnosis

Leptospirosis should be suspected in all cases of febrile jaundice associated with severe myalgia, prostration and conjunctival congestion, especially during local outbreaks.

Laboratory Diagnosis

Polymorphonuclear leucocytosis, occasionally with toxic granules and band forms and elevated ESR are seen in about 90% cases. Mild thrombocytopenia may occur in up to 50% cases. Urine examination reveals proteinuria with leukocytes, erythrocytes, hyaline casts, and granular casts in the sediment. As noted earlier the gross elevation in serum bilirubin is associated with only a mild or moderate elevation in transaminase values. Creatine phosphokinase (CPK) is markedly elevated, particularly in patients with muscle tenderness. Higher values of serum alkaline phosphatase suggests cholestasis.

Demonstration or culture of leptospira from blood or urine samples demand advanced laboratory facilities. Dark field examination and use of immunoflourescent techniques are helpful in early stages. The serologic tests become positive by the end of the first week. These include macroscopic and microscopic agglutination using antigens for identifying the strains, and ELISA tests using monospecific antigens to identify serovars. False positive and false negative results are common. Rising titres are more helpful in diagnosis. More recently, rapid commercial tests such as dipsticks (Dry-dot) which contain antigens and used to detect leptospira antibodies in blood, have been made available. CSF may show moderate lymphocytic pleocytosis (200-300/cm).

Differential Diagnosis

Leptospirosis mimics almost any febrile illness at different stages. These include dengue fever, encephalitis, hantavirus hemorrhagic fever with renal syndrome, hepatitis, cholecystitis, yellow fever, rickettsial diseases, falciparum malaria, meningitis, infectious mononucleosis and even enteric fever.

Prognosis

Leptospirosis is a serious illness with mortality ranging from 10- 30% depending on the stage of disease at which people seek treatment and proper early diagnosis. Serious patients may die within 24 hours of hospitalization. Death is due to renal failure, generalized bleeding, shock, ARDS or myocarditis. Hepatic failure per se is not a common cause of death even in jaundiced patients. Infection acquired in the early months of pregnancy is associated with higher incidence of spontaneous abortion.

Treatment

General measures like correction of fluid balance, inotropic support, platelet transfusions and others must

be instituted as in the case of any serious illness. All patients with oliguria, confusion, irritability and bleeding should be hospitalized. Fluid and nutrient intake-output chart should be meticulously maintained in order to detect renal involvement early. Renal failure requires early dialysis. Myocarditis, hepatic failure and bleeding manifestations demand special management in appropriate facilities.

Antibiotics

Leptospira are sensitive to several antibiotics such as penicillin, tetracyclines, erythromycin, quinolones, third generation cephalosporins doxycycline and others. Penicillin is the drug of choice. Benzyl penicillin G in a dose of 1.5 mega units IV every 6 hours produces dramatic improvement in 24-72 hours. Penicillin is continued in the same dose till the acute symptoms subside, and thereafter in a reduced dose. Rarely Jarisch-Herxheimer reaction develops at the commencement of bactericidal therapy. This has to be managed with antihistamines, supportive measures and corticosteroids. In those patients who are allergic to penicillin, doxycycline erythromycin, chloramphenicol and quinolones are also effective alternative drugs.

Prevention

Prevention of leptospirosis in animals is difficult. Environmental sanitation to avoid contamination of water sources by animal and rodent urine and care during bathing and wading through contaminated water should reduce infection. Proper washing with soap and water and quick drying of the skin after exposure to contaminated water reduce risk of infection. Treatment with bleaching powder kills the organisms.

Vaccination of domestic cattle and dogs has been tried with success. Dogs are regularly vaccinated in many countries including India.

Chemoprophylaxis

Doxycycline administered orally in a dose of 200 mg once weekly during the period of exposure is protective.

Points to remember

- 1. Leptospirosis has become a very common infection in many parts of India
- 2. Several serovars cause the disease
- 3. Brunt of the disease is borne by the liver and kidney, but several other organs may also be affected
- 4. Early diagnosis and treatment with penicillin or other antibiotics ensure cure in the vast majority.
- 5. Prompt dialysis therapy saves life in severe renal involvement

45

Rickettsial Diseases and Q Fever

K.V. Krishna Das, V.P. Gopinathan

Chapter Summary

- General Considerations 242
- Epidemic Typhus 243
- Endemic Typhus 244
- Scrub Typhus 244
- Tick-borne Typhus 245
- Q Fever 245

General Considerations

242 Rickettsiae are obligate intracellular parasites. These organisms are naturally found in arthropods which act as

active vectors without themselves suffering. Rickettsiae are classified into three genera-**Rickettsia**, **Rochalimea**, and **Coxiella**. Tissue culture or the yolk sac of the embryonated egg has to be employed for growing them. Sulphonamides may enhance the growth of rickettsiae, whereas tetracycline and chloramphenicol inhibit.

All of these organisms except *Coxiella burnetii* are transmitted by insect vectors like the body lice, ticks, mites and fleas.

Serological Diagnosis of Rickettsial Diseases

Agglutination of *Proteus vulgaris* (Weil-Felix reaction): Rickettsiae and *Proteus vulgaris* share common antigenic

TABLE 45.1

Details of rickettsiae pathogenic to man			
Group	Agent	Vector and reservoir	Weil-Felix reaction
A. Typhus group			
1. Epidemic typhus	<i>R. prowazekii</i>	Body louse (man)	+++ for OX-19
2. Endemic typhus	<i>R. typhi</i>	Rat flea (rat) (formerly <i>R. mooseri</i>)	+++ for OX-19
3. Brill-Zinsser disease	<i>R. prowazekii</i>	Body louse (man)	Usually negative
B. Spotted fever group			
1. Rocky mountain spotted fever	<i>R. rickettsii</i>	Ticks (rabbit, dog and rodents)	++OX-19 and ++OX-2
2. Mediterranean fever (fever boutonneuse)	<i>R. conori</i>	Ticks (rodent, dogs)	++OX-19 and ++OX-2
3. Rickettsial pox	<i>R. akari</i>	Gamasid mite (mouse)	Negative
4. North Asian tick borne typhus	<i>R. siberica</i>	Tick (wild animals cattle, birds)	+OX-19 and OX-2
5. Queensland tick typhus	<i>R. siberica</i>	Tick (Bush rodents)	+OX-19 and OX-2
6. Indian tick typhus	<i>R. conori</i>	Tick (rodents)	+OX-19 and OX-2
7. African tick bite fever	<i>R. africae</i>	Tick (cattle and goat)	
C. Scrub typhus (Tsutsugamushi fever)	<i>R. tsutsugamushi</i>	Trombidulid mite (small rodent, birds)	+++ OXK
D. Q.fever	<i>Coxiella burnetii</i> which is a coccobacillus	Ticks transmit diseases In animals, human disease is occupational-cattle, sheep, goat	Negative

components and therefore infection by some rickettsial strains lead to the development of antibodies that agglutinate some strains of *Proteus vulgaris*. Detection of these antibodies by agglutination forms the basis of the Weil-Felix reaction which is a commonly used diagnostic test (Table 45.1).

The diagnosis can be confirmed by serologic, molecular, immunohistochemical and/or culture assays. A monoclonal antibody against a lipopolysaccharide has been shown to react with a stable antigen of *R. Akari*, *R. conori*, *R. rickettsii* that survive fixation with formaldehyde and embedding in paraffin before immunoperoxidase staining of tissue. Skin biopsy in relevant cases yields diagnosis even when serology is negative.

Epidemic Typhus

Syn: Louse borne typhus, Typhus exanthematicus, gaol fever

Epidemic typhus is a severe febrile disease caused by *Rickettsia prowazekii*. Man is the only known host for this parasite. As age advances the disease assumes more serious proportions. Several epidemics have occurred during famine, war, and other natural calamities, when people had to be kept in camps under unhygienic conditions.

Rickettsia prowazekii is transmitted by the body louse (*Pediculus humanus corporis*) and rarely the head louse (*Pediculus humanus capitis*) from man to man. The lice

are infected by the blood meal. An infected louse passes the organisms in feces for the rest of its life (4 weeks) when the patient scratches, the lice are crushed and their body contents are smeared on to the bite wound through which organisms enter the host. Inhalation of the dried lice feces is another possible mode of entry. Lice leave dead bodies to seek new hosts and in this process they spread infection. Persons who suffer from typhus acquire life long immunity. In some cases, relapse occurs after a long latent period and this is referred to as Brill-Zinssers' disease. Occasionally epidemics have followed such sporadic cases.

Pathology

Pathologically, the lesions are characterized by angiitis seen in the small blood vessels of various organs including the skin, heart, skeletal muscles and brain. The blood vessels are thrombosed or they may rupture. Rickettsiae are seen in the proliferated endothelial cells. Various tissues show infiltration by round cells, macrophages, and sometimes lymphocytes and plasma cells. The vascular changes lead to patchy gangrene of the skin, sloughing of skeletal muscles and myocarditis.

Clinical Features

Average incubation period is 7 days (5-21 days). Fever is sudden in onset with malaise and myalgia. Temperature rises to 39–40°C and remains continuous. The face is

flushed, conjunctiva are injected and there is severe sore throat. A macular skin rash appears on the fifth day. It is particularly seen in the axilla, abdomen, chest, back and extremities. The rash starts to fade by about the tenth day. Involvement of the central nervous system leads to headache, stupor, coma, and urinary incontinence. Bleeding from the mucous membranes gives rise to hematemesis, epistaxis, melena, and hematuria. Respiratory involvement leads to bronchitis, bronchopneumonia, lung abscess, or gangrene of the lung. Myocardial involvement is manifested by tachycardia, hypotension, and cardiac failure. In uncomplicated cases the temperature comes down by the twelfth to fourteenth day by lysis.

Complications include patchy gangrene of the skin over the extremities, parotitis, cardiac failure, and renal failure. Death may occur in the latter part of the second week due to complications. Though the disease used to be associated with high mortality during the epidemics, early diagnosis and specific therapy have considerably lowered the mortality rate.

Diagnosis

The disease has to be diagnosed by the clinical features. Epidemic typhus has to be differentiated from typhoid, malaria, tuberculosis, pneumonia, relapsing fever, and other rickettsial diseases. Laboratory diagnosis is by the Weil-Felix reaction and other specific tests including isolation of the organisms. The organisms can be isolated from blood collected during the early phase of the illness. Four-fold rise in titre of Weil-Felix reaction is suggestive. Specific anti-rickettsial antibodies can be demonstrated.

PCR studies, western blot and microimmuno-fluorescence can be done in advanced laboratories for specific diagnosis.

Treatment

Chloramphenicol and tetracyclines are specific and highly effective, when given in a dose of 2 to 4 g daily. They have to be continued for a week after the temperature reaches normal in order to avoid relapse.

Prevention

On admission to the wards the clothes of the patient should be disinfested by heat or 10% DDT or 1% Lindane powder. Any ectoparasite remaining on the patient should be removed manually or, by use of the pesticides such as benzylbenzoate 20% emulsion, permethrin, synergized pyrethrin or malathion.

Personal prophylaxis may be achieved by vaccination. Vaccines containing either killed rickettsiae (Cox vaccine) or live virulent strains are available.

Doxycycline given in a dose of 100 mg oral daily prevents infection in contacts.

Endemic Typhus

Syn: Murine typhus, Flea typhus

This is an acute febrile illness caused by *R.typhi* (*R. mooseri*) transmitted from rat to man by the rat flea *Xenopsylla cheopis*.

Etiology

The rat flea and the rat louse (*Polypax spinulosus*) transmit *R. typhi* among rodents. The insect acquires the infection while feeding on an infected rat. The organisms are passed in the feces of the flea after multiplication in the intestinal cells. Man is infected by the flea when it takes a blood meal. The bite wound is contaminated with flea feces and the organisms get in. Infection may also enter through the respiratory tract or the conjunctiva. Since the urine of infected rats contains the organisms, contamination of food with rat's urine is also a possible source of spread. Rats and mice may harbour the organisms in their brain for long periods. Lice have been incriminated as vectors in some areas in Kashmir and China. Compared to epidemic typhus, endemic typhus is milder.

Clinical Features

After the incubation period of 8-16 days, prodromal symptoms like headache, malaise, backache, and arthralgia develop, followed soon by the onset of fever. Fever may be associated with frequent chills, rigors, nausea, vomiting, photophobia, and congestion of the eyes. The fever persists continuously for 12 days and then comes down by lysis. A morbilliform rash develops in the axillae, arms, abdomen, chest, shoulders and thighs by about the fifth day and it fades away. Bronchitis may develop and this is manifested as cough and the presence of rales on examination. Rare complications include stupor, coma, prostration and renal failure.

Diagnosis

The clinical suspicion should be supported by laboratory investigations.

Treatment

The disease responds to chloramphenicol or tetracycline in doses of 2-4 g/day given orally for 10-14 days.

Scrub Typhus

Syn: Mite typhus, mite fever, Tsutsugamushi fever, Japanese river fever

Infection by *Rickettsia tsutsugamushi* (new name *orientia tsutsugamushi*) leads to a febrile illness, which lasts for about 2 weeks.

Epidemiology

The disease occurs in several states in India including Kerala, south east Asia, including Japan, Soviet Union, Australia and several other countries. It is transmitted by different species of trombiculid mites. In India scrub typhus is endemic in many regions especially the north and the vector is *Trombicula deliensis*. Mites are seen in scrub jungles mainly, but they are also seen in sandy beaches, deserts, and dense forests. Reservoir of infection is formed by wild rodents and birds. Mites are infected when they take their blood meals during the larval stage (chiggers). Only larval mites suck blood and they transmit the disease. The infected mites transmit the organisms transovarially to the offspring. Thus a colony of mites which harbour organisms develops which acts as a reservoir of infection for long periods. Man gets the infection from the bites of mites, which are acquired when engaged in jungle clearing operations, warfare, picnicking, and similar activities. Pathologically the lesions resemble those caused by *Rickettsia prowazekii*.

Clinical Features

The incubation period varies from 6 to 18 days. The onset is abrupt with rigor, severe headache, fever and lymphadenopathy. At the site of bite a necrotic ulcer (eschar) develops with local lymphadenopathy. Fever may go up to 38 to 39.5°C. It is associated with relative bradycardia. The cutaneous rash appears after the fifth day, first on the trunk and then it spreads to the extremities. It may persist for a few days. Fever lasts for about two weeks and comes down by lysis.

Serious complications may occur. These include myocarditis, cardiac failure, renal failure and meningo-encephalitis. The mortality is around 6%. Convalescence tends to be prolonged.

Diagnosis

The diagnosis is made clinically by the presence of eschar rash, high fever, bradycardia, body ache, malaise and/or lymphadenopathy. The disease however is to be differentiated from other febrile conditions relevant to the area/country.

The Weil-Felix reaction is positive for OX-K in 50% of cases by two weeks of illness. Rising titers of antibodies demonstrated at the end of three weeks all more suggestive. More sophisticated tests are available. Micro immunofluorescence is the test of choice. Latex agglutination, indirect hemagglutination, immunoperoxidase assay, ELISA and PCR are the other tests available. A dipstick test has been developed for rapid diagnosis. Nonspecific, but very suggestive laboratory findings include moderate elevation of liver enzyme such as SGOT and SGPT (100-200 IU/L) and elevation of CRP.

Treatment

Doxycycline in the usual dose of 100 mg bid orally for 5-7 days is quite effective and safe. Chloramphenicol and tetracycline are effective against the organisms when given in a dose of 2-4 g/day. Within 24 hours of starting therapy, the temperature falls and recovery starts. Rifampicin in a daily dose of 600 mg given oral is quite effective and clearance of fever and febrile symptoms occurs more rapidly. Azithromycin is also effective in usual doses.

Infection can be avoided in endemic areas by wearing protective clothing and using insect repellants. Hot shower bath with lathering soap will remove most of the mites. Drug prophylaxis consists of chloramphenicol or tetracycline 500 mg given once every five days for 35 days. An alternative is doxycycline 100 mg given once a week for the period of exposure and for 6 weeks after leaving the endemic area.

Tick-borne Typhus – (Spotted Fever Group)

Tick-borne typhus group is characterized by the development of prominent rash. Most of them are transmitted by hard ticks (Ixodidae), except *R. akari* which is transmitted by mite. Rickettsiae of this group possess a common antigen and, therefore, may show serological overlap. These organisms are found in animals and enzootics occur periodically. They constitute the reservoir for infection. In addition, trans-ovarian transmission of rickettsiae by the female tick to its offspring leads to the formation of an insect reservoir, which tends to persist for long periods on account of the long lifespan of the ticks. Man is affected accidentally. The course of the disease is similar to that of epidemic typhus. Mortality differs from place to place, but is around 15-18%. The organisms causing this group of diseases are listed in Table 45.1.

The classic disease in this group is **Rocky Mountain spotted fever**. Hard ticks transmit the diseases. At the site of bite an eschar may develop. Eschar is the necrotic ulcer developing about a week after the bite. The rash occurs around the third day. It is maculo-papular and morbilliform. In severe cases petechiae may develop.

In India spotted fevers are caused by *R. conori*, which is distributed over extensive areas at the foothills of the Himalayas. The main vector is the dog tick *Rhipicephalus sanguineus*, but other species of ticks like *Hemaphysalis leachi*, *Amblyomma* and *Hyalomma* may also take part in transmission. **Rickettsial pox** is caused by *R. akari*. It is seen in the USA.

Q Fever

It is a zoonosis caused by *Coxiella burnetii*. It is a gram negative pleomorphic coccobacillus which is having homology with *Legionella pneumophila*. Two forms exist

Diseases Caused by Infections

1. A small cell variant (SCV) and
2. A large cell variant (LCV)

The SCV exists in nature and it is resistant to environmental factors. The LCV develops in the host's monocytes and multiplies. It is the pathogenic form. The disease exists in Australia, India, USA and other areas. In India the disease has been reported from Delhi, Punjab, South Canara and Rajasthan. Animal reservoirs include cows, goats, sheep, dogs cats and others. Organisms are shed in milk, feces, urine and products of conception. Humans become infected by ingestion of infective material or droplet infection through the respiratory tract. Incubation period is 12 to 30 days.

Acute Q Fever

This resembles influenza clinically, with varying degrees of pneumonia and hepatitis. Fever lasts for an average of 10 days (range 10-57 days).

Chronic Q Fever

This occurs in 60-70% of infected persons. It leads to endocarditis which supervenes on pre-existing valvular

lesions. Untreated, the condition is fatal. Q fever may recrudesce during pregnancy and lead to abortion. Other manifestations include osteo-articular infections and hepatitis.

Diagnosis

Antibodies can be detected by indirect immunofluorescence.

Treatment

Acute Q fever —doxycycline 100 mg bid po for 14 days. *Chronic Q fever*—life long doxycycline therapy may be necessary.

Addition of hydroxychloroquine 200 mg tds po given for 18 months favours recovery. It acts synergistically with doxycycline.

Prevention

Pasteurization of milk is partly protective. Occupational risk can be reduced by vaccination in persons exposed to the risk.

Anaerobic Infections: Tetanus and Gas Gangrene

K.V. Krishna Das

Chapter Summary

General Considerations	246
Diseases Caused by Clostridia	248
Tetanus	248
Clinical Features	248
Treatment	249
Prevention	251
Gas Gangrene	252

General Considerations

Many areas in the body such as the mouth, nasopharynx, paranasal sinuses, tonsillar crypts, gastrointestinal tract, and female genital tract harbour anaerobes as commensals

and they far outnumber aerobes. Anaerobes thrive in the anaerobic environment provided by the facultative anaerobes such as *enterobacteriaceae*, *staphylococci*, *streptococci*, *E. coli* and *K. pneumoniae* which use up oxygen. They multiply further and acquire virulence if there is reduction in vascular supply, tissue injury, or presence of dead tissue. Most of the anaerobic infections are mixed. These organisms act to facilitate each other to grow, invade tissues, and resist the action of drugs. Their multiplication is promptly inhibited even by moderate increase in oxygen tension. For the isolation and identification of anaerobes, special microbiological techniques have to be adopted in collecting specimens and culturing the organisms. Since anaerobic infections produce septic venous thrombosis and embolism, pyemic

abscesses are common. They liberate endotoxins from their cell walls which lead to endotoxic shock and disseminated intravascular coagulation. Anaerobes can affect all tissues, especially so, if there is tissue necrosis and presence of foreign material.

Anaerobes which are pathogenic to man:

1. Gram-negative bacilli:
 - a. *Bacteroides*: *B. fragilis*, *B. oralis*, *B. melaninogenicus*, *B. corrodens*
 - b. *Fusobacterium*: *F. nucleatum*, *F. varium*, *F. necrophorum*
2. Spore forming gram-positive bacilli:
 Clostridium: *C. botulinum*, *C. tetani*, *C. perfringens*, *C. histolyticum*, *C. septicum*, *C. novyi*, *C. bifermentans*
3. Non-spore forming gram-positive bacilli:
 Actinomyces, *subacterium*, *bifidobacterium*, *propionobacterium*, *catenabacterium*
4. Anaerobic cocci:
 - a. Gram-positive: *Peptococcus*, *peptostreptococcus*, *microaerophilic streptococci*, *anaerobic pneumococci*.
 - b. Gram-negative: *Veillonella*

Anaerobic infections should be suspected under following situations:

1. Location of lesion, in close proximity to mucosal surfaces.
2. Foul smelling exudates.
3. Presence of gas in the tissues.
4. Black discoloration of exudates, e.g. *B. melaninogenicus*.
5. Infections associated with gut perforation and ulceration.
6. Infections after human or other bites.
7. Aspiration pneumonia and infection associated with the presence of foreign bodies.

Lesions Caused by Anaerobes

Central nervous system: Brain abscess, subdural empyema, septic thrombophlebitis of the cortical veins and venous sinuses.

Head and neck: Chronic sinusitis, mastoiditis, chronic otitis media, dental infection (caries), periodontal disease, Vincent's angina, peritonsillar abscess, cervicofacial actinomycosis and Ludwig's angina.

Female genital tract: Endometritis, myometritis, parametritis, pyometra, pelvic cellulitis, pelvic abscesses, pelvic thrombophlebitis, vulvovaginal abscess, Bartholinitis, Skene's gland infection, salpingitis, tubo-ovarian abscess, vaginal cuff infection, chorioamnionitis, intrauterine or neonatal sepsis and pneumonia, septic abortion, and puerperal sepsis.

Respiratory tract: Aspiration pneumonia, necrotizing pneumonia, lung abscess, empyema, mediastinitis, bronchiectasis, and pulmonary actinomycosis.

Bloodstream spread: Septicemia and endocarditis.

Abdomen: Peritonitis, appendicitis, diverticulitis, pyelephlebitis, intra-abdominal abscess, liver abscess and abdominal actinomycosis.

Soft tissues: Cellulitis, gangrene, infected deep wounds, wound infections after gastrointestinal or gynecologic surgery, infections following human bites, necrotizing fasciitis, decubitus ulcer (perineal or gluteal area), infected sebaceous or pilonidal cysts, diabetic ulcers on the feet.

Musculoskeletal: Pyogenic arthritis, osteomyelitis and gangrene.

Urinary tract: Renal abscess, perirenal abscess, pyelonephritis, wound infection after nephrectomy, cystitis, chronic prostatitis and abscess, and testicular abscess.

Therapeutic principles: The polymicrobial nature of anaerobic lesions demand the use of antibiotic combinations active against anaerobes and aerobes.

Surgical measures should be employed in time and these are most important. They consist of drainage of abscesses, debridement of necrotic tissue, and relief of obstruction to natural passages.

Penicillin is effective against all anaerobes except *Bacteroides fragilis* and it is the drug of choice. It has to be given in very high doses (20-30 mega units in 24 hours). Gentamicin, clindamycin and chloramphenicol act synergistically with penicillin against anaerobes and therefore these antibiotics are combined for therapy. When the organisms are resistant to penicillin these antibiotics are used as the primary drugs. Beta-lactamase-resistant cephalosporins—cephoxitin and cephmandole—are also effective. Metronidazole, given intravenously in a dose of 400 mg 8 h as infusion is a useful drug against many of the anaerobes. It has to be combined with other antibiotics. Oral doses are effective to a lesser degree (Table 46.1).

Other measures include the administration of antitoxins, hyperbaric oxygen, local oxygen therapy, and use of oxygen-releasing agents locally, e.g. hydrogen peroxide.

Major drawbacks of the antibiotics in treating anaerobic infections

Agent	Major disadvantages
Penicillin G	Ineffective against <i>B. fragilis</i>
Chloramphenicol	Hematotoxicity
Clindamycin	Poor penetration into CSF, occurrence of pseudomembranous colitis.
Carbenicillin	upto 5-10% of <i>B. fragilis</i> strains are resistant, sodium overload, bleeding tendency.
Metronidazole	All aerobes are resistant.
Cephmandole	Poor penetration to CSF.
Cephoxitin	Poor penetration CSF.

TABLE 46.1

Effectiveness of antibiotics against the common anaerobes							
Antibiotic	<i>B. fragilis</i>	<i>B. melanino-</i>	<i>Fuso-</i>	<i>Clostridia</i>	<i>Propiono-</i>	<i>Actinomyces</i>	<i>Peptostrepto-</i>

Diseases Caused by Clostridia

These include tetanus, gas gangrene, food poisoning including botulism and pseudomembranous colitis.

<i>C. tetani</i>	Tetanus
<i>C. perfringens</i>	gas-gangrene
Syn: <i>C. welchii</i>	
<i>C. Septicum</i>	-do-
<i>C. novyi</i>	-do-
Syn <i>C. edematiens</i>	
<i>C. histolyticum</i>	-do-
<i>C. sordelli</i>	-do-
<i>C. botulinum</i>	botulism
<i>C. perfringens</i>	also food poisoning
<i>C. difficile</i>	pseudomembranous colitis

Tetanus

Syn: Lockjaw

Tetanus has been in existence over several millennia, as is seen from descriptions from the ancient texts of Ayurveda (Susruta Samhita) and the writings of Hippocrates.

Definition

Tetanus is an acute infectious disease characterized by rigidity, intermittent spasms of the voluntary muscles and convulsions. Trismus, which is a prominent feature, gives it the name “lockjaw”. The disease is caused by the exotoxin produced by *Clostridium tetani*. *C. tetani* is a gram-positive (also can be gram-negative), obligate anaerobe which is motile and sporing. The spores resist boiling water for three hours and dry heat up to 160°C for one hour.

Etiology

Clostridium tetani is commonly found in the soil and the intestinal tract of animals and man. The organism exists

as vegetative forms and spores. They can remain viable *in vitro* for several years. Spores are destroyed by autoclaving at 121°C for 20 min. After entry into tissues through wounds they germinate and grow. Rarely, they may remain dormant for considerable periods. *Clostridium tetani* produces exotoxins among which two are most important. (1) a powerful neurotoxin tetanospasmin, and (2) a hemolysin-tetanolysin. Tetanospasmin is responsible for the clinical disease.

Clostridium tetani remains strictly localized to the site of multiplication, but the toxin reaches the central nervous system through the peripheral nerves and bloodstream. Tetanus toxin which is a polypeptide with mol. weight 148000 daltons enters the bloodstream and reaches the nerve endings in the muscles. From here it ascends though the nerves to the central nervous system. From the motor cells of the brain and spinal cord the toxin passes retrogradely to bind to the terminals of the inhibitory neurons. Tetanospasmin causes disinhibition of both the alpha and gamma motor systems and thereby leads to generalized muscle rigidity. Spasms occur when external stimuli are applied and also spontaneously. Direct effect of the toxin on the muscle leads to contraction. The toxin acts also on the central sympathetic system and possibly on the cerebral cortex and brainstem. The effects of tetanus toxin are self-limited and they pass off within weeks or months if further absorption of toxin is prevented.

Tetanus is more common after sustaining deep wounds with tissue devitalization and introduction of foreign materials inside. In such sites anaerobic conditions are established and *C. tetani* multiplies. In addition to wounds, chronic otitis media, umbilical sepsis of neonates, parturition, septic abortion, burns, intramuscular injections, and chronic ulcers may be complicated by tetanus. In about a fifth of the cases there may be no obvious focus of entry. This is termed cryptogenic tetanus. Despite all advancements in antimicrobial therapy, and

effective vaccination tetanus still occurs frequently in all parts of the country and accounts for considerable mortality.

Clinical Features

Since it is not essential that infection and injury coincide, it is difficult to ascertain the incubation period exactly in all cases. The incubation period is generally less than 2 weeks, although it may range from 2-60 days. Cases with shorter incubation periods tend to be more severe and are associated with higher mortality.

The disease starts with premonitory symptoms like vague discomfort, pain around the site of injury, and restlessness. The diagnosis becomes evident when lock-jaw sets in. It is painless or only mildly painful. Severe pain should suggest a local cause for trismus.

Within hours to days the abdominal and trunk muscles become spastic. Rigidity of the abdominal muscles may simulate peritonitis. Rigidity and spasm of the back muscles result in hyperextension of the spine and neck (opisthotonus). All muscle groups (both the agonists and antagonists) go into spasm at the same time. Risus sardonicus is the characteristic grinning expression brought about by the sustained contraction of facial muscles. Rarely dysphagia can be the first presenting symptom. Spasm of the sphincters leads to retention of urine and feces.

Spasmodic contractions involving different parts of the body develop at variable intervals after the onset of rigidity. The interval between the first symptom and the first convulsion is called the **onset period**. External stimuli or emotions precipitate these painful spasms which cripple the patient. In severe cases they may develop spontaneously. Asphyxia results from spasm of the laryngeal and respiratory muscles. Regurgitation of gastric contents leads to aspiration into the respiratory tract. With progress of the disease the spasms become frequent and prolonged and this leads to muscular exhaustion, hyperpyrexia, and cardiac failure. Sympathetic overactivity causes hypertension, hyperpyrexia and cardiac arrhythmias. Mind remains alert till the end and in many cases the patient is very anxious. Deep tendon reflexes are generally exaggerated, but the plantar response is flexor.

Course and prognosis: It takes about three days for the disease to manifest fully. If complications are prevented the condition remains stable for the next 5-7 days. Thereafter the spasms gradually subside in frequency and intensity to disappear in 2 weeks. Complete recovery may take 4 weeks or more, though in some cases the rigidity may persist even longer.

Local tetanus: In this form, rigidity and other symptoms are confined to a part near the site of injury. This generally runs a mild course and ends in complete recovery.

Cephalic tetanus: This term is used when local tetanus involves the facial muscles only. It is usually unilateral but can be bilateral.

Tetanus neonatorum: This form of tetanus occurs within 10 days of birth. It is usually severe. It manifests as inability to suck the nipple, irritability, and excessive crying associated with grimacing movements of the face. The muscles of the back, neck, and abdomen may become spastic. In many instances the classical signs may not develop in neonates and premature infants.

Tetanus neonatorum is still an important cause of infant mortality in many developing countries including India.

Complications: Respiratory obstruction and aspiration pneumonia are the most frequent complications accounting for death in many cases. Peripheral venous thrombosis may develop and lead to pulmonary embolism. Myocarditis gives rise to cardiac failure and hypotension. Hyperpyrexia is the result of excessive muscular activity and the effect of the toxin on the hypothalamus. Decubitus ulcers and urinary tract infection result from prolonged immobility. Fractures of the spine and other bones are seen at times. Sudden death due to laryngeal spasm, cardiac arrhythmias, or massive aspiration of gastric contents may occur and these have to be anticipated.

Diagnosis

The disease has to be diagnosed clinically. Repeated observations may be required to make the diagnosis in doubtful cases.

Tetanus has to be differentiated from meningo-encephalitis, strychnine poisoning, local causes of trismus, dystonia due to phenothiazines, tetany and hysteria. Cerebrospinal fluid is normal in tetanus.

Treatment

The outcome depends on proper therapy based on the severity of this disease (Tables 46.2 and 46.3).

All cases should be hospitalized. An apparently simple case may rapidly deteriorate and demand specialized care. Best results are obtained if tetanus is managed in institutions where specially trained teams are available. Depending on the severity, treatment has to be planned from the beginning.

General measures: The patient is nursed in an environment where external stimuli such as drafts of air, cold winds, noises, and vibrations are minimal. Nutrition is provided by giving adequate calories in the form of glucose and cereals. Fluid and electrolyte balance should be maintained. *The main aim of treatment is to arrest the growth of C. tetani in the local lesion, prevent further production of toxin, neutralize the toxin already in*

TABLE 46.2

Prognostic factors

1. Age	Neonates and older patients fare badly.
2. Type of injury	Large wounds contaminated with soil, lacerated wounds, compound fractures, and septic abortions are associated with severe tetanus. Though rare, tetanus following intramuscular injections tends to be serious.
3. Incubation period	Short incubation periods indicate greater severity. Apparently long incubation period does not necessarily mean that the case is mild.
4. Interval between the onset of trismus and at all the first spasm	Shorter this period, more severe is the disease. In mild cases spasms may not occur
5. Frequency of spasms	More frequent and more prolonged spasms are poor prognostic signs.
6. Autonomic disturbances	Dysphagia, hypertension, hyperpyrexia, and cardiac arrhythmias indicate poor prognosis.
7. Treatment	Early administration of antitoxin, proper surgical toilet, institution of antibiotics, proper anticonvulsive therapy, availability of a team of physicians, surgeons, and anaesthetists, and proper nursing care are the most important factors determining a successful outcome. Inadequacy of treatment is a common cause of death in many cases.

circulation and to abolish the excitatory effect of the toxin on the muscles. Since the toxin attached to nerve endings cannot be neutralized, antitoxin should be administered without delay to neutralize circulating toxin.

Tetanus antitoxin (anti-tetanus serum—ATS): The best available preparation is human tetanus immunoglobulin (TIG) which is to be given in a dose of 2000-5000 units intravenously or intramuscularly. If the wound is heavily contaminated and in severe cases, up to 10000 units may be required. This is more potent and free from risk of anaphylaxis. Human TIG can also be given intrathecally in a dose of 250-500 units. This measure may help in controlling convulsions more effectively when other measures fail.

The other preparation is ATS prepared from the horse. It may cause anaphylactic shock in allergic individuals and hence it should be administered only after testing for allergy (skin test and later intravenous test) and if human immunoglobulin is not available.

All measures to combat anaphylactic shock should be available ready at hand. The dose is 10,000 to 25,000 units given intravenously or intramuscularly. Ordinarily, there is no need to repeat the antiserum.

Surgical toilet of the wound: It aims at debridement and removal of necrotic material and foreign bodies, with a view to removing the anaerobic environment. Surgical toilet should be done only after giving the antitoxin.

Antibiotics: *Clostridium tetani* is sensitive to penicillin and benzyl penicillin in a dose of 0.5 mega unit 6 hourly administered intravenously helps in preventing the multiplication of the organism and further toxin production. When the infection is controlled, procaine penicillin can be used in a dose of 0.5 mega unit daily. Metronidazole given in doses of 400 mg IV bd has also been found to be effective.

Control of convulsions: Diazepam in adequate doses controls the muscle spasms; 50 mg is added to 600 mL of 5% glucose and it is run as an intravenous drip, at a

TABLE 46.3

A working classification of the severity of tetanus

	Mild	Moderately severe	Severe
Incubation	Above 14 days	7-14 days	Less than 7 days
Onset time	6 days	3-6 days	Less than 3 days
Trismus	Present	Marked	Severe
Dysphagia	Absent	Present	Present
Rigidity	Absent	Mild	Severe
Spasms	Brief and mild	Present, frequent	Frequent, prolonged and generalized convulsions
Ventilation	Not affected	Inadequate ventilation during spasm	Often ventilatory insufficiency
Mortality	Up to 5%	25%	80-90%
Treatment intravenous	ATS, oral medications, intramuscular diazepam	ATS, intravenous drip and medication, Ryle's tube, elective tracheostomy	Early tracheostomy, drips and medication, muscle relaxant, artificial ventilation

Practical clues to determine immune status and administer TIG

	<i>Immune if:</i>	<i>non-immune if:</i>
Injection of tetanus toxoid	Within 6 months of injection 2 doses; for 5-10 years after full course with booster	No vaccination more than 6 months after a course of 2 doses or 10 years after a course of 3 doses without booster
Equine ATS Human TIG	Within 2 weeks within 6 weeks	after 2 weeks after 6 weeks any doubt about vaccination status
Procedure to be followed	Boost up immune status with a shot of TT	Human TIG 250-500 units stat. Start 3 injection TT schedule, the first injection given simultaneously at a different site.

rate required to control the spasms. Even up to 200 mg may be required in 24 hours. Paraldehyde 7 mL every 6 h given orally, chlorpromazine 50 mg every 6 h given intramuscularly and phenobarbitone 200 mg twice daily given intramuscularly are effective in controlling the spasms and producing the required sedation when used in combination with diazepam. A combination of anticonvulsants can be used. Midazolam given IV as a continuous drip in a dose of 5-15 mg/hour is an effective alternative.

In severe tetanus that cannot be controlled effectively by drugs, curarization and assisted ventilation are essential and this regimen has to be undertaken by a team trained for ventilatory assistance (Table 46.4).

Tracheostomy: It maintains patency of the airway and helps in giving effective tracheal toilet. A cuffed endotracheal tube protects against aspiration of gastric contents. In moderate and severe tetanus tracheostomy is indicated which should be performed without delay.

In severe sympathetic overactivity beta adrenergic blockers like propranolol have to be used.

Prevention

Tetanus is an easily preventable disease. Clinical tetanus does not confer immunity and, therefore, the patient should be actively immunized when he recovers. Three subcutaneous injections of adsorbed toxoid in a dose of 0.5 mL at monthly intervals produces lasting immunity. As a part of the total immunization program for children the first dose may be given as the DPT vaccine at the fourth month of life and two further doses at monthly

TABLE 46.4

Procedure to be followed in the management of severe convulsing tetanus

1. Sedation	Diazepam 5 mg I V given at 5 minutes intervals until muscle relaxation is achieved.
2. Airway	Preferably tracheostomy and cuffed tracheostomy tube.
3. Nutrition	Naso-gastric tube feeding, 2500 cal with 70 g proteins in 24 hrs. Fluids adequate to maintain urine output of 60 mL/hour
4. Control of spasms	Diazepam in large doses 10-18 mg or more in 24 hours may be required.
5. Attention to fatal complications such as respiratory arrest, appropriate life saving measures cardiac arrest and shock	
6. Antitoxin	Human tetanus immunoglobulin 1500 units I M injection or administration equine ATS 10000 units I V.
7. Wound toilet	Surgical debridement
8. Immunization	Tetanus toxoid to start early.
9. Severe cases	Management in intensive care room-paralysis by pancuronium 2-6 mg I V and ventilatory support.

intervals. If the full course of DPT vaccine is given, the child gets life-long immunity. Boosters are needed once every 5-10 years. When severe injuries are sustained, one dose of 0.5 mL of toxoid may be given as a precautionary measure. Passive immunization can be achieved in nonimmunized subjects by the administration of 250 IU of TIG or 3000 IU of ATS after test dose. The immunity lasts for about two weeks. Passive immunization is given along with a booster dose of toxoid in separate syringes at different sites to non-immunized individuals who sustain injury. Active immunization of pregnant women ensures adequate antibodies in the neonate and prevents tetanus neonatorum.

Primary care of the wound like surgical toilet and penicillin therapy considerably reduce the risk of tetanus.

Points to remember

1. Tetanus is a life-threatening infection occurring widely in India.
2. It is preventable by suitable vaccination starting during pregnancy of the mother.
3. Diagnosis is clinical.
4. Early treatment using appropriate measures depending on prognostic factors saves lives.

Gas Gangrene

Syn: Clostridial myonecrosis

Gas gangrene is caused by *Clostridium perfringens* (*C. welchii*), *C. septicum*, *C. novyi* (*C. oedematiens*) *C. histolyticum* and *C. sordelli*. These clostridia are commensals in human gut and soil. They produce local necrosis and distant lethal effects.

Pathogenesis

Necrosis of tissue brought about by anoxia, ischemia or injury is complicated by clostridial infection which may be exogenous (introduced along with the wounds) or endogenous (derived from the intestinal tract). The organisms multiply locally and produce toxins which diffuse out and lead to generalized toxemia. The affected tissues are avascular and appear as if cooked.

Clinical Features

After an incubation period of 1-4 days the wound becomes swollen and tender and exudes brownish foul-smelling fluid. Due to the presence of gas, crepitus may be felt. Blebs filled with purplish foul-smelling fluid develop. These blebs rupture and ulcerate. General symptoms such as restlessness and fever develop and the patient may rapidly go into shock and anuria.

Diagnosis

The condition has to be diagnosed clinically. The organism can be identified by culture. X-ray of the affected part shows gas in the tissues. Gas in the tissues may occur in other conditions such as surgical emphysema and infections by streptococci, staphylococci and *E. coli*.

Treatment

Early institution of therapy is most important for success. Shock is treated on the lines of septic shock. Penicillin which is the drug of choice is given intravenously in a dose of 2 mega units 2 hourly. Other antibiotics may be tried depending on the sensitivity tests. Metronidazole and gentamicin are effective in most cases. Antitoxin is available for intravenous use (anti-gas gangrene serum—AGGS). It should be given in a dose of 40,000 units initially to be followed by 20,000 to 40,000 units repeatedly till the condition improves. Keeping the patient under hyperbaric oxygen (3 atmosphere pressure) remarkably improves the result of therapy and this should be instituted wherever it is available. Surgical excision of dead tissue and removal of foreign bodies should be undertaken after administration of AGGS. Gas gangrene can be prevented by taking proper care of the wound and early recognition of the condition.

General Considerations

Infectious diseases which are transmitted by heterosexual or homosexual intercourse and contacts are included under this group. In many developed countries this group constitutes the main bulk of infectious diseases in adults and the incidence is increasing. Increase in promiscuity, change in sex practices, asymptomatic infections, facilities for intercontinental travel, failure to trace sources of infection and lack of awareness of healthy sex practices have contributed to the increase in prevalence.

The present tendency is to include several other diseases like viral hepatitis B which can also be transmitted sexually in the group of STD.

Syphilis

(Syn: Lues venerea)

GENERAL CONSIDERATIONS

This chronic infection is caused by the spirochete, *Treponema pallidum*. Syphilis is present in all parts of the world. Though the incidence of primary infection continues to be steady, late complications are distinctly rare at present.

Treponema pallidum is aerobic, very susceptible to antiseptics, and is killed by exposure to light in 1-2 hours. It may survive in stored blood for 72 hours. Infection is acquired by the entry of the organism through abrasions in the skin and mucous membranes. In the vast majority of cases, infection is acquired by sexual intercourse. Rarely skin abrasions may be contaminated by infective discharges. The disease can also be transmitted occasionally by needle pricks, blood transfusion or by the transplacental route. *T. pallidum ssp pallidum* (syphilis), *T. pallidum ssp pertenue* (yaws) and *T. pallidum ssp endemicum* (endemic syphilis or bejel) and *T. carateum* (Pinta) are all morphologically identical. They are tightly coiled helical rods 5-15 µm long and 0.1-0.5 µm in diameter, motile and demonstrable by dark ground illumination or special staining methods.

Classification

Based on its course, syphilis can be described in 3 stages—primary, secondary, and tertiary.

Primary stage: In the primary stage, local lesions occur at the site of inoculation.

Secondary stage: The secondary stage is characterized by generalized lesions, most obviously seen in the skin and mucous membranes.

Tertiary stage: In the tertiary stage, which develops 3-10 years after the initial infection, gummatous and destructive lesions develop in many tissues.

For practical therapeutic purposes, the disease can be conveniently considered in two phases—the early and the late. The early phase extends over the first two years after infection and this includes the primary, secondary, early recurrent and early latent stages. This phase is more contagious. Syphilis of more than 2 years duration is called late phase.

Latent syphilis: Latent syphilis is that stage in which there are no abnormal clinical features. Blood serology is positive, but the CSF does not show any abnormality. History of primary or secondary lesions and abortion during the earlier pregnancies help in identifying this stage.

Clinical types of syphilis

1. **Congenital syphilis** (prenatal infection):
 - a. *Infantile form* which manifests within two years of birth
 - b. *Tardive congenital syphilis* (late congenital syphilis)—manifests 2 years or more after birth
2. **Acquired syphilis:**
 - a. Primary
 - b. Secondary
 - c. Latent
 - i. early phase—within 2 years of infection
 - ii. late phase—2 years later
 - d. Late manifestations.

PATHOLOGY

The lesions show a chronic granulomatous inflammation and are histologically characterized by epithelioid cells, plasma cells, lymphocytes, and giant cells. The small vessels are occluded by obliterative endarteritis. This results in necrosis and scar formation. Inflammation, vascular occlusion and probably immunological factors are contributory to the production of gummata. During the primary and secondary stages the lesions teem with the organisms. In the late phases, the number of organisms comes down and infectivity diminishes. Syphilitic lesions show a propensity to attract activated CD4-T lymphocytes. This makes the syphilitic lesions more efficient in disseminating HIV infection as well.

CLINICAL FEATURES—ACQUIRED SYPHILIS

Primary stage of syphilis: The incubation period varies from 1-3 weeks in most cases, though it may extend up to 90 days. A small macule develops at the site of inoculation which later becomes a papule and ulcerates. This is the primary chancre. It presents a characteristic appearance; a punched out ulcer with a dull red areola and a clear granular base exuding colorless serum which teems with the spirochetes. The regional lymph nodes enlarge a few days later. They are discrete, rubbery in consistency, and are generally described as ‘shotty’. Even without treatment the chancre heals in 8-10 weeks leaving

Fig. 47.1: Syphilis primary chancre

6

behind a thin scar. Even after the healing of the chancre the lymph node enlargement persists. Generalized lymphadenopathy may develop at this stage before the secondary stage sets in Figure 47.1.

Other ulcers occurring in the genitalia such as Herpes genitalis, traumatic ulcers, chancroid, lymphogranuloma venereum, scabies, and carcinoma, have to be differentiated from syphilitic chancre.

Secondary stage of syphilis: This stage develops 6-8 weeks after the appearance of the chancre. General symptoms such as malaise, fever, headache, anorexia, hoarseness of voice, arthralgia, nocturnal pains, generalized lymphadenopathy, jaundice, and anemia develop.

The *skin lesions of the second stage* have certain common characteristics, though some degree of variability is evident. The distinguishing features of secondary syphilitic lesions are:

1. generalized and symmetrical distribution,
2. pink, coppery, or dusky red color,
3. absence of pruritus,
4. induration, and
5. polymorphic (macular, papular, or pustular) presentation.

Mucous membrane lesions: Condylomata lata are seen in the mucocutaneous junctions. Basically they are papules which are modified due to the constant moisture and rubbing. They are flat topped, hypertrophic fleshy masses with broad bases. They exude serum rich in treponemes. Mucous patches and snail track ulcers occur in the oral cavity and genitalia. Systemic manifestations of secondary syphilis include acute uveitis which may be unilateral or bilateral, meningitis and hepatitis.

Late syphilis: About 3-12 months after the primary and secondary stages, which are easily distinguishable, the disease enters the latent phase. The first two year period of the latent phase is termed the “*early latent phase*”. The organisms are present deep in the tissues and the only evidence of infection is the positive serology. Syphilis may

Fig. 47.2: Syphilis tertiary stage Gumma

of the patient's life. In the early part of the latent phase the patient may be infective, but the infectivity diminishes with time.

Tertiary stage: During this stage typical destructive lesions called “*gummata*” develop. These are granulomas which may be single or multiple. Histologically the lesions show perivascular infiltration by lymphocytes and plasma cells, followed later by fibrosis. Gummata may occur on the skin, mucous membranes, subcutaneous tissue, bones or viscera. These are asymmetric, small to large in size and indolent with a tendency for healing in the center and spreading at the periphery (Fig. 47.2).

Bone lesions: Bony lesions occur more commonly in men than in women and the symptoms are very variable and are likely to be missed if clinical suspicion is not strong. The tibia, skull, clavicle and femur are affected most, but any bone may be involved. Two types of lesions may develop—granulomatous periostitis and gummatous osteitis. Periostitis leads to bony proliferation and deposition of new bone beneath the periosteum. Gummatous osteitis produces circumscribed areas of osteolysis surrounded by areas of sclerosis. Syphilitic osteitis and periostitis may occur in the same *bone*.

Visceral Syphilis: Liver is affected most commonly, and it is enlarged by multiple gummata. As the lesions heal, sheets of fibrous tissue are formed and the liver is shrunk and distorted. The surface of the liver becomes lobular and this is termed “*hepar lobatum*”. Stomach, intestines, lungs and reproductive organs are affected less commonly.

Cardiovascular and central nervous system lesions occur 10-40 years after the initial infection. Cardiovascular lesions include syphilitic aortitis, aortic regurgitation and aneurysms of the aorta. Neurological involvement is more varied and this may be meningovascular or parenchymal. Meningitis occurs in the secondary stage, but in the tertiary

stage meningovascular involvement leads to *meningo-myelitis*, *transverse myelitis*, *syphilitic pachymeningitis*, *Erb's syphilitic paraplegia*, and *occlusive vascular lesions*. *Parenchymal lesions* are *tabes dorsalis*, *general paralysis of the insane (GPI)*, *taboparesis*, and *optic atrophy* (See also Chapters 120 and 188).

CONGENITAL SYPHILIS

Treponema pallidum can pass from the infected mother to the fetus through the placenta. An infected mother can transmit the disease to her child even in the late stages, but in the late latent phase there is less infectivity to the fetus. Since *T. pallidum* is transmitted only through the fully formed placenta which develops by the fourth month of pregnancy, the fetus is unaffected in the early period. Abortions occurring earlier during pregnancy are not attributable to syphilis. Birth of a syphilitic baby is often preceded by repeated abortions occurring at progressively later months.

The primary stage is not evident in congenital syphilis. The early manifestations are similar to those of secondary acquired syphilis. Sometimes, a syphilitic infant may be clinically normal at birth. The skin lesions consist of dusky red papules with bullae containing serum or pus, most prominent in the palms and soles ("*syphilitic pemphigus*"). The discharge contains a large number of *T. pallidum*. Generalized widespread papular skin rashes are seen at times. At the mucocutaneous junctions the papules develop into condylomata. The infant has a wasted and dehydrated appearance which is described as "*old man facies*". The baby fails to thrive and becomes marasmic. Alopecia may occur. Occasionally there may be growth of black hair called the "*syphilitic wig*". Mucous patches may be seen on the nose, mouth, throat and larynx. Radiating fissures may form at the angles of the mouth (*rhagades*). Bloodstained, thick, purulent nasal discharge may block the nostrils and produce a bubbling sound during breathing termed as "*syphilitic snuffle*". Feeding problems may develop due to blockage of the nose.

Bony lesions develop within 6 months of birth. The ends of long bones are swollen and tender due to osteochondritis. The restriction of movement is sometimes referred to as *syphilitic pseudoparalysis*. Osteochondritis clears up by six months of age, but syphilitic periostitis persists and tends to become more marked. Subperiosteal new bone is laid down irregularly over the shaft of bones leading to thickening and deformity, e.g., *sabre tibia*. Due to concentric layering of new bone, the skiagram may reveal a characteristic onion peel appearance. Painless effusions in one or both knee joints ('*Clutton's joints*') develop between the ages of 10 and 20 years.

Eye lesions include choroiditis and retinitis which develop after the first two years of life. Invasion of the

nervous system by *T. pallidum* during intrauterine life may lead to arrest of development of the brain.

Late non-infectious congenital syphilis: This stage sets in after the second year of life. Lesions are more common between 7 and 15 years of age but may occur at any age. Gumma may develop in the skin, mucous membranes, or viscera. The lesions resemble those of acquired syphilis.

Interstitial keratitis is one of the common lesions occurring in late congenital syphilis. This may develop at any age between 3 and 30 years or even later.

Neurological lesions: Nerve deafness develops due to involvement of the 8th cranial nerve endings and this lesion is suggestive of congenital syphilis. It presents as bilateral progressive loss of hearing which may become total. Congenital neurosyphilis leads either to general paralysis of insane or tabes dorsalis, but these patients develop the disease at a younger age. Meningovascular neurosyphilis is rare. When it occurs it presents as cranial nerve palsies, hemianopia, and hemi- or monoplegia.

Stigmata of congenital syphilis: Damage to the developing organs *in utero* leads to the permanent stigmata of congenital syphilis. These include localized thickening of the frontal and parietal bones of the skull due to periostitis giving rise to frontal bossing, *hot cross bun skull* and *Parrot's nodes*. *Saddle nose* develops due to the destruction of nasal bones. *High arched palate* and *bulldog facies* are all characteristic. The permanent teeth show diagnostic abnormalities. Peg-like incisors (*Hutchinson's teeth*) are diagnostic. *Hutchinson's triad* is a combination of *interstitial keratitis*, *Hutchinson's teeth* and *nerve deafness* (Fig. 47.3).

DIAGNOSIS

Serodiagnosis of syphilis: Two types of serological tests have been developed; the nonspecific tests using cardiolipin from beef heart and specific tests using live or killed laboratory strains of treponemes or their

Fig. 47.3: Congenital syphilis Hutchinson's teeth

components. The commonly used nonspecific tests are the *rapid plasma reagin* test (RPR) and the *venereal disease reference laboratory* (VDRL) test. Among the specific tests the commonly used one is *treponema pallidum* hemagglutination test (TPHA). *Fluorescent treponemal antibody-absorption* (FTA-ABS) test and the *treponema pallidum immobilization* (TPI) test are done usually for research purposes. There are several other tests used in different laboratories.

Interpretation of serological tests: The nonspecific serological tests become positive about 4 weeks after infection and the titer progressively increases in the secondary stage. If the disease is treated and cured at this stage the titers fall and the test may become negative in 4-6 months. Treatment instituted late in the disease may not eliminate seropositivity. False positive reactions not due to any technical error are known as biological false positive reactions. This may occur in connective tissue disorders like SLE and rheumatoid disease, malaria, leprosy, hepatitis, infectious mononucleosis, and tuberculosis.

The FTA-ABS test becomes positive early after infection. The TPI test becomes positive only later than the FTA-ABS test. Once positive, they remain so for life. Early treatment in primary stage prevents the development of seropositivity. Nonspecific tests are useful to determine cure since they decline in titer if the disease is treated sufficiently early.

Frequency of serological tests			
Tests	Primary stage	Secondary stage	Tertiary stage
Non specific	50-70 %	98-100 %	70%
Specific	70-85 %	100%	98-100%

In the primary and secondary stages diagnosis is established by demonstration of the organism by dark ground microscopy and serological tests. All genital ulcers should be investigated for syphilis irrespective of their appearance. Treatment should always be given only after an accurate diagnosis has been made. All suspected cases should be kept under observation for a minimum period of three months and serological tests for syphilis should be performed at regular intervals. All sexual contacts of the patient during the past six months should be traced and examined.

Latent syphilis is diagnosed when the standard serological tests for syphilis are positive in the blood without any clinical evidence of the disease.

Late syphilis: It is essential to confirm the diagnosis by serological examination before starting the treatment. The cerebrospinal fluid should be examined in all cases of secondary syphilis to exclude meningeal involvement.

Diagnosis of Congenital syphilis: The disease should be suspected in children born to mothers who are syphilitic. In the early infectious stage diagnosis can be established by finding *T. pallidum* on dark ground examination of the discharge from the lesions of the skin, mucous membrane and nose. Serological tests have to be interpreted with caution in the early weeks of life. Maternal reaginic antibodies of IgG class may be passively transferred across the placenta and these may lead to positive serology in the infant even though the baby is not suffering from syphilis. These disappear with time. If the baby is really affected, IgM antibodies develop and the rise in titers can be demonstrated by specific tests (IgM-FTA-ABS).

TREATMENT

The principal aim of therapy is to make the patient non-infectious within the shortest time and to achieve cure. A treponemicidal level of penicillin (0.018 mg/L) has to be maintained in the serum and cerebrospinal fluid for 7-10 days or more to achieve cure.

Treatment regimen for syphilis:

Early syphilis (primary, secondary, and early latent) Benzathine benzyl penicillin, 2.4 million IU by IM injection, given as two injections at separate sites in a single session.

Alternative regimen: Procaine benzyl penicillin, 1.2 million IU, IM injection for 10 consecutive days.

Treatment of patients allergic to penicillin:

Non pregnant patients: Doxycycline 100 mg orally twice daily for 14 days or tetracycline 500 mg orally 4 times daily for 14 days. A single dose of Azithromycin 2 g orally is also effective.

Pregnant patients: Erythromycin 500 mg qid p.o for 14 days.

Late latent syphilis The dose and choice of the drugs is the same as for early syphilis but the duration is longer. Benzathine penicillin is given once weekly for 3 consecutive weeks, procaine penicillin for 20 days, doxycycline, tetracycline and erythromycin for 30 days.

Neuro syphilis Aqueous benzyl penicillin (crystalline penicillin) 12-24 million IU by IV injection, administered daily in doses of 2-4 million IU every 4 hours for 14 days.

Alternative regimen: Procaine benzyl penicillin 1.2 million IU IM once daily and probenecid 500 mg qid po, both for 10- 14 days.

Congenital syphilis Congenital syphilis (up to 2 years of age) and infants with abnormal CSF: Aqueous benzyl penicillin 100 000 – 150 000 IU/kg/day administered as 50000 IU/kg/dose, IV, every 12 hours, during the first 7 days of life and every 8 hours thereafter for a total of 10 days. Alternative regimen is procaine penicillin, 50 000 IU/kg, IM, as a single daily dose for 10 days.

Congenital syphilis of 2 or more years: Aqueous benzyl penicillin, 200000–300000 IU/kg/day, IV or IM, administered as 50000 IU/kg/dose every 4–6 hours for 10–14 days.

Penicillin allergic children: Erythromycin 7.5–12.5 mg/kg qid p.o for 30 days.

Adverse effects of penicillin: In addition to all the adverse side effects of penicillin, syphilitic subjects receiving the drugs may develop *Jarisch-Herxheimer reaction* caused by rapid destruction of spirochetes. In addition to the products of spirochete disintegration, cytokines such as tumour necrosis factor (TNF) and others may also play a role. It may develop in up to 50% of cases of secondary syphilis and in a smaller proportion of late syphilis. 2–3 hours after receiving penicillin the patient becomes restless and apprehensive and develops severe rigor, fever, tachypnea and rise in blood pressure. In a few hours sweating starts, becomes profuse and the blood pressure drops. The reaction subsides within a few hours with symptomatic management. However, in patients with general paresis or high CSF cell counts further neurological damage may develop and lead to extension of paralysis. The lesions of syphilitic aortitis may extend and lead to coronary occlusion which can be fatal. Administration of 20 mg prednisolone starting 24 hours prior to penicillin injections and continued for two days prevents Herxheimer reaction. If Herxheimer reaction occurs, management is the same as for anaphylactic shock. Antibody to TNF which blocks its action has been employed with benefit in severe cases where other routine measures are inadequate.

Follow-up: Patients should be followed up at the end of 3 months, 6 months and 12 months, clinically and serologically, using a non-treponemal test like VDRL or RPR to assess the results of therapy and to detect possible reinfection.

At all stages of the disease, repeat treatment should be considered when clinical signs or symptoms of active syphilis persist or recur or there is confirmed increase in the titre of a non-treponemal test. Examination of CSF should be undertaken before repeat treatment, unless reinfection and a diagnosis of early syphilis can be established. Retreatment is with schedules as for late syphilis.

When congenital syphilis is detected, the mother also should be investigated serologically. Surveillance plan is the same as for late syphilis. The baby should be followed up late into adult life. *Interstitial keratitis* should be treated with local corticosteroids and atropine drops in addition.

PREVENTION

Congenital syphilis is preventable if the mother is treated before the fourth month of pregnancy. Treatment

administered later in pregnancy usually cures both the mother and the fetus, though residual stigmata may be seen in the baby. If syphilis is detected in the pregnant woman, the course of treatment is the same as for primary syphilis. Tetracycline should be avoided in pregnancy. Azithromycin in a dose of 1.8 g orally given on two occasions within six days has been found to prevent the development of syphilis in persons who had infective exposure. This may serve as a short term measure.

Social measures: When primary or latent syphilis is detected, all sexual contacts should be traced out and examined. Since a social stigma has been attached to the sexually transmitted diseases, patients tend to conceal the infection and do not come up for treatment. Hence, great care is required to avoid psychological trauma to the patient and his contacts. The doctor should not take an admonishing attitude. *Proper instruction on healthy sexual practices, avoidance of direct contact by the use of condoms, and periodic examination of prostitutes and other personnel engaged in similar practices help to limit to some extent the incidence of sexually transmitted diseases.*

Syphilis and HIV: There is increased interest in syphilis at present since it often coexists with AIDS, and each aggravates the manifestation of the other. Genital ulceration facilitates sexual transmission of HIV. All patients with syphilis should be screened for HIV and vice versa. Clinical manifestation of syphilis in HIV may be atypical. A rapid progression from early to late disease is reported. Progression to neuro syphilis occurs more frequently. The diagnosis of syphilis by serologic means become unreliable. Serological tests like VDRL and TPHA may be false negative or quantitatively higher or lower than expected. Dark field microscopy, histology and clinical acumen have to be relied upon. Failure to respond to treatment is also common. Treatment with higher and more prolonged doses is required.

Points to remember

- The primary chancre on the genitalia appears 3 weeks after the sexual contact.
- The generalized symmetrical, non-pruritic papules of the secondary stage develops 6–8 weeks following the chancre
- Tertiary stage develops years later.
- Serological diagnosis includes VDRL and TPHA and demonstration of treponema by dark ground microscopy.
- Treatment is with benzathine benzyl penicillin or procaine penicillin.

Gonorrhea

Gonorrhea is one of the most common sexually transmitted diseases all over the world. This is caused by *Neisseria gonorrhoeae*, which is present throughout the

world. Several strains of *N. gonorrhoeae* produce *betalactamase* and this helps them to develop resistance to penicillin to which they were sensitive. At present occurrence of penicillin-resistant gonorrhea is widespread. The lesions also occur over a wider area, depending on the sexual practices.

Gonococci attach themselves to cells with the help of pili before initiating infection. The organisms are ingested by polymorphs and they survive within the cells for variable periods, being protected from adverse environment. Four types can be distinguished by cultural characteristics. Types T1 and T2 are virulent whereas T3 and T4 are not. Gonococci are gram-negative diplococci seen intracellularly and also free in the exudate.

6

Pathology

Gonococci affect columnar and transitional epithelium mainly and infection is initiated in the urethra, anal canal, conjunctiva, pharynx, and endocervix. Pus is produced locally. Direct extension from the site of infection leads to complications such as endometritis, salpingitis, peritonitis, and Bartholinitis in the female, and periurethral abscess, epididymo-orchitis, and prostatitis in the male. Ocular conjunctiva is affected. Metastatic spread of the organisms leads to arthritis, dermatitis, endocarditis, meningitis, myopericarditis, and hepatitis.

CLINICAL FEATURES

In men the onset of the disease is more acute than in women. Incubation period is usually 3 to 5 days.

Gonorrhea in the male: In over 90% of cases urethritis presents with a constant burning sensation in the penis and discharge of infective pus which teems with the organisms. Meatal inflammation and penile edema may be obvious. Variable amounts of pus can be milked from the urethra. Micturition is painful and the patient is severely distressed. Other adnexal structures like epididymis, testes, and spermatic cord become inflamed. Rarely the Tyson's glands and the median raphe of the scrotum may be inflamed. Gonococcal prostatitis and seminal vesiculitis are seen but they are rare. If left alone, the acute manifestations subside over a period of weeks or months even-without treatment. Exacerbations occur frequently as a result of sexual indulgence, alcoholism, or undue exertion. Ultimately, the anterior and posterior urethra develop stricture. Periurethral abscesses may develop at times. Extension of suppuration into the periurethral tissues and scrotum result in fistulous openings discharging urine from multiple sites ("water-can scrotum"). In 10% of subjects the lesion may be asymptomatic and has to be detected by examination.

The rectum is an important site of ulceration in persons who are habitual catamites in homosexual

relationship. The rectum and anal canal are ulcerated and show blood-stained mucopurulent discharge. The condition may present as proctitis and may be mistaken for other ulcerating lesions of this region.

Gonorrhea in the female: In a good number of women gonorrhea may remain asymptomatic. Symptoms include leucorrhea, dysuria, menstrual abnormalities and features of pelvic inflammation. Rectal lesions develop in about 40% of affected women due to contamination by cervical discharges.

The gonococci may pass up from the endocervix leading to acute salpingitis and oophoritis. Chronic salpingo-oophoritis and tubo-ovarian masses may develop. Exacerbations occur during menstrual periods or one or two weeks thereafter. Gonococcal salpingo-oophoritis is a common cause of sterility.

Gonococcal infection in the newborn: Inoculation of gonococci into the baby's eyes from the maternal genital passages leads to ophthalmia neonatorum. This presents with purulent conjunctivitis which may result in blindness. The infection can also disseminate to other tissues and result in arthritis in the newborn.

Disseminated gonococcal infection: This occurs in up to 30% of infected patients, 80% of them being females. Bacteremic spread occurs. Manifestations include cutaneous lesions, septic arthritis, septicemia, endocarditis, myocarditis and rarely, pericarditis and meningitis. Risk of dissemination depends on the type and virulence of the organism. Dissemination is more common from silent foci in the pharynx, rectum, or endocervix. The cutaneous lesions take the form of vesicles and pustules which do not usually ulcerate.

Oropharyngeal infections: Pharyngitis and tonsillitis result from oral sex and may affect both sexes. In the majority of cases symptoms are not severe enough to seek medical care. Strong clinical suspicion and microbiological investigations are required to make the diagnosis. Gonococcal pharyngitis may give rise to dissemination.

DIAGNOSIS

Gonorrhea should be suspected in all clinical situations where there is purulent urethral discharge, leucorrhea in women, atypical oropharyngeal ulceration, proctocolitis and ophthalmia neonatorum. Bacteriological diagnosis is established by demonstrating gram-negative diplococci inside polymorphonuclear cells in the exudates. The organism can be identified by culture and further studies. Culture of cervical discharge is required in women with late manifestations to establish the diagnosis. On rare occasions purulent material may have to be collected by culdocentesis or laparoscopy. Fluorescent antibody techniques help in making quick diagnosis where such

facilities exist. Complement fixation test is useful in selected cases of chronic gonorrhea with systemic manifestations.

TREATMENT OF GONORRHEA

The sheet anchor of the treatment of gonorrhea upto the 1970’s used to be penicillin to which the organisms were invariably sensitive. A large proportion of gonococcal isolates world wide are now resistant to penicillins, tetracyclines and other older antimicrobial agents. Therefore, these drugs can no longer be relied upon for the cure of gonorrhea. Since dual infections with gonococcus and chlamydia are common it is recommended that concurrent anti-chlamydia therapy may also be given.

Recommended regimens (WHO and CDC guide lines 2003)

Ceftriaxone 125 mg IM injection or cefixime 400 mg orally or spectinomycin 2 g by IM injection, as a single dose, is curative. These drugs are also effective in adult gonococcal conjunctivitis.

Ciprofloxacin 500 mg or ofloxacin 400 mg as a single dose.

Neonatal gonococcal conjunctivitis:

Ceftriaxone 50 mg/kg IM as a single dose to a maximum of 125 mg. Alternative regimen includes kanamycin or spectinomycin 25 mg/kg IM single dose, to a maximum of 75 mg.

Disseminated gonococcal infection:

Ceftriaxone 1 g IM or IV injection, once daily for 7 days or spectinomycin 2 g IM twice daily for 7 days.

Gonococcal endocarditis: same dosages of ceftriaxone or spectinomycin for 4 weeks.

Prophylactic treatment: Instillation of 1 to 2% silver nitrate solution or 1% tetracycline ointment into the eyes of newborn babies effectively prevents all forms of ophthalmia neonatorum whether it is of bacterial, viral, or chlamydial origin. Use of condoms helps to reduce transmission of STDs.

Follow up: Patients should be reviewed after 48 hours for subsidence of acute symptoms and at longer intervals for recurrence.

Points to remember

- Males present with dysuria, frequency and urethral discharge
- Females complain of vaginal discharge, dysuria and abdominal pain
- Pelvic inflammatory disease and infertility are late sequelae
- Treatment is with ciprofloxacin or ceftriaxone
- Concurrent antichlamydia therapy should be given to all patients with gonorrhea.

Non-Gonococcal Urethritis
(Syn: Nonspecific Urethritis)

Definition

Urethritis, from which gonococci cannot be isolated, is termed as non-gonococcal urethritis (NGU). While in men the condition is well defined, in women it is not so. The possible causative organisms are *Chlamydia trachomatis* in 60% cases. Other organisms include mycoplasma such as *Ureaplasma urealyticum*, *Mycoplasma hominis*, *M fermentans* and *M genitalis*. Other pathogens such as *Herpes simplex virus*, *Trichomonas vaginalis* and *Candida albicans* may rarely produce the picture of NGU. In a proportion of patients organisms may not be identified.

Human Chlamydial Infections	
Diseases	Organisms
Trachoma	<i>C. trachomatis</i> A, B, Ba, C
Inclusion conjunctivitis	<i>C. trachomatis</i> D-K Ophthalmia neonatorum -do-
<i>Genital tract</i>	
<i>Male</i>	
Urethritis, epididymitis	<i>C. trachomatis</i> D-K
<i>Female</i>	
Urethritis, cervicitis proctitis, salpingitis, perihepatitis, periappendicitis, infertility abortion, stillbirth	<i>C.trachomatis</i> D-K
Lymphogranuloma venereum	<i>C. trachomatis</i> L1-L3
<i>Respiratory tract</i>	
Pneumonitis of infants	<i>C. trachomatis</i> D-K
Pharyngitis, pneumonia	<i>C. pneumoniae</i>
Psittacosis	<i>C. psittaci</i> (avian strains)
Pneumonia	<i>C. psittaci</i> (ovine strains)

Note: Ovine-pertaining to sheep.

Epidemiology

Non-gonococcal urethritis occurs worldwide and it is common in India. Infection is initially acquired by sexual intercourse, though relapses may occur without such contact. The chain of transmission is not as clear cut as in gonorrhea. This infection develops only in a few of the sexual partners of patients in both sexes. The reason for this phenomenon is not known. In many centers NGU outnumber gonorrhea.

Clinical Features

NGU in men: The incubation period ranges from a few days to two months. This wide range may suggest the possibility of different pathogens. Clinical features resemble a mild attack of gonorrhea with a subacute onset and a watery, mucoid, mucopurulent, or rarely frankly purulent urethral discharge. Gram staining shows the absence of gonococci. Even in untreated cases the urethritis subsides, but mild exacerbations occur from time to time. Treatment with tetracycline, which is the drug of choice, rapidly clears the condition in 90% of cases. Non-gonococcal proctitis may occur in homosexual individuals.

Post-gonococcal urethritis (PGU): This term is used for patients with gonococcal urethritis who develop non-gonococcal urethritis after successful treatment with penicillin. It is possible that these patients harbor the organisms of gonorrhea and NGU simultaneously.

Local complications of NGU and PGU: Local abscesses may develop in some cases. Acute unilateral epididymitis develops rarely. *Chronic prostatitis* is the most common complication. Identification of this condition may not be easy. The most significant symptom is prostatic pain which is felt in the perineal region as a vague discomfort and this may be referred to the groins, thighs, and suprapubic region. Presence of pus cells and numerous prostatic threads in the first sample of urine collected after prostatic massage suggests prostatitis. Around 1-2% of males who develop NGU may suffer from Reiter's syndrome later.

Non-gonococcal genital infections in women: This infection is much less clear cut in women than in men. Some women may complain of vaginal discharge. The most important manifestation is salpingitis, which may extend to pelvic tissues to produce pelvic inflammatory disease. Perihepatitis, bartholinitis, postpartum and post-abortion fever, ascending pyelonephritis, infertility and birth of underweight babies have all been recorded as complications.

Non-gonococcal infections in infants and children: Infections may be acquired by the baby during birth, from the maternal genital passages. The newborn may develop non-gonococcal ophthalmia neonatorum and infantile pneumonia caused by *C. trachomatis*.

Diagnosis is by culture of discharges, cervical swab or urethral discharge, in both sexes. Other methods include PCR for *C. trachomatis*.

Treatment of Non-gonococcal Genital Infections

Doxycycline 100 mg orally bd for 7 days or
Azithromycin 1 g orally in a single dose

Alternative regimen (7 days treatment)

Amoxycillin 500 mg tid or

Erythromycin 500 mg qid or

Ofloxacin 300 mg bd or

Tetracycline 500 mg qid

Epididymitis responds to ceftriaxone 250 mg IM bd with doxycycline 100 mg bd for 10 days. Azithromycin 1 g, single dose is a suitable alternative.

Points to remember

- NGU presents as urethral discharge which is watery, mucoid or mucopurulent
- Some patients harbor organisms of gonorrhea and NGU simultaneously and their urethritis persists if gonorrhea alone is treated.
- Treatment is with doxycycline or azithromycin

Lymphogranuloma venereum

Syn: Climatic bubo, Lymphogranuloma Inguinale

Definition

Lymphogranuloma venereum is a common sexually transmitted disease caused by *Chlamydia trachomatis* strains L1, L2 and L3, manifesting as inguinal buboes, pseudo-elephantiasis of the genitals and anorectal involvement in the late stages.

It is present all over the world, more frequently in developing countries. The incubation period ranges from 2 weeks to several weeks.

Clinical Features

The organisms enter by sexual intercourse and a small herpetiform ulcer develops under the prepuce or the labia. This ulcer disappears within 24 to 48 hours. Rarely it may become secondarily infected and persistent.

The manifestations are different in the two sexes. In **males** the prominent feature is development of inguinal buboes since lymphatics from the prepuce and penis drain into the inguinal group of lymph nodes. On the other hand, in the females they drain into the anorectal lymph nodes or directly into the hypogastric lymph nodes. The buboes are usually unilateral, painful, matted, firm or fluctuant, and tender. The overlying skin is indurated. If the femoral and inguinal nodes are enlarged, they are separated by Poupart's ligament producing a groove called *Groove sign of Greenblatt*, which is pathognomonic. Buboes may be bilateral at times. Sooner or later, the bubo suppurates and multiple sinuses develop and discharge pus. Some buboes may remain indolent for a long time.

In **females** mild constitutional symptoms like fever, malaise and lower abdominal pain on the side of the bubo, are fairly common. Local peritonitis may develop through peritoneal lymphatics. Other lesions in the female include stricture of the urethra, destruction of the floor of urethra and rectovaginal, urethro-vaginal, or vesico-vaginal fistulae. In debilitated patients extensive tissue damage may develop. Pelvic inflammation may follow.

Esthiomene: This is a pseudo-elephantoid condition of the genitalia caused by lymphatic obstruction, due to extensive involvement of deeper pelvic lymph nodes and lymphatics. It is more common in women. Hypertrophy involves the labia, prepuce of the clitoris, and sometimes the clitoris. They enlarge to big sizes and the surface is warty, mammilated, verrucous or ulcerated.

Anorectal lesions: These develop late in the disease and are more common in women and in male passive homosexuals. Initial lesion is ano-proctitis which may resemble dysentery, but does not respond to usual treatment. Finally it leads to rectal stricture. Rarely, stricture may develop without evidence of preceding anoproctitis. Below the stricture extensive polyposis and cock's comb like condylomatous masses may develop in the perianal region.

Extragenital manifestations are rare in LGV. These are meningitis, cutaneous eruptions, episcleritis, iridocyclitis, and arthritis.

Diagnosis

Diagnosis is clinical. The causative organism can be grown in chick embryo or tissue culture, where facilities exist. The *LGV complement fixation test* becomes positive in 1-3 weeks in 90 to 95% cases. This test is nonspecific since other chlamydiae may give rise to positive reactions, though not in the same titers as seen in LGV. A four-fold rise in the titer can be taken as diagnostic of LGV. Other more specific tests are the *immunofluorescent tests* and *radio-isotope precipitation tests* (RIP).

Treatment

The recommended regimen is

Doxycycline 100 mg orally bd for 14 days or
Erythromycin 500 mg orally qid for 14 days.

Alternative regime is to treat with oral tetracycline in doses of 500 mg qid for 14 days. The suppurating buboes should be aspirated through healthy skin and not incised. Some patients with advanced disease may require prolonged treatment.

Surgery is required for excising elephantoid lesions and dilating strictures after treating adequately with tetracycline. Sometimes, even established strictures resolve with simple medical treatment.

Points to remember

- Caused by L1, L2 and L3 strains of *Chlamydia trachomatis*.
- Primary asymptomatic ulcer that develops two weeks after the sexual contact is usually unnoticed.
- Males present with tender, unilateral inguinal bubo.
- Complications are more common in females.
- LGV responds to doxycycline or erythromycin

Granuloma inguinale

(Syn: Granuloma Venereum, Donovanosis)

Definition

Granuloma inguinale is a specific chronic granulomatous disease affecting primarily genitalia in both sexes. It is particularly prevalent in the tropical and subtropical regions. It constitutes 1.5 to 6% of the total number of STD cases seen in clinics in India. There is a higher incidence of this disease in the eastern coastal states particularly in the states of Orissa, Andhra Pradesh, and Tamil Nadu. It has been reported from all regions.

The disease is caused by *Donovania granulomatis* (syn: *Calymmatobacterium granulomatis*) which is seen either as bacillary forms inside phagocytes in discharges or biopsy specimens. The organism can be cultured *in vitro*.

Clinical Features

The incubation period ranges from a few days to a few months. The disease starts as a subcutaneous papule or vesicle which ulcerates to give rise to a granuloma. The lesion extends by contiguity. Draining lymph glands are not affected and this helps to differentiate the lesion from a primary chancre. Rarely it can present as a subcutaneous swelling in the inguinal region which bursts open to produce a granulomatous ulcer. This is called "pseudo bubo". The initial lesion may be in the genitalia, groin, thigh, perineum, or oral mucosa depending on the sex practices. It may extend to the buttocks or anterior abdominal wall. In most of the cases extragenital lesions on the tongue, cheek, or oral cavity are accompanied by a primary lesion in the genitalia. Fusospirochetal infection supervenes as secondary invader and this result in tissue destruction. The ulcers show pouting granulation tissue. Healing leads to scarring and local elephantiasis of the genitalia. Epidermoid carcinoma may develop in 0.5% of cases.

Diagnosis

Granuloma inguinale has to be differentiated from syphilitic chancre and carcinoma. Diagnosis is confirmed by biopsy and demonstration of the organism in tissue spreads obtained from the margins of the ulcer.

Treatment

Recommended regimen: Azithromycin 1 g orally on first day, then 500 mg orally once a day or doxycycline 100 mg orally bid until all lesions have completely epithelialized. Alternatives are erythromycin or tetracycline 500 mg q.i.d or trimethoprim 80 mg/sulfamethoxazole 400 mg, 2 tablets orally b.d for a minimum of 14 days. Patients

Diseases Caused by Infections

should be followed up clinically until signs and symptoms have resolved.

Points to remember

- Granulomatous lesion in the genitalia and neighboring sites.
- Lymph nodes are not affected.
- Treatment is with azithromycin or doxycycline till the lesions heal.

Chancroid

(Syn: Soft Chancre, Soft Sore, Ulcus Molle)

Chancroid is caused by *Hemophilus ducreyi*. The organism is seen in clusters or singly in smears from ulcers and can be grown in special media. The disease is seen more in the poor with bad personal hygiene. Incubation period is 5 days.

Clinical Features

Multiple, superficial, non-indurated, painful ulcers which bleed easily develop along the corona glandis or inner aspect of the labia. Inguinal glands may be enlarged and in many cases they suppurate to form inguinal buboes called (inflammatory bubo). Secondary infection with *Vincent's spirochetes* may develop. In such cases balanoposthitis with offensive discharge may be prominent.

Diagnosis

Diagnosis is confirmed by demonstrating *H. ducreyi* in gram stained smears from ulcers or by culture. Other ulcerating lesions have to be excluded.

Treatment

Ciprofloxacin 500 mg bd for 3 days or erythromycin 500 mg qid for 7 days or azithromycin 1 g orally as a single dose is recommended. Alternatively ceftriaxone 250 mg IM as a single dose can be given.

Trichomoniasis

Trichomoniasis is infection by the flagellate protozoan *Trichomonas vaginalis* that causes vaginitis in women and

rarely urethritis in men. In women the condition is localized to the vagina. In most of the cases infection is acquired by sexual intercourse.

Pathology

The infection is most common in the second and third decades of life and may be associated with gonorrhea. The superficial layers of the vagina are affected. There is marked polymorphonuclear infiltration and changes in the epithelium of the vagina.

Clinical Features

Females: In young women there is a florid, profuse, irritating, offensive, yellow vaginal discharge. Severe cases may show vulval swelling with excoriation of the adjacent skin. The vaginal pH tends to become more alkaline (pH 5-8) than normal (pH 4-5). Symptoms are milder in older women.

Males: Many are asymptomatic carriers. Some may suffer from true trichomonal urethritis or they may harbour *T. vaginalis* in addition to non-gonococcal urethritis. Occasionally frank purulent urethritis may occur due to this flagellate.

Laboratory diagnosis is established by demonstrating the active flagellates in fresh exudates.

Treatment

Metronidazole or tinidazole, 2 g orally in a single dose is recommended. Alternatively, metronidazole 400 mg or 500 mg orally b.d for 7 days or tinidazole 500 mg orally b.d for 5 days can be used. Patient should be followed up after 7 days. If not cured, the treatment is repeated with the 7 day regimen. If there is no response to repeat treatment, metronidazole 2 g orally daily together with 500 mg applied intravaginally at night for 3-7 days is recommended. Vaginal preparations are advised only in refractory infections. Relapse is prevented by treating both sexual partners simultaneously. Relapses of trichomoniasis are unusual. Recurrence of symptoms is usually due to reinfection.

Management of HIV Infection 272

Prevention 273

Several viruses may be transmitted by sexual contact. Important among them are herpes simplex, human papilloma virus, molluscum contagiosum, hepatitis B virus, cytomegalovirus, Marburg virus, and AIDS.

Herpes Genitalis

Herpes genitalis is caused by *herpes simplex virus (HSV) type 2 and less frequently by HSV type 1*. It is moderately infectious. The virus remains dormant in the presacral sensory ganglion cells. Periodically it moves into the skin through the axons of sensory nerves to produce recurrent attacks of herpes simplex locally. Factors which produce the reappearance of herpes are not clear. In many western countries herpes genitalis is emerging as the commonest among the STD. The disease is transmitted by sexual intercourse. The virus is shed from the lesions for up to 2 weeks after apparent healing. Infection of the baby during birth leads to neonatal herpes.

Clinical Features

The incubation period is 2-4 days or rarely longer. The onset of local lesions may be preceded by burning pain in the S1 to S5 dermatomes.

The lesions occur in the external genitalia of men and in the anal canal of homosexuals. Over the penis, it starts with erythema followed by the appearance of papules or vesicles which soon rupture to form shallow painful ulcers. Ultimately, crusts form which dry up and fall off leaving healed scars which fade. Tender inguinal adenopathy develops in the primary attack but not with recurrences. The lesions are infective throughout. Recurrences are generally much milder (Fig. 48.1).

In women the primary lesion and recurrent attacks differ from each other considerably. Primary attack is severe, whereas, subsequent attacks are milder. Lesions occur usually in the vulva and adjacent skin areas. Morphology of the lesion is the same as in men. During the primary attack retention of urine may develop due to extreme pain on micturition. Herpes virus infection is directly or indirectly related to the development of carcinoma of the cervix, vagina, or vulva in later life as the virus is oncogenic. HSV 2 can also act as a cofactor with human papilloma virus for invasive cervical cancer.

Fig. 48.1: Herpes genitalis male

Diseases Caused by Infections

Dissemination of the infection is rare in adults, but if it occurs it can be fatal. The skin, the central nervous system, and other internal organs may be affected. HSV2 can also act as a cofactor with human papilloma virus for invasive cervical cancer.

The newborn may acquire herpes during delivery if the mother has active lesions in the genitalia. Lesions develop in the baby usually within two weeks after birth. These occur more commonly with primary maternal herpes than with recurrent attacks. Both HSV-1 and HSV-2 may be responsible but the latter is more common. The lesions in the newborn include meningoencephalitis or generalized herpetic lesions involving several organs. If not treated, mortality and morbidity are very high.

Laboratory diagnosis is established by isolation of the virus from the lesions. Serological tests using blood include complement fixation test which becomes positive about a week after infections. In primary infection, the first sample is seronegative, the second sample shows a marked rise in titer. In recurrent herpes both samples give the same low titer. Herpes virus can be demonstrated by electron microscopy of vesicle fluid or tissue specimens. In herpes simplex encephalitis the CSF shows antibodies.

Cytology

Papanicolaou's stained smears from vesicles show multinucleated giant cells with eosinophilic inclusions. In meningoencephalitis CSF shows changes. CT scan, MRI imaging and brain biopsy are employed to diagnose herpetic encephalitis.

Treatment and Prophylaxis

Treatment options for genital herpes:

First clinical episode: Treatment duration-7 days

Acyclovir 200 mg orally 5 times daily or
400 mg t.i.d or

Valacyclovir 1 g orally b.i.d or

Famciclovir 250 mg t.i.d.

Recurrent infection: Treatment duration-5 days.

Acyclovir (oral) 200 mg 5 times daily or
400 mg t.i.d or

800 mg b.d or

Valacyclovir 500 mg b.d or 1g once daily or

Famciclovir 125 mg twice daily.

Suppressive therapy: The condition tends to recur often on cessation of treatment. If the recurrence is too frequent, >6 times a year, suppressive therapy is indicated for prolonged periods.

Acyclovir 400 mg bid or

Valacyclovir 500 mg or 1 g or

Famciclovir 250 mg bid continuously.

Recommended regimen for *severe disease* is acyclovir 5-10 mg/kg IV every 8 hours for 5-7 days or until clinical resolution is attained.

Severe herpes with *coinfection with HIV*: Acyclovir 400 mg orally 3-5 times daily until clinical resolution is attained.

Neonatal infection: Acyclovir 10 mg/kg IV 3 times daily for 10-21 days.

If the mother develops primary attack of herpes genitalis after the 36th week of pregnancy, caesarean section is indicated before the rupture of the membranes to avoid infection of the baby and the baby has to be watched for 2-4 weeks for the development of generalized herpes.

Points to remember

- Commonest STD.
- Primary herpes is severe and is characterized by shallow painful ulcers on the genitalia.
- Recurrent attacks are milder
- Acyclovir is effective.

Genital Warts

(Syn: Condyloma Acuminata)

Genital warts are benign growths of the skin and adjacent mucous membrane, caused by the *human papilloma virus*. More than 100 types exist. They can be broadly classified into 1) low risk non-oncogenic types e.g types 6 and 11 which cause benign anogenital warts, condyloma acuminata and 2) high risk oncogenic types e.g types 16, 18, 31, and 45 which occasionally lead to cancer. Majority of cases of genital warts are sexually transmitted. Though usually the incubation period is two to three months, it may be up to a year in some cases.

Clinical Features

Warts are commonly seen on the moist surfaces of the male and female genitalia, especially the coronal sulcus, glans penis, frenum, and shaft of the penis in the male and posterior part of the introitus, labia majora, labia minora, and clitoris in the female. Warts may develop in the urethral meatus and the cervix uteri. The wart virus is always present in the cervix, even if warts are not seen there. In females the genital warts enlarge during pregnancy and regress during the puerperium (Fig. 48.2).

Treatment

No specific treatment is effective in eliminating the virus and, therefore, recurrences are frequent.

Recommended treatment: Podophyllin resin 10-25% in spirit or tincture of benzoin should be applied carefully to the warts avoiding normal tissue at weekly intervals. It should be washed thoroughly after 1-4 hours of application. Podophyllin is teratogenic and should not be used during pregnancy. Podophyllotoxin 0.5 %, one of the active constituents of podophyllin can be self applied

Fig. 48.2: Condyloma acuminata. Note the warty growth on the labia minora. Other large lesions on the neighbouring skin were removed by electrosurgery

and it is less toxic. It is used twice daily for 3 days followed by 4 days of no treatment, the cycle repeated up to 4 times. Imiquimod 5 % cream applied with a finger at bed time, left on overnight, 3 times a week for as long as 16 weeks can be self applied by the patient. The treatment area should be washed after 6-10 hours of application.

The warts can be cauterized under local anesthesia, using electrocoagulation. Cryotherapy with liquid nitrogen, solid carbon dioxide, or a cryoprobe has been used. Large warts are removed surgically.

Molluscum Contagiosum

Molluscum contagiosum is a viral disease which can be transmitted from person to person by sexual or nonsexual contact, the latter is more common. The infective agent is a virus belonging to the pox group. Cellular proliferation occurs in the deeper layers of the skin in the stratum malpighii. Many cells contain ovoid eosinophilic intracytoplasmic inclusions which can be demonstrated by Romanovski's stains. These are called *molluscum bodies* and they are diagnostic. The cheesy material exuding when the lesion is squeezed is taken up for demonstrating the molluscum bodies. Lesions may develop on any part of the skin. The incubation period varies from 3 weeks to several months. The sexually transmitted lesion develops on the genitalia. The lesions are papular, ranging in size from 2 mm to 1 cm, waxy and pale pink with central depression.

Treatment

Local application of pure phenol or concentrated trichloroacetic acid by a sharpened match stick will destroy the virus. Electrocoagulation is also useful.

Human Immunodeficiency Virus (HIV) Infection and Acquired Immunodeficiency Syndrome (AIDS)

R. Sajith Kumar, K.V. Krishna Das

AIDS is the name given to a group of disorders related to immunodeficiency produced as a result of the infection by the *Human Immunodeficiency Virus (HIV)*. The syndrome was first described in 1981 in Los Angeles in male homosexuals. In a short span of twentyfour years, it has spread all across the globe, affecting various spheres of human life. AIDS is the final consequence of various changes that take place in the immune status of the individual and is characterized by the occurrence of opportunistic infections and specific malignancies.

It is estimated that there are about 40 million cases of HIV infection worldwide as of end 2005. Five million people have been infected with the virus last year itself. Three million AIDS patients have died in one year. As a continent, Africa has maximum number of cases (26 million). The current estimates put India as the second largest country with 5.3 million infected persons. As per the statistics released by the National AIDS Control Organisation (NACO), Govt of India, the maximum number of cases have been identified in the state of Tamil Nadu, even though states like Maharashtra, Andhra Pradesh, Manipur and Karnataka also have increasing number of cases. Serosurveillance studies in different states have brought out the prevalence of the infection- 44.7% of all female sex workers in Mumbai, 17.6% of all STD clinic attendees in AP, 22% of IV drug users (IVDUs) in Manipur and 2.2% of all expectant mothers in AP. Maharashtra, Tamil Nadu, Manipur, Andhra Pradesh, Karnataka and Nagaland have been identified as high prevalence states with the HIV prevalence exceeding 5 % among high-risk groups and 1 percent among antenatal women. Gujarat, Goa and Pondicherry which are adjacent to the high prevalence states report HIV prevalence exceeding 5 percent among high-risk groups, but only less than 1 % among antenatal women. All other Indian states are classified as low prevalent states.

The present situation in India reveals the following:

1. 87.7% are in the age group of 15-44 years.
2. The predominant mode of transmission of infection is through heterosexual contact in 85.7%. Other sources include injecting drug use in 2.2%, blood and blood components transfusion in 2.6% , perinatal transmission in 2.7% and various other causes in 6.8%.

3. The HIV sentinel surveillance of 2003, show that males accounted for 73.5% and females, 26.5% of the total, the ratio being 3:1.

Further reading: Steinbrook R. HIV in India—A complex epidemic. *NE J Med* 2007;356:1089-93.

The Causative Organism

The disease is caused by infection with HIV which is a retrovirus and belongs to the family of lentiviruses. Infections with lentiviruses typically show a chronic course of disease, a long period of clinical latency, persistent viral replication and involvement of the central nervous system. There are many viruses which are classified under this name. HIV-1 and HIV-2 are the major ones. Using electron microscopy, HIV-1 and HIV-2 are almost similar. However, they differ with regard to the molecular weight of their proteins, as well as having differences in their accessory genes. Both HIV-1 and HIV-2 replicate in CD4⁺ T cells and are regarded as pathogenic, HIV-2 being less pathogenic. HIV-1 is subdivided into groups: M (for main) and O (for outlier), antigenically. Within group M are the vast majority of HIV-1 strains subdivided into subtypes (currently 10: A-J) based on genetic variation. HIV-1 subtype B is more prevalent in homosexuals and IV drug users. However most of the ongoing HIV-1 epidemic around the world is due to non-B subtypes, especially subtype C in sub-Saharan Africa and India. But almost all subtypes have been identified in all parts of the world.

HIV viruses are RNA viruses. HIV-1 viral particles have a diameter of 100 nm and are surrounded by a lipoprotein membrane.

During the process of budding, the virus may incorporate, different host proteins, such as HLA class I and II proteins, or adhesion proteins from the membrane of the host cell into its lipoprotein layer.

HIV has greatest affinity towards CD4 receptor bearing T helper lymphocyte group. Two newly identified proteins found on immune cells, CCR5 and fusin (also known as CXCR4) are considered as co-receptors. Certain chemokines are also considered important in modulating the entry of virus into the CD4 cell. After HIV successfully attaches and fuses with the cell, the RNA strands are transcribed to DNA by the timely activation of reverse transcriptase, a viral enzyme. The DNA strands thus formed in the cytoplasm migrate to the nucleus and integrate with the human DNA (with the help of enzyme integrase). This is an irreversible bonding and leads to the beginning of a permanent HIV infection.

The integrated human CD4 cell may take various routes. Some of them are detected by the person's immune system and are eliminated promptly. Some of them get activated against other antigens or allergens and start producing chemical mediators. When parts of the DNA

correspond to that of the virus, the proteins so produced will contain the amino acid sequences needed for the virus replication too. These 'viral' proteins are cleaved into correct sequence by the enzyme protease. The newly synthesized viral proteins acquire their coating from the CD4 cell surface and 'bud out' damaging the cell membrane. This leads to significant damage to the cells and they are destroyed in large numbers. Some of the cells undergo fusion and form syncytia. Some may be destroyed by cell mediated, complement mediated or antibody dependent cytotoxic mechanisms. Some CD4 cells undergo apoptosis (programmed and premature cell death). Thus the virus infection over a period of years leads to fall in the number of CD4 cells. The virus can also produce direct effects on cells in the brain, heart and bowel and reticulo endothelial system. HIV can replicate aggressively and upto 10 billion virus particles may be produced in a day with an average half life of 6 days.

The CD4 count in a normal person is between 800 and 1200 cells per cmm in peripheral blood. The CD4 cell is responsible for the smooth and coordinated function of all arms of the immune system. Once the CD4 function is compromised, various abnormalities occur. Both physiologic and dysregulated activation contribute to the profound immune activation and accelerated cell death that characterizes HIV infection. In early HIV infection, CD8⁺ T-cell numbers tend to increase, reflecting expansion of memory CD8⁺ T cells, particularly HIV-reactive cells. CD8 cell expansion persists until far advanced stages of HIV disease, when all T-cell numbers tend to fall. A number of immunological abnormalities have been described including:

1. leukopenia and lymphopenia.
2. loss of T4 lymphocytes from the peripheral blood.
3. hypergammaglobulinemia.
4. skin anergy.
5. decrease in lymphocyte proliferation, cytotoxic T cell response and antibody production to new antigens.
6. elevated levels of immune complexes, interferon and β_2 microglobulin

Immunodeficiency manifest in three different patterns:

- a. reactivation of dormant infections like tuberculosis and herpes infections
- b. infections by opportunistic pathogens
- c. atypical manifestations of common infections.

The immune dysregulation also leads to development of specific malignancies such as Kaposi's sarcoma related to HHV 8 infection

Route of Transmission

HIV is susceptible to destruction by many physical and chemical agents. Close contact and exchange of blood or body fluids is necessary for transmission. The most rampant route is sexual intercourse. Male homosexuals

practicing anal sex have the highest risk. Heterosexual anal sex, heterosexual vaginal sex, oral sex and sex using condoms have been stratified in the decreasing order of risk involved. The infection is common amongst IV drug users in whom sharing of contaminated needles, syringes and drugs is the risky factor. The infection can also be transmitted from the mother to the child during pregnancy, at the time of labor or during breast feeding. The transmission is most effective following transfusion of infected blood. Occasionally needles and sharps used in hospitals can act as sources of infection to health care professionals if proper precautions are not taken. HIV does not spread through casual contact, furniture, touching, sharing the food, utensils, toilet or through air or water.

Route	Percentage	Efficiency (%)
Sexual	85.96	0.1-1
Perinatal transmission	3.64	14-45%
Blood and blood products	2.00	~100%
Injecting Drug users	2.39	0.5%
Others (not specified)	6.01	

Transmission by sexual intercourse is increased in the presence of other sexually transmitted diseases leading to ulcerative or inflammatory lesions in the genitalia. HIV infected mothers transmit the disease to their babies. Efficiency of transmission depends upon the viral load and clinical stage of the mother, the nature of delivery and time spent in labor. It can vary from 14 to 40%. The risk of transmission by accidental needle pricks in hospitals is around 0.3%.

Definition and Diagnosis

HIV infection is a laboratory diagnosis and is made by demonstration of

- HIV antibodies by ELISA or solid state card/spot tests
- Circulating antigens (p24) or
- The viral RNA itself by PCR –qualitative and quantitative- in peripheral blood.

Since false positive tests are not uncommon, it is advisable to repeat the tests using different types of ELISAs or different antigens before labelling an asymptomatic person as positive. If clinical symptoms have manifested two positive tests are considered enough.

Fallacies of the tests:

- The test become positive only after the ‘window’ period i.e. 4-6 weeks or more after infection, by which time only the antibodies appear.
- In the late stage when antibodies are too low, the tests may be only weakly positive or even negative.

Note: Testing for HIV should be done after counselling the patient and getting his permission.

AIDS is defined as the presence of one of the AIDS defining conditions or a decline of CD4 cells to less than 200 per cmm in an HIV infected person.

Clinical Features

The spectrum of diseases caused by HIV is quite wide. The clinical patterns are grouped into four stages.

- Acute Retroviral syndrome
- Asymptomatic stage
- Early symptomatic stage
- Advanced immunodeficiency

AIDS Indicator Conditions

- Candidiasis, of esophagus, trachea, bronchi or lungs
- Cervical cancer, invasive*
- Coccidioidomycosis, extrapulmonary*
- Cryptococcosis, extrapulmonary
- Cryptosporidiosis with diarrhea longer than 1 month
- Cytomegalovirus of any organ other than liver, spleen, or lymph nodes
- Herpes simplex with mucocutaneous ulcer for more than 1 month duration or bronchitis, pneumonitis, esophagitis
- Histoplasmosis, extrapulmonary*
- HIV-associated dementia: disabling cognitive and/or motor dysfunction interfering with activities of daily living*
- HIV-associated wasting: involuntary weight loss >10% of baseline plus chronic diarrhea (2 loose stools/day 30 days) or chronic weakness and documented enigmatic fever 30 days*
- Isosporiasis with diarrhea greater than 1 month*
- Kaposi's sarcoma in patient under 60 years (or over 60 years*)
- Lymphoma of brain in patient under 60 years (or over 60 years*)
- Lymphoma, non-Hodgkin's of B-cell or unknown immunologic phenotype and histology showing small, noncleaved lymphoma or immunoblastic sarcoma
- Mycobacterium avium complex or *M. kansasii* disseminated tuberculosis*
- Nocardiosis*
- Pneumocystis carinii* pneumonia
- Pneumonia, recurrent-bacterial (2 episodes in 12 months)*
- Progressive multifocal leukoencephalopathy
- Salmonella septicemia* (non-typhoid), recurrent*
- Strongyloidiasis, extraintestinal
- Toxoplasmosis of internal organs

* Requires positive HIV serology

Note: Criteria of Center for Disease Control (CDC) Atlanta

Fig. 48.3: AIDS persistent lymphadenopathy neck

Fig. 48.4: AIDS oral candidiasis

Acute retroviral syndrome (also called Primary HIV infection or seroconversion illness) occurs 2-6 weeks after the entry of HIV into human body. The illness is associated with fever, papular eruptions, arthralgia, lymph node swelling and oral ulcers (Figs 48.3 and 48.4).

The CD4 count falls and viral load increases during this period. The symptomatic phase of acute HIV-1 infection lasts between 7 and 10 days, and rarely longer than 14 days. The severity and duration of symptoms have prognostic implications. Severe and prolonged symptoms are associated with more rapid disease progression, which may be unnoticed in the majority of cases (Fig. 48.5). The infected person recovers completely to an asymptomatic

Fig. 48.5: AIDS cachexia diarrhea

stage with the return of CD4 count to normal but becomes HIV antibody positive thereafter.

In the next few years many changes take place in the immune system even though the person is grossly asymptomatic. Immune mediated events like lymph node enlargement, thrombocytopenia, demyelinating disorders of central nervous system, occur with increasing frequency. Most of these are because of misdirected immunologic activity. The occurrence of persistent generalized lymphadenopathy (defined as enlargement of two or more extra inguinal lymph nodes of size 2-3 cm persisting for more than a month) is common at some time in this stage.

As the CD4 count drops to below 500 cells per cmm the person experiences reactivation of dormant organisms like tuberculosis (pulmonary and extra pulmonary), herpes zoster, disseminated herpes, molluscum contagiosum etc. Fungal infections of the genital tract, extensive non genital warts, exaggerated insect bite reactions on the exposed skin etc. are seen in this stage (Fig. 48.6).

Fig. 48.6: Severe herpes zoster

Pulmonary complications in patients with HIV infection		
Infections	Neoplasia	Others
<i>Pneumocystis jiroveci</i>	Kaposi's sarcoma	Lymphocytic interstitial pneumonia
Bacterial pneumonia		Non-specific interstitial pneumonia
<i>S. pneumoniae</i>	Non-Hodgkin's lymphoma	Pulmonary hypertension
<i>S. aureus</i>		COPD
<i>H. influenzae</i>	Hodgkin's lymphoma	Bronchial hyperreactivity
<i>B. catarrhalis</i>	Bronchial carcinoma	
<i>P. aeruginosa</i>		
<i>Rhodococcus equi</i>		
<i>Nocardia asteroides</i>		
Mycobacteria		
<i>M. tuberculosis</i>		
Atypical mycobacteria		
Other		
Cytomegalovirus		
Aspergillus spp.		
Cryptococcus		
neoformans		
<i>Histoplasma capsulatum</i>		
<i>Toxoplasma gondii</i>		

As the CD4 count drops below 200 cells per cmm, the opportunistic infections appear. This is also the time when neoplasms like high grade B cell lymphoma, Kaposi's sarcoma, cervical intra-epithelial neoplasia and primary CNS lymphoma appear. Many infections which remain localized in immunocompetent subjects tend to become disseminated (e.g. *M.tuberculosis*, *Toxoplasma gondii*, *Cytomegalovirus*, *Cryptococcus neoformans* and *Histoplasma capsulatum*).

Respiratory System in AIDS

Respiratory system gets involved in almost all patients at some stage.

The most important among these are *Pneumocystis carinii* *Pneumonia* (now re-named as *P. jiroveci*) and tuberculosis (Fig. 48.7).

***Pneumocystis Carinii* *Pneumonia* (PCP):** The organism is an unusual type of fungus. PCP gives rise to interstitial pneumonia with the classic triad of symptoms:- dry cough, without fever and gradual onset of dyspnea on exertion. The diagnosis may be delayed weeks or months. Diagnosis is clinched by a chest X-ray and, if possible, high resolution computed tomography (HRCT) of the lungs. The chest X-ray often shows relatively characteristic findings with a butterfly-shaped (perihilar) interstitial infiltrate. In the early stages, the focus is on the mid and lower fields (Fig. 48.7). Cystic changes may also occur. Indistinct, diffuse changes are more easily visible on HRCT than on chest X-ray. There is almost always partial respiratory insufficiency, which should be confirmed by arterial blood gas analysis. Lactate dehydrogenase (LDH) is often elevated. High levels of LDH reflect the severity

Fig. 48.7: X-ray chest pneumocystis pneumonia

of the PCP. Sputum specimens are generally not useful for identification of the organism. Bronchoalveolar lavage (BAL) aspirate is usually necessary. Methenamine silver staining and PCR demonstrate the fungus. The organism may be demonstrable for a few days more after starting treatment.

Treatment should be initiated immediately if there is clinical suspicion. In cases of mild PCP with arterial PO₂ > 70-80 mm Hg, ambulatory treatment can be attempted; oral medication is effective. Respiratory insufficiency is an indication for hospitalisation. **Therapy** with cotrimoxazole (2 DS tablet three times daily for adults) should be given for 21 days. Prednisolone 20-80 mg bid should always be co-administered initially for

5-10 days. In patients who cannot tolerate cotrimoxazole intravenous pentamidine is the drug of second choice. Induction therapy consists of 200-300 mg pentamidine in 500 ml 5 % glucose or normal saline, as IV trip. Half this dose is given from days 6 to 21.

Prevention Patients with CD4 T cell count less than 200 / μ l are at risk and should therefore receive prophylaxis, ideally with cotrimoxazole daily or three times weekly. Monthly inhalation of pentamidine is a well-tolerated alternative. PCP prophylaxis regimens can be discontinued safely when the CD4 T cell count rises above 200 /cmm and remain so for at least for three months.

Tuberculosis and HIV disease are closely linked. This is described in Chapter 49.

6

Cutaneous Manifestations

Cutaneous manifestations these are quite common in AIDS. A broad spectrum of cutaneous infections caused by viruses, bacteria, fungi, protozoa, and parasites as well as many unusual manifestations of common dermatoses is seen.

Acute primary HIV infection may lead to a transient, generalized, morbilliform eruption on the trunk and the arms. With the person developing immunosuppression, nonspecific skin changes occur. These include common disorders with atypical clinical features, including recurrent varicella zoster, numerous hyperkeratotic warts, treatment-resistant seborrheic dermatitis, and oral hairy leukoplakia.

Chronic *Herpes simplex virus* (HSV) and *Cytomegalovirus* (CMV) infections, mycobacterial infections and mucocutaneous candidiasis occur in late stages.

Kaposi's sarcoma (KS). This was the first malignancy detected to be associated with HIV infection. The worldwide prevalence of KS in patients with AIDS may approach 34%. Most of the patients are homosexual men. KS is due to proliferation of endothelial cells induced by *Human herpesvirus type 8*. KS begins as pink macules that become disseminated and palpable. Purplish or brown macules and plaques may become nodular. Mucosal involvement is common. The clinical progression of KS in patients infected with HIV is more aggressive than the other clinical types of KS (Fig. 48.8).

Other malignancies can also occur more commonly with HIV infection. AIDS-related B-cell non-Hodgkin's lymphomas may lead to skin nodules. Anal carcinoma and cervical intraepithelial neoplasia are papillomavirus-associated tumours. These tumours tend to be more progressive and aggressive. An increase in squamous cell carcinoma of the anal mucosa has been reported, especially in young homosexual men. Intraoral or multiple squamous cell carcinoma, Bowen disease, and metastatic basal cell carcinoma have occasionally been reported.

Fig. 48.8: Kaposi's sarcoma. Note (1) General appearance—pigmented lesions (2) Enlarged view $\times 100$

Malignant melanoma occurring in patients with HIV is more aggressive than in individuals without HIV. Children with AIDS have a higher risk of developing leiomyosarcoma, although the incidence is still low in this population.

Fungal infections occur extensively on the skin and mucous membranes. Recurrent and persistent mucocutaneous candidiasis is common. Recurrent vaginal candidiasis can occur in any stage of the disease. In adults, generalized dermatophytosis, or tinea capitis, which is typically caused by *Trichophyton rubrum* is common. Onychomycosis in HIV infected may continue for many years.

Deep fungal infections like cryptococcosis, histoplasmosis and coccidioidomycosis may disseminate to the skin, usually as hemorrhagic papules or nodules.

Other infections: *Mycobacterium tuberculosis*; *Mycobacterium avium-intracellulare* complex; and, rarely, *Mycobacterium kansasii* may present as acneiform papules and indurated crusted plaques. Impetigo and folliculitis may be recurrent and persistent in HIV disease, particularly in children. Disseminated furunculosis, gingivitis, gangrenous stomatitis, and abscess formation can occur. Bacillary angiomatosis, which is caused by *Bartonella henselae* and rarely by *Bartonella quintana*, usually manifests as red papules and nodules. Atypical or Norwegian scabies, which is characterized by widespread hyperkeratotic, scaly maculopapular eruptions or crusted plaques, can occur. Seborrheic dermatitis like eruptions are observed in 83% of patients with AIDS. Seborrheic dermatitis may be the initial cutaneous manifestation of HIV disease. The eruption, which is characterized by widespread inflammatory and hyperkeratotic lesions, may progress to erythroderma in some patients.

Pruritic papular eruption and eosinophilic folliculitis also presents with papular eruptions.

Nail and hair changes (graying and other pigmentary changes), photosensitive eruptions, and diffuse alopecia are noticed.

Among sexually transmitted diseases, chancroid, syphilis in homosexual men, and lymphogranuloma venereum, are more commonly associated with AIDS. Syphilis coexisting with HIV creates special problems. (refer Chapter 47).

Treatment: Almost all cutaneous manifestations in HIV can be managed by the same modalities as in seronegative persons.

Neurological Manifestations

1. **AIDS encephalopathy** Infection of the CNS by HIV leads to encephalopathy (HIVE) which is also known by terms such as *AIDS dementia complex*, *AIDS dementia*, and *HIV associated cognitive motor complex*. HIVE is a late manifestation when there is a profound immune suppression with CD4 counts below 200 per cmm. HIVE is a subcortical dementia, caused by leukoencephalopathy typically emerging over the course of weeks and months. Typical complaints are slowing of reasoning, forgetfulness, difficulties concentrating, lack of energy and drive, mild depressive symptoms and emotional blunting. Magnetic resonance imaging often shows patchy, diffuse, hyperintense and relatively symmetrical lesions in the white matter. These changes indicate leukoencephalopathy. HIV-associated myelopathy whose histopathological hallmarks are vacuoles, most prominent in the cervical and thoracic parts of the spinal cord, hence called *vacuolar myelopathy*.
2. **Progressive multifocal leukoencephalopathy (PML)** is a severe demyelinating disease of the central nervous system predisposed to by AIDS. It is caused by JC virus (JCV), which is a polyoma virus found worldwide. The main focus of disease is the white matter of the cerebral hemispheres, but the cerebellum and in some cases the grey matter may also be affected. The median interval between the onset of the first symptoms and death was between 3 and 6 months. Patients usually die of secondary complications after being bedridden for many weeks. In addition to cognitive disorders, which may range from mild impairment of concentration to dementia, focal neurological deficits are very typical of PML. Mono- and hemiparesis are observed most frequently, as well as defects of speech and vision. MRI usually shows asymmetrical high signal intensity lesions in T2-weighted imaging, hypointense in T1-weighted images. Usually they do not show gadolinium enhancement or mass effect. Non-involvement of the grey matter is characteristic. The lesions are almost always asymmetrical.
3. **Cerebral toxoplasmosis** almost always results from the reactivation of a latent infection with *Toxoplasma gondii*. Patients may present with seizure, headache or focal neurological deficits. Cerebral toxoplasmosis is extremely rare above a CD4 T cell count of 100/cmm. It should always be expected when the CD4 T cell counts fall below 100/cmm. A CT or MRI scan of the head should be performed promptly in all cases of focal neurological deficit. Ring enhancing lesions and solitary or multiple abscesses should suggest the infection. Up to 97 % of patients with cerebral toxoplasmosis have IgG antibodies, and therefore absence of these antibodies help to rule out toxoplasmosis. Treatment is described in page 389.
4. **Cryptococcal meningitis** is more common in advanced immunodeficiency when the CD4 count is less than 200 cells per cmm. *C. neoformans* is transmitted by droplet infection.
5. **Primary CNS lymphomas** are late complications of HIV infection, occurring in up to 10 % of AIDS patients. Almost all cases are EBV- associated. Neurological deficits occur depending on their location.
6. **Peripheral neuropathy** may complicate all stages of HIV infection. Acute inflammatory demyelinating polyneuropathy (AIDP) and Guillain-Barré syndrome (GBS) usually occur during seroconversion or during the latent stages of HIV infection. Chronic inflammatory demyelinating neuropathy, vasculitic neuropathy, distal symmetrical sensory polyneuropathy and drug induced neuropathies may occur are all reported.
7. **Reactivation of CMV infection:** When the CD4 count falls below 50/cmm reactivation of CMV infection can lead to retinitis. Any visual impairment occurring subacutely or acutely, such as blurred vision or floaters especially unilaterally should prompt immediate ophthalmological examination. Oral and/or intravitreal gancyclovir or valacyclovir will be useful if started early. Primary prophylaxis is not effective against CMV retinitis.

Cardiovascular System Involvement

Cardiovascular involvement is common in HIV-infected patients.

Pericardial diseases: Pericardial effusion, Pericarditis (viral, bacterial, fungal), neoplasms (Kaposi's sarcoma, lymphoma).

Myocardial involvement: HIV-associated dilated cardiomyopathy, acute or chronic myocarditis, Kaposi's sarcoma or lymphoma and adverse effects of antiretroviral drugs.

Endocardial involvement: Infective endocarditis—bacterial or fungal and nonbacterial thrombotic endocarditis.

Vascular diseases: Arteriosclerosis, vasculitis, perivascularitis, pulmonary artery hypertension.

Other Miscellaneous Infections

Oroesophageal candidiasis: Candidiasis takes the form of extensive and persistent superficial lesions over the oropharynx, the buccal mucosa, tonsillar ring, tongue and the oesophagus. Candida esophagitis usually occurs with oropharyngeal involvement, but in about one third of the cases there may not be oral lesions. Esophagitis presents with odynophagia and retrosternal pain. Fluconazole therapy rapidly clears the infection.

Atypical Mycobacterial Infections: *M. avium* complex infection supervenes when the CD4 cell count falls below 50/cmm. The symptoms of disseminated MAC infection are usually nonspecific. Fever, weight loss and diarrhea in a patient with CD4 count less than 100/cmm should always raise the possibility of atypical mycobacteriosis. Elevation of serum alkaline phosphatase is a strong evidence for the diagnosis of MAC infection. Similarly development of anemia with constitutional symptoms may be due to bone marrow involvement by MAC. Hepatosplenomegaly and lymphadenopathy may occur. Atypical mycobacteria grow more readily in blood culture compared to *M. tuberculosis*. MAC infection responds to treatment with a macrolide, clarithromycin or azithromycin with ethambutol and rifabutin given for a period of six months or more.

Cryptosporidiosis: Cryptosporidiosis, caused by *Cryptosporidium parvum* may occur as a complication in AIDS. It presents as severe diarrhea (refer chapter 65).

Penicilliosis: Most fungi belonging to the *Penicillium* species are not pathogenic. One exception is *Penicillium marneffei*, which seems to be a problem mainly for HIV patients in south east Asia including parts of Manipur state in India. The clinical symptoms consist of prolonged high fever, lymphadenopathy, hepatosplenomegaly, weight loss, malaise, cough and hemoptysis, diverse cutaneous and mucocutaneous lesions resembling molluscum and abnormal increase in liver enzymes. Amphotericin B and itraconazole are effective in control in the infection.

HBV and HCV infections: Co-infection of hepatitis B and/or C viruses with HIV occurs frequently, since they share the same modes of transmission. Parenteral drug users and recipients of blood products are particularly susceptible. Primary HBV infection leads to chronic hepatitis in 2-5 % of immunocompetent adults, whereas in HIV-infected patients the chance for the disease to become chronic is five times more. Viral replication of HBV is more active in AIDS patients. In general, patients with chronic hepatitis B should be screened for hepatocellular carcinoma (HCC) every 6 to 12 months.

The progress of hepatitis C is also more rapid, particularly in patients with CD4 counts below 100/cmm. The unfavorable course of hepatitis C in HIV infection can be improved by treatment of HIV infection by HAART. In addition, the development of liver failure can also be delayed. Hepatitis C infection can aggravate the potential hepatotoxicity of several drugs used in HAART regimens, especially nevirapone. Up to 10 % of patients have to discontinue HAART due to severe hepatotoxicity. The response to treatment of HCV infection is less satisfactory due to lower clearance rates and adverse side effects of drugs which prevent continuation of therapy. Results are better if HCV RNA is < 2 million copies/mL, HCV genotype is 2 or 3 and the age of the patient is < 50 years. Histologically low grade fibrosis of the liver, normal γ -glutamyl transferase and stable HIV infection are good prognostic factors. Treatment is given in chapter 55.

MANAGEMENT OF HIV INFECTION

General measures: HIV infection should be confirmed beyond doubt by appropriate investigations. The immunological status is assessed by CD4 estimation. Severity of infection can be assessed by estimating the viral load using PCR test or other methods. The co-existence of opportunistic infections should be confirmed by investigations. Regular repetition of CD4 T-cell count and RNA viral load helps to assess the progress of the disease.

The interventions in HIV disease can be grouped into three major headings.

- nonpharmacologic modifications,
- prophylaxis and treatment of opportunistic infections and
- antiretroviral therapy. Specific guidelines for all these aspects have been laid down by the Association of Physician of India

(API consensus guidelines for use of antiretroviral therapy in adults

(Ref: JAPI. 2006;54:57-74).

Antiretroviral therapy aims at bringing down the virus levels to undetectable levels, i.e. below 20 copies per mL with the presently available tests. This will ensure immune reconstitution with the return of CD4 counts above 200 per cmm. Symptom free survival is also prolonged. Different groups of drugs are used. These include reverse transcriptase inhibitors, (RTIs) protease inhibitors (PIs) and entry inhibitors. The RTIs belong to two groups, the nucleotide and nucleoside RTIs (NtRTIs and NRTIs) and nonnucleoside RTIs (NNRTIs). The reverse transcriptase inhibitors block the transcription of DNA from viral RNA, without which the genetic material cannot be incorporated into the human DNA. The Protease inhibitors block the protease enzyme, effectively preventing the formation and

TABLE 48.1

List of currently available antiretroviral drugs. Several new drugs are in the process of development

Nucleoside reverse transcriptase inhibitors (NRTIs)

Zidovudine (AZT, ZDV)
Didanosine (DDI)
Zalcitabine (DDC)
Stavudine (D4T)
Lamivudine (3TC)
Abacavir (ABC)
Emtricitabine

Non Nucleoside RTIs (NNRTI)

Nevirapine
Delavirdine
Efavirenz

Nucleotide (Nt RTI)

Tenofovir

Protease Inhibitors (PI)

Saquinavir
Ritonavir
Indinavir
Nelfinavir
Amprenavir
Lopinavir
Atazanavir
Fosamprenavir

Entry (Fusion) inhibitors

Enfuvirtide (T-20)

release of new virions. The newly added class of fusion inhibitors blocks the virus fusion with the CD4 and other receptors on the cell membrane, thus preventing the entry of the virus into a new cell (Table 48.1).

The principle of treatment is to use a combination of three or more synergistic drugs belonging to the different groups. Several protocols are under trial. The current protocols use two NRTI + one NNRTI or one PI. Three NRTI based regimes are also considered. Monotherapy should be avoided due to the risk of developing resistance by HIV. The importance of adherence with regard to dosage and relationship with food must be stress in a therapeutic counselling setting. More than 95% adherence to the schedule is needed for the desirable result. There is no consensus at present about the duration of therapy. Therefore, once started, the drugs have to be continued for long except when the person living with HIV/AIDS (PLWHA) develops drug intolerance, adverse effects or failure.

Indications for Starting Therapy

The major indications to start therapy are (i) symptomatic stage of AIDS (ii) CD4 count less than 200 cells per cmm (iii) asymptomatic person with a CD4 count of 200-350 with a viral load of more than 1,00,000 copies per mL. In other cases, treatment must be started after considering

the long life span of the PLWHA and individual considerations.

Out come of therapy The desired outcome of therapy will be a rise in CD4 count in 6-8 weeks and a fall in viral load to 'undetectable' range in 3-6 months. Following initiation of therapy, viral load should fall below 5,000 copies/mL within one month. Fall in viral load is measured in logs and one log reduction (ten times fall) is to be expected in 6-8 weeks. At present it is possible to arrest the multiplication of HIV and reduce the chances for opportunistic infections by judicious drug combinations. This highly active retroviral therapy (HAART) is the goal initiated by the WHO and accepted by several countries.

Adverse side effects All ARV drugs are associated with adverse side effects.

Drug	Major side effects
Zidovudine	Bone marrow suppression
Nevirapine	Skin rash
Protease inhibitors	Mitochondrial toxicity and lipodystrophy
Stavudine	Lactic acidosis and lipodystrophy

Severe toxic effects warrant change of drug schedule. Failure of response can also happen when the virus acquires resistance. This is due to the changes in the nucleoside sequence of the new viruses occurring during reverse transcription and other stages of viral multiplication. Development of resistance can be identified by two types of tests. (a) Genotypic resistance: This is detected by testing for the occurrence of alterations in the nucleotide chains. This gives an indirect clue to resistance of the virus. (b) Phenotypic resistance: Studies look for the survival patterns of growth of the virus in a cell culture medium in the presence of ARV drugs.

With the introduction of HAART death rates have come down and the quality of life of AIDS patients has improved considerably. Review of the therapy in developing and developed countries has shown very encouraging results.

Pregnancy complicating AIDS: The foetus may be infected by the virus. Infection rate is higher in mothers who have HIV RNA levels exceeding 1000 copies /mL. Viral loads are higher if the baby is infected early in pregnancy. Most of the antiretroviral drugs cross the placenta if administered during pregnancy. Treatment reduces the transmission rate to $\pm 2\%$ if started early. HIV infection during pregnancy does not produce congenital birth defects in the baby.

Prevention

AIDS, though a dreaded disease, is preventable too. Sex with a regular uninfected partner is the safest way to

prevent HIV infection through sex. However condoms, if properly used offer almost complete protection against acquiring infection during natural sexual intercourse. Strict screening of blood products for transfusion reduces the risk considerably. Transmission in parenteral drug abuse groups is tackled by supply of sterile syringes by governmental and other agencies. Other measures to reduce illicit use of habituating drugs include counselling, group therapy and legal measures to prevent drug trafficking. Transmission in hospital settings can be reduced by proper practice of universal (standard) precautions.

Post exposure prophylaxis protocols in health care personnel are mandatory. These consist of the administration of basic antiretroviral regimen as early as possible after exposure to the risk, ideally within 2 hours. The standard regimen is to give zidovudine 300 mg and lamivudine 150 mg twice daily for a period of four weeks. In the expanded regimen a protease inhibitor is also added.

Prevention of parent to child transmission (PPTCT) protocols (e.g. ACTG 076, Thai Harward, HIVNET012, PeTRa) are available, which includes the use of Zidovudine and nevirapine in the expectant mother, during labour and to the newborn child after delivery. Administration of single drugs to the mother for preventing transmission to the child should be avoided due to the risk of developing drug resistance in the child later. Caesarean delivery without trial of labour reduces the risk of transmission to the baby from 10.5 to 1.8%. Women with HIV RNA loads above 1000 copies / mL should be offer Caesarean delivery.

Vaccines: Several attempts to produce anti-HIV vaccines for prevention and therapy are taking place under the International AIDS Vaccine Initiative (IAVI). National

AIDS Research Institute (NARI) Pune also has developed a vaccine which is undergoing field trials. The need for proper health education and awareness are promoted as the major preventive strategy.

Global measures: Provision of regular supply of anti-retroviral drug to patients in developing countries has been taken up by the WHO aided agencies and several philanthropic non governmental funding sources. At present the government of India and State Governments have made primary anti-HIV drugs available free of cost in major government hospitals. Several international governmental and non governmental organizations have come forward to help needy nations with funds, manpower and drugs. Several Indian drug manufacturers have contributed to this global venture.

Male circumcision has been found to reduce the rate of acquisition of HIV infection by several studies in African countries.

Ref: Newell Marie-Looise The Lancet 2007;369:617-9.

Points to remember

1. India has the potential to become one of the most heavily affected countries by AIDS if the medical fraternity government and non-governmental organizations take steps to arrest the spread of infection
2. AIDS involves directly or indirectly almost all systems in the body
3. Morbidity caused by AIDS and the heavy cost of treatment and rehabilitation of bereaved families cause heavy financial burden to the country
4. Several drugs have been introduced to arrest progress of the disease, if started early.
5. Primary treatment for AIDS patients is available in several centers in the country free of charge.
6. This devastating illness is preventable by adopting safe sex habits, especially meticulous use of the condom.

Tuberculosis

K.V. Krishna Das

GENERAL CONSIDERATIONS

Tuberculosis is one of the most widely prevalent chronic infectious diseases affecting mankind. The global incidence of tuberculosis (TB) is gradually coming down at the rate of 0.5 to 1% per annum but in parts of Russia and sub Saharan Africa this trend is not seen. Though the developed countries have brought down its prevalence and incidence, in developing countries it is still a major cause of ill-health and mortality. Tuberculosis is caused by *Mycobacterium tuberculosis* which may involve all organs in the body, but lungs are the most common sites. Robert

Koch discovered the organism in 1882. Man is affected most commonly by the human strain and less commonly by the bovine strain. With the availability of pasteurized milk and improved animal husbandry practices, the frequency of the bovine tubercle bacillus infection has fallen considerably. Phage typing helps to sub-classify the strains further. *Mycobacterium tuberculosis* can survive in dark moist environment for very long periods (up to years). In sputum it remains viable for 20-30 hours. In droplet nuclei and dust the viability is much longer.

Tubercle bacilli are non-motile, non-spore-forming non-capsulate straight or curved rods about $3 \times 0.3 \mu\text{m}$ in size. They grow only in special enriched media. They are obligate aerobes. Ultraviolet light and pasteurization of milk destroy the bacillus. Genotyping of *M. tuberculosis* has been completed and the fingerprint is available. Genetic studies employing *restriction fragments length polymorphism* (RFLP) help to make accurate epidemiological observations. Genetic studies also help to distinguish relapse from re-infection. In many countries shelters, workplaces, healthcare facilities and bars are common sites for transmitting the disease. Infection in teachers spreads readily to the children at school.

Epidemiology

All over the world, tuberculosis was in the forefront as a major cause of morbidity and mortality before the middle of this century. The present estimate of the World Health Organisation (WHO) is that there are about 15-20 million infectious cases in the world at any one time and that three million deaths occur annually. The three major killers in the developing world are HIV disease, tuberculosis and malaria. In India TB still remains as a major cause of death from a curable infection. In the study launched by Indian Council of Medical Research (ICMR) in 1955-58 the prevalence of sputum positive pulmonary tuberculosis was 4/1000. Such nationwide surveys have not been performed subsequently. Only limited data is available.

Tuberculin surveys are employed to detect infection in the community. A limited study conducted in

Trivandrum (South India) in 1980 showed that by the age of 14 years 7.4% of school children was tuberculin positive. The WHO has suggested that the tuberculin positivity rates in children below 14 years has to be brought down below 1% to achieve control of this disease. It is evident that India has still a long way to go in achieving this goal. Despite the vigorous measures to control the disease undertaken by the *National Tuberculosis Control Program*, the disease tends to persist because of the poor socioeconomic and educational levels of the population, reluctance to accept treatment and non-compliance with the prolonged drug regimen.

Immunodeficiency states—both iatrogenic and AIDS led to a resurgence of the disease in several parts of India. Vitamin D deficiency impairs the ability of monocytes to inhibit growth of *M. tuberculosis*. HIV predisposes to tuberculosis infection because of the reduction of Th1 lymphocytes which produce gamma interferon. Tuberculosis accelerates the progression of AIDS and thereby hasten death. Both pulmonary and extrapulmonary lesions are more frequent.

Susceptibility to Tuberculosis Conferred by Other Disease State

The lifetime risk of developing overt tuberculosis in an infected child is 10%. Among such children 50% develop TB within 2 years of infection. There is a genetic predisposition to develop TB in some individuals.

Human immunodeficiency virus (HIV) infection increases the susceptibility to get primary infection as well as reactivation of acquired TB lesion by 10-folds. In HIV negative individuals who develop TB, over 80% manifest as pulmonary tuberculosis (PT). In HIV positive individuals the occurrence of non-pulmonary manifestations is relatively higher. In India co-infection of HIV and TB is seen in 10-11% of TB cases. Co-infection by the two diseases decreases the cure rate with treatment and also increases mortality. Susceptibility to develop TB is increased 2.4 times in patients with chronic renal failure. In persons receiving corticosteroid therapy for immunosuppression the risk is twice the normal. Tuberculosis remains predominantly a disease of the poor. 22 countries where the per-capita income is < \$ 760 contain more than 80% of the total global burden of TB patients.

PATHOGENESIS AND PATHOLOGY

The portal of entry of the organisms is inhalation, ingestion, or inoculation. Inhalation is the most common route. Droplets containing MTB are released when a PT patient coughs. Larger droplets fall to the ground. Medium sized droplets are trapped in the mucosa of the upper respiratory tract from where they are cleared without causing infection. Tiny droplets < 25 µm in diameter

evaporate immediately leaving particulate organisms to float in the air. These particles escape the trapping mechanisms and reach the lungs, where even a single bacterium can initiate infection. Given adequate exposure, tuberculosis is highly contagious. 45-60% of children of parents with sputum positive PT gets the infection. One open case may infect at least 20 persons of whom 10%, i.e. 2 persons develop overt disease—one will be infectious and the other non-infectious. Smoking may increase the incidence of TB.

Ref: Vendhan, Ajalekshmy, et al. The Lancet 2003;362: 507-15.

The primary site of infection depends on the mode of entry. It may be in the lungs, tonsils, mucous membranes, intestines or skin. The development of hypersensitivity plays a major role in determining further events. The pathological process occurring in an individual who has not been sensitized to the organisms, i.e. occurring for the first time, is known as *primary tuberculosis*. Subsequent infection occurring in the sensitized individual who possesses immunity gives rise to a different course of events. This is known as *post-primary tuberculosis*. T-lymphocytes play a major role in conferring immunity against *M. tuberculosis*. Tuberculosis bacillus circulates in blood and the number of circulating bacteria may reach high counts in immunocompromised hosts. They can be detected by PCR.

The host's reaction to the bacilli which enter is initially exudative, and later proliferative. Initially the exudate is composed mainly of neutrophils. Later, lymphokine activated macrophages accumulate and these engulf the organisms. These phagocytes are derived from the fixed tissue macrophages, the alveolar macrophages of the lungs, and the monocytes from blood. Macrophages with engulfed organisms get transformed into epithelioid cells. Multi-nucleated foreign body type of giant cells (*Langhan's giant cells*) are formed by the fusion of epithelioid cells. These are surrounded by lymphocytes and fibroblasts. At the centre of the lesion caseation necrosis occurs. The secret of the organism's success is its ability to evade the immune system by penetrating into macrophages without being destroyed by them. Activated macrophages prevent replication of the tubercle bacillus, but may not kill them altogether. The pathological hallmark of tuberculosis is the tubercle which consists of an area of central caseation, around which there is infiltration by epithelioid cells, giant cells, round cells and peripherally by fibroblasts. Several such microscopic tubercles form the macroscopic tubercles which are seen in affected tissues.

Granuloma formation is usually adequate to limit the infection. The lesion becomes quiescent and surrounding fibroblasts produce scar tissue which may become calcified. Some bacilli remain in this tissue as "*persisters*" which, when reactivated produce postprimary disease.

In a minority of cases the infection progresses without being localized and gives rise to serious manifestations of the primary infection such as progressive primary lesion in infants, pleurisy, renal lesion, bone tuberculosis, meningitis and so on. If a primary focus ruptures into a blood vessel, miliary tuberculosis develops, with affection of all organs, particularly the meninges and brain.

Immunity against tuberculosis: Organisms possess non-specific and specific immunity against tuberculosis. Nonspecific immunity is present in people living in areas of high prevalence. Depression of the general immune mechanism in diseases such as diabetes, malnutrition, immunosuppressed states, and therapy with corticosteroids predispose fresh infection by *M. tuberculosis* and reactivation of quiescent lesions.

Specific immunity in tuberculosis is T-lymphocyte mediated. Though humoral antibodies are demonstrable, they do not play any protective role. *M. tuberculosis* can survive and replicate within macrophages thereby evading the immune defences of the host. The infection also suppresses the reaction of macrophages to activating cytokines. One attack of tuberculosis does not confer solid immunity so that both reactivation of a quiescent focus and reinfection are possible. Abdominal tuberculosis occurring in HIV +ve subjects is characterized by visceral involvement with necrosis, best made out on CT scans. Abdominal tuberculosis in HIV –ve subjects leads to omental thickening, ascites and peritonitis more often. Though the T-lymphocyte function is demonstrable as tuberculin sensitivity (Mantoux testing), sensitivity and immunity are not identical. Tuberculin sensitive individuals possess a degree of resistance to further infection by tuberculosis, but this immunity is not absolute.

Pulmonary Tuberculosis

In man, lungs are the most frequently affected organs. All those who develop the disease for the first time manifest primary tuberculosis irrespective of their age. The pathological lesions in primary tuberculosis show prominent lymph nodular enlargement (usually hilar) with only minimal parenchymal lesions. Post-primary tuberculosis presents mainly as parenchymal disease with only minimal lymph node enlargement.

In primary tuberculosis the bacilli multiply rapidly in the lesions and dissemination by lymphatics and bloodstream is frequent. Extensive tissue necrosis is rare.

PRIMARY PULMONARY TUBERCULOSIS

Lung is the commonest site for primary tuberculosis. Children are affected most, though no age is immune. The initial lesion is a subpleural tubercle located in the lower part of the upper lobe, upper part of the lower lobe, or middle lobe. This parenchymal lesion (*Ghon's lesion*)

Fig. 49.1: X-ray chest tuberculosis—middle lobe consolidation right

with its enlarged regional lymph nodes and interconnecting lymphangitis is known as the primary complex (*Ghon's complex*). More than 80 per cent of cases of primary tuberculosis do not produce systemic disturbances and the lesions heal spontaneously. These remain undetected. The tuberculin test becomes positive within 4 to 6 weeks of infection. Once it becomes positive, it usually remains so for life.

In 10-15% of children the primary lesion goes on to progressive disease. This may be due to poor general resistance, immunosuppression, high infective dose, or virulent strains of bacilli. AIDS, measles and whooping cough lower the resistance and favour progression. The hilar lymph nodes enlarge progressively and undergo caseation. Compression of the neighbouring bronchi, especially of the middle lobe, leads to collapse-consolidation and bronchiectatic changes. This may present later as the 'middle lobe syndrome' (Fig. 49.1). When a caseated node ruptures into a bronchus, spread occurs to other parts of the lungs and tuberculous bronchopneumonia develops. Erosion of a vessel and discharge of the caseous material into the bloodstream lead to wide dissemination and the development of miliary tuberculosis. Rarely the pulmonary lesion may increase in size to produce cavitation. It may also spread to the other regions of the lung parenchyma. Spread to the pleura results in pleurisy with effusion.

CLINICAL FEATURES

Progressive primary tuberculosis is invariably symptomatic. Onset may be acute or insidious. Fever, loss of **277**

appetite, loss of weight and cough are early symptoms. Lethargy, vague ill-health, failure to thrive and delay in the milestones may be the presenting features in children. At this stage the disease can be diagnosed only if the clinical suspicion is strong. Allergic manifestations like **phlyctenular conjunctivitis** or **erythema nodosum** may herald primary tuberculosis in some cases. Erythema nodosum manifests as reddish, indurated, painful, swellings usually seen in front of the tibia. These persist for varying periods. Occasionally the disease predisposes to recurrent respiratory infection. Acute pleural effusion may develop in some. Other presentations in children include tuberculous pneumonia, hemoptysis, or *asthma*. Miliary tuberculosis may manifest as meningitis in many.

Physical examination may not give any positive finding in many patients and the diagnosis has to be based on investigations. In some, the signs of pulmonary consolidation, collapse, or pleural effusion may be present. Tuberculin skin test is positive in the vast majority. Blood examination shows raised ESR and lymphocytosis.

If the parenchymal lesion is small, expectoration may not be present. Chest X-ray reveals hilar lymphadenopathy and on careful examination the pulmonary lesion may be detectable. The diagnosis of primary tuberculosis is based on the history of tuberculous contact, clinical symptomatology, X-ray findings, and recent tuberculin positivity. Bacteriological confirmation is usually difficult to get.

POST-PRIMARY TUBERCULOSIS

Pathogenesis and Pathology

Post-primary tuberculosis occurs in one of four ways:

- 1. Direct progression of primary lesion,
- 2. Reactivation of a quiescent primary focus,
- 3. Hematogenous infection of lung from lymph nodes, tonsils, etc., and
- 4. Re-infection or superinfection.

Post-primary pulmonary tuberculosis is characterized by tendency for early cavitation, limitation of the disease process and healing. The upper lobes are more commonly affected, unlike as in primary tuberculosis. Depending upon the resistance two pathological forms are seen.

- 1. Slowly progressive nodular form in individuals who possess resistance, and
- 2. Fibrocaceous form with tendency for cavitation if the resistance is low.

In the nodular form the sputum shows only less number of tubercle bacilli, whereas the reverse is true in the latter.

Mainly the lung parenchyma shows lesions, the lymph nodular changes are minimal. The initial lesion is an exudative pneumonia. Subsequently tubercles form. They coalesce to give rise to large macroscopic lesions. The caseous material is discharged into a bronchus and

coughed out, leaving behind a cavity. The wall of the cavity teems with the bacilli and its surroundings show many tubercles. Blood vessels in the cavity become unsupported. Many of them are occluded by thrombosis, but those that remain patent become aneurysmal (*Rassmussen's aneurysms*). They may rupture and give rise to massive haemoptysis. Healing, occurs with replacement fibrosis.

Clinical Features

Adolescents and young adults are more frequently affected, though no age group is spared. The disease manifests insidiously with respiratory symptoms such as mild and persistent cough, low-grade evening fever, anorexia, loss of weight, and general weakness. The fever is moderate and comes on in the evening to subside with sweating by midnight. In a few cases the onset may be acute with high fever, cough and hemoptysis, and the lesion may resemble lobar pneumonia. The nodular type is generally silent and in many cases it is detected radiologically. Sputum is mucoid or mucopurulent, initially scanty, later it is more copious. Mild streaky hemoptysis may occur initially, but later, profuse hemoptysis occurs due to erosion of blood vessels. The larynx is affected and laryngitis results in hoarseness of voice. In some cases pleural effusion, empyema or pneumothorax may be the initial presentation.

Physical examination of the chest may reveal signs of consolidation, cavitation, collapse, fibrosis, pleural effusion, or pneumothorax. As the condition proceeds, the patient becomes emaciated. Cough with expectoration is pronounced and extreme cachexia develops (Phthisis). If left untreated, death occurs due to extensive disease, cachexia, intercurrent infection, or any of the complications. The classic picture of well-established lesion is rarely only encountered at present. Due to the free availability of X-ray chest and strong clinical suspicion, cases are diagnosed at earlier stages.

COMPLICATIONS

Several complications may develop during different stages of the disease. These may occur in the early part of the disease or much later. Some may be delayed by several years.

COMPLICATIONS OF PULMONARY TUBERCULOSIS

These are listed below

Early: Occurring within months

- 1. Mild hemoptysis
- 2. Pneumothorax
- 3. Pleural effusion
- 4. Poncet's syndrome

Intermediate: Occurring within several months or a few years

1. Massive hemoptysis
2. Secondary infection of cavities
3. Pneumothorax, pleural effusion, empyema
4. Progressive fibrosis with dyspnea
5. Spread to other organs such as larynx, pericardium and others
6. Non-healing of lesion due to drug resistance of organisms.

Late: Occurring after several years.

1. Pulmonary fibrosis with compensatory emphysema, cor pulmonale, pleuropulmonary fibrosis.
2. Bronchiectasis
3. Persistence of open cavities without healing
4. Aspergilloma i.e., growth of *Aspergillus fumigatus* in the cavities in the form of a fungus ball
5. Coexistence of apical tuberculosis with carcinoma
6. Secondary amyloidosis.

Diagnosis

Tuberculosis should be suspected in all patients suffering from chronic respiratory disease, especially if associated with night sweats, fever, emaciation, and hemoptysis. Other conditions which should be differentiated are bronchiectasis, lung abscess, cystic disease of the lung, chronic pneumonias, malignancy and tropical eosinophilia. Cough persisting for more than two weeks without other obvious causes should alert the physician to investigate for pulmonary tuberculosis.

Differential Diagnosis

In bronchiectasis, the lesions are often bilateral, involving usually the lower lobes. The condition is more chronic extending over several years. Finger clubbing and history of postural cough with copious sputum may be present. In the majority of cases of pulmonary tuberculosis finger clubbing does not occur, except in the bronchiectatic form and in the chronic fibrotic stage. Tuberculous bronchiectasis is usually confined to the affected part, unlike as in primary bronchiectasis.

Lung abscess usually affects the lower lobes. Postural coughing is prominent, symptoms are more pronounced, and finger clubbing occurs early. History of pneumonia or aspiration into the respiratory tract may be elicitable in some cases.

Congenital cystic disease manifests in adolescence or adulthood. Lesions are more widespread, clubbing is only minimal, and radiographs show thin walled multiple cysts, more in the lower zones.

Some types of pneumonias may become recurrent or chronic, especially if there are underlying conditions such as bronchial obstruction or malignancy.

Carcinoma of the lung has to be considered when lesions are unilateral. Carcinoma is more common in heavy

smokers. It affects persons in the fourth and fifth decades. Males are affected more. The lesion is more around the hilum. Signs of consolidation, collapse, pressure effects like Horner's syndrome or diaphragmatic paralysis should suggest this possibility. Clubbing of fingers occurs early and supraclavicular or pretracheal lymph nodes are palpably enlarged in most cases.

Tropical eosinophilia may present with cough, fever, and loss of weight, especially in adolescents and young adults. Physical examination may reveal signs of bronchospasm and scattered rales. There may not be evidence of any localized lesions. Blood eosinophil count is high (often above 3000/cmm). The sputum shows numerous eosinophils.

Tuberculosis should be considered as a probable underlying cause in all cases presenting with asthma of recent onset, prolonged fever, and pneumonias which tend to persist even after administering a standard therapy. Onset of tuberculosis in otherwise apparently healthy persons should raise the possibility of diabetes mellitus or AIDS as possible predisposing factors.

Poncet's syndrome is a hypersensitivity reaction to the infection, manifesting as arthritis, which may resemble rheumatoid or other forms of arthritis.

Investigations

Sputum examination: The most important diagnostic investigations are the demonstration of acid-fast organisms in sputum by Ziehl-Neelsen method and radiology. Positivity of smears and cultures depends on the bacterial count in the sputum. While examining a sputum smear, at least 100 fields should be seen for 10 minutes before declaring it as negative. At least 3 bacilli should be seen before the smear is declared positive (Fig. 49.2). Concentration methods are available using 24-hr collection of sputum to detect AFB when direct smears are negative. Fluorescence microscopy is being employed to identify tubercle bacilli. It is more rapid and this method has the advantage of better coverage of the smear. Modern techniques using polymerase chain reaction (PCR) have

Fig. 49.2: Sputum Zeihl-Neelsen stain

been found to be very useful in making early specific diagnosis.

Further confirmation is obtained by identification of *M. tuberculosis* in sputum culture. In high prevalence areas, it may not be practicable to do culture in all cases. For all practical purposes, two consecutive morning sputum examinations can be accepted as confirmatory of the diagnosis. When the sputum is difficult to get, as in children and psychiatric patients, laryngeal swab or material collected by gastric aspiration may be used. Laryngeal swab is 25% and gastric aspirate about 50% as efficient as sputum examination in identifying the organism. Sputum may be collected by transtracheal aspiration in comatose patients. Bronchoscopic aspiration is resorted to in exceptional cases. In high prevalence areas, sputum culture and animal inoculation studies should be reserved for cases with negative sputum smears, but with suggestive radiological features and in whom drug resistance is suspected.

Radiology

In day to day practice, radiology is the easiest and most readily available investigation to visualize the pulmonary lesion. Early cases show infiltration in the upper zones (Fig. 49.3). Later the lesions coalesce to produce consolidation. When cavitation occurs thin-walled cavities are seen, often multiple, with intervening fibrosis. As the lesion becomes fibrotic, the opacities become dense, with reduction in pulmonary volume and shifting of the trachea and mediastinum towards the side of lesion. Such lesions occupying the upper zones, especially if bilateral, should raise the strong suspicion of tuberculosis and the diagnosis has to be confirmed or excluded by appropriate tests. In

Fig. 49.3: X-ray chest tuberculosis. Infiltration bilateral

untreated cases sputum examination is invariably positive for acid-fast bacilli. A common cause for sputum-negativity in India is partial treatment with anti-tuberculosis drugs.

With treatment, infiltration, consolidation and even early cavitation may heal completely leading to full resolution of the radiological abnormality. Once cavitation is chronic and fibrosis has set in, the radiological abnormalities do not clear up with further treatment even though the disease becomes arrested. In such cases, it is essential to distinguish residual radiological abnormalities from active disease.

Blood examination shows mild lymphocytosis and raised ESR in most cases. Since these findings are non-specific, they have only a limited diagnostic value. Progressive fall of ESR and clearance of radiological abnormalities are fairly reliable and simple practical methods to follow up the progress of the disease with treatment.

Presence of organisms in blood can be detected by PCR. PCR is a highly sensitive and specific test taking only a few hours for diagnosis. Sputum, blood, CSF, pleural fluid and other tissues may be subjected to PCR. Different kits containing appropriate probes are available. DNA detected by PCR may remain so for long periods even after the infection is cured or suppressed.

Amplified mycobacterium tuberculosis detection (AMTD) test uses the principles of transcription mediated amplification of ribosomal RNA of MTB. The detection of t-RNA indicates the presence of actively multiplying MTB. RNA is a much more short-lived molecule compared to DNA which persists for long periods. Specimens such as sputum, aspirated fluid, CSF, bone marrow and FNAC tissue can be used for the test. It takes 24 hours to get the result and costs approximately Rs. 1000/-.

Enzyme linked immunospot assays (ELLISPOT technique) have been developed and different commercial kits are available. These are based on detection of interferon- γ produced by T-cells in response to antigens specific to *M. tuberculosis* (T-SPOT.TB, QuantiFERON-TB Gold) which have been tested in children and approved by the FDA. It has sensitivity of 83% to detect TB in children whereas Mantoux test has sensitivity of only 63%.

Moreover, unlike Mantoux test which may be influenced by immunosuppressed conditions, the ELLISPOT test is unaffected. Non-TB mycobacteria and BCG vaccination does not interfere with the ELLISPOT test.

(Ref. Susan Liebeschuetz et al The Lancet 2004. 364: 2196-2203).

Proteomic finger printing methods are being developed to detect tuberculosis early, by identifying serum markers.

Tuberculin skin test (Mantoux Test): This test is usually done by injecting one unit of purified protein derivative (PPD) in the volar surface of the forearm intradermally.

Fig. 49.4: Forearm showing accelerated reaction to Mantoux test in a male having active tuberculous lymphadenopathy

The result is read after 48 h and the area of induration is recorded. In a positive test, the diameter of the induration exceeds 12 mm. Negative results do not always rule out tuberculous infection since conditions like malnutrition, immunosuppression therapy and Hodgkin's disease, suppress the test. Patients suffering from active tuberculosis show an accelerated Arthus reaction with necrosis. Though the occurrence of '*accelerated reaction*' is not a wholly reliable parameter, invariably it points to active tuberculosis.

The diagnostic value of tuberculin test is in those individuals who are '*recent converters*'. This should suggest the occurrence of infection by mycobacteria. In infants below the age of one year, tuberculin positivity should be taken as recent infection and therefore it is an indication for starting anti-tuberculosis treatment.

Tuberculin testing is widely employed to assess the prevalence of the disease in the community. Prevalence of tuberculin positivity in the young subjects is related to the number of infective cases. This is of help in planning tuberculosis control programs. BCG vaccination if successful, gives rise to tuberculin-positivity.

Other methods to test tuberculin-sensitivity include Heaf multiple puncture test and tuberculin Tine test. Infection by non-tuberculosis mycobacteria may give rise to positive tuberculin test. Differential tuberculin testing using PPD prepared from these mycobacteria helps to identify such infections.

TREATMENT

The goals of treatment are

1. To ensure cure without relapse
2. To prevent death
3. To prevent spread and
4. Prevent the development of resistance. Since MTB can remain dormant for long periods, all anti-tuberculosis treatment programmes have two phases.

- a. An active phase intended to kill actively growing and a proportion of the dormant organisms and
- b. The second phase intended to eliminate the persisting bacilli.

Modern therapy is mainly dependent on the powerful antituberculosis drugs currently available. With judicious combinations, virtually all lesions can be rendered bacteria-free and allowed to heal. Early lesions heal without any residual damage, whereas late lesions heal with fibrosis and calcification in some cases. It is important to institute treatment without delay after establishing the diagnosis. The drugs are always given in combination to avoid the development of resistance and for synergistic effect. A strict schedule should be instituted. Patient compliance is absolutely necessary to ensure cure and prevent the development of resistance. Lack of motivation of the patient and the long course of treatment are the most important factors which account for many drop-outs after receiving incomplete therapy. Since most of the cases can be treated at home with excellent results, domiciliary treatment is preferable. Moreover, it is now well understood that once the case is notified, the risk of spread to contacts is only slight. Simple precautions like isolation at home, use of separate utensils and disinfection of the sputum are advised to the patient and his family members. Since there is likelihood of other cases occurring in the family and other contacts, detection of all fresh cases should be followed up with a survey of the family members and other immediate contacts. Hospitalization is required for cases with high fever and toxemia, hemoptysis, pleural effusion, pneumothorax, extreme cachexia and coexistence of other diseases like uncontrolled diabetes mellitus. Rendering the patient sputum-negative is the most effective method to control spread to others.

Drug schedules: Adequate chemotherapy administered without interruption for the optimal duration is the cornerstone of success. The available drugs are classified into standard or first line drugs and reserve or second line drugs based on their efficacy, cost, availability and toxicity (Table 49.1).

Short Course Chemotherapy

At present short course chemotherapy using INH, rifampicin, ethambutol and pyrazinamide is the preferred method, on account of its efficacy, ease for supervision and better patient compliance. Though the drugs are expensive, the Government supplies the drugs free of cost from the TB control centres. Short course chemotherapy extending over 6-9 months is adequate to cure 95-98% of all forms of tuberculosis, and in all age groups. Alternate drugs or longer period of treatment are indicated when drug resistance or intolerance of the primary drugs exists. Among the anti-tuberculosis drugs INH, rifampicin,

TABLE 49.1

Drugs used in the treatment of tuberculosis, dosage, route or administration and toxicity

Name of drug	Daily dose for adults	Children	Route of administration	Diffusion in CSF	Main toxic effects
A. First line drugs					
1. Isoniazid	5 mg/kg bw for ordinary cases 12 mg/kg bw in miliary TB and meningitis	10 mg/kg bw	Oral	Good	Hypersensitivity hepatitis, peripheral neuropathy
2. Rifampicin	Persons weighing below 50 kg 450 mg above 50 kg 600 mg	10-20 mg/kg	Oral	Good	GI toxicity, hepatitis, elevation of hepatic enzymes, hypersensitivity, flu-like syndrome, blood dyscrasia esp. thrombocytopenia.
3. Pyrazinamide	Persons weighing up to 50 kg 1.5 g 51-74 kg 2 g above 75 kg 2.5 g (i.e.) 20-35 mg/kg bw	40 mg/kg maximum 2 g	Oral	Good	Arthralgia hepatitis, hyperuricemia
4. Ethambutol	800 mg/day (24 mg/kg bw) for 2 months thereafter 15 mg/kg bw		Oral	Good	Retrobulbar neuritis, rare if dose is kept below 15 mg/kg.
5. Streptomycin	below 30 kg bw or above the age of 60 years, 0.75 g above 30 kg bw lg (20 mg/kg bw)	20 mg/kg bw	I.M inj.	Fair	Deafness, nephrotoxicity vestibular dysfunction
B. Second line drugs					
1. Thiacetazone	150 mg	4 mg/kg bw	Oral	±	Gastrointestinal hepatitis, exfoliative dermatitis.
2. Ethionamide	500-750 mg	—	Oral	±	Gastrointestinal, metallic taste in the mouth, hepatitis.
3. Cycloserine	0.5-1.0 g	—	Oral	Good	Confusion, slurring of speech, convulsions, psychosis.
4. Kanamycin	15 mg/kg bw	—	I.M inj.		Ototoxicity and nephrotoxicity
5. Capreomycin	30 mg/kg bw, up to 1 g/daily for 4 months, followed by 1 g 2-3 times a week.	—	I.M inj.		Nephrotoxicity vestibulotoxicity.
6. Viomycin	3-4 g weekly	—	I.M inj.		Nephrotoxic and vestibulotoxic.
7. Amikacin	15 mg/kg bw	—	I.M inj.		Ototoxicity, nephrotoxicity
8. Rifabutin is an analogue of rifampicin—used for treatment of rifampicin resistant mycobacteria.					
9. Rifapentine	600 mg once a week	oral	serum half-life 10-15 hours suitable for once-a-week schedules		
C. Reserve drugs					
Ofloxacin	400 mg b.i.d		Oral		Abdominal distress, headache, anxiety, tremor, thrush, druginteraction Allergy
Ciprofloxacin	750 mg b.i.d or t.i.d		Oral		
Clarithromycin	500 mg b.i.d		Oral		

Morphazinamide is a derivative of pyrazinamide given orally in a dose of 40 mg/kg bw which is less toxic. Prothionamide is a derivative of ethionamide, given in the same dosage. Its toxicity is possibly less. Both these drugs are only seldom used. Para-aminosalicylic acid (PAS) is not used in regular therapy, but at times it is used as a second line drug.

pyrazinamide and streptomycin are bactericidal, the other drugs are bacteriostatic.

Response to therapy occurs in three stages.

1. Within the first two weeks of starting therapy the majority of actively replicating bacteria in cavity walls are killed, mainly by INH, but also by rifampicin and pyrazinamide.
2. In the succeeding few weeks, rifampicin and pyrazinamide kill the less active bacteria lurking within macrophages, caseous material and exudates.
3. With maintenance therapy, the dormant bacilli are killed by rifampicin during their short bursts of activity.

Emergence of drug resistant bacilli is uncommon if the short-course therapy is given properly under supervision. Relapses, if they occur, are still caused by drug-sensitive bacilli, though rarely it may be by drug-resistant strains. Several regimens for short course chemotherapy are recommended.

Domiciliary Treatment

Success of domiciliary treatment has been established by several studies. Contacts of a notified case naturally maintain isolation and therefore spread from such cases is less common. Open cases of TB should maintain restricted isolation so that they do not transmit the disease to others. They may be advised to confine to home till the sputum becomes AFB- negative. Separate utensils for eating and drinking are preferable. Infective materials like sputum should be disinfected by burning or burying deep in soil. All contacts with an infective case of TB should be followed up with a view to detect infection early.

DIRECTLY OBSERVED THERAPY (DOT) SCHEDULE

Standard therapy

Drugs

Initial phase first 2 months

Rifampicin	450 mg	
INH	600 mg	given under observation
Ethambutol	1200 mg	thrice a week
Pyrazinamide	1500 mg	

Maintenance treatment 4 months

Rifampicin	450 mg	given under observation
INH	600 mg	thrice a week

Modifications are done under special circumstances

Category I	Severe forms of pulmonary TB with sputum positivity
Category II	Defaulters of past treatment and failed cases from category I

To the standard regimen add streptomycin 0.75 g IM thrice a week for 3 months. This period is extended to 4 months if clearance of lesion is not satisfactory.

Maintenance with three drugs INH 600 mg, rifampicin 450 mg and ethambutol 1200 mg thrice a week for 4 months. Total 8 months.

Category III Extrapulmonary tuberculosis and sputum negative cases—regimen is the same as for standard therapy.

Note: Some regimen do not include ethambutol in the initial phase. Only three drugs are used.

India has launched the **Revised National Tuberculosis Control Programme (RNTCP)** in 1993 based on directly observed treatment schedule (DOTS). This has been very successful. RNTCP has achieved cure rates of 80%.

All the anti-TB drugs are given together in full dosage on an empty stomach in the morning since absorption is best at this time. Any food is allowed only at least 30 minutes later.

Since *M. tuberculosis* develops drug resistance rapidly when exposed to a single drug, combination therapy should always be insisted upon. Late relapses are more likely to occur if the full duration of treatment is not completed. INH which is still the most popular anti-tuberculosis drug behaves differently in slow acetylators and fast acetylators. Fast acetylators are persons who have high levels of acetyl transferase activity in the liver. This enzyme metabolizes INH much faster and so fast acetylators require higher doses. In slow acetylators the half-life of INH is over 2 hours, whereas in fast acetylators it is 0.5-1.5 hours. Above 70% of Indian subjects are slow acetylators.

The standard regimen is adequate for all forms of tuberculosis, both for human and bovine strains of mycobacteria.

Patients with uncomplicated tuberculosis, receiving uninterrupted treatment for the entire period, should be considered cured, unless proved otherwise. Upto 2% cases relapse after successful chemotherapy. The risk of relapse is more in the first three years after completing treatment. The DOTS programme launched in 1993 has achieved the following results in India. More than 200000 health workers have been trained. 40% of the population has access to DOTS regimen 800000 received treatment. The World Bank, Danish and UK National Agencies and the Government of India have funded the programme.

Course and prognosis: With successful regimen the lesions become sterile and the vast majority heal by fibrosis. Surgery is indicated only under exceptional situations. These include open healed cavities with aspergilloma, grossly destroyed lung with secondary infection, bronchiectasis and persistence of tubercle bacilli resistant to all drugs, especially in cavitory lesions.

Common causes for failure of therapy are:

- i. inadequate drug dosage,
- ii. noncompliance with the schedule,
- iii. early stopping of therapy,

- iv. drug toxicity, and
- v. initial drug resistance.

DRUG RESISTANCE AND RESERVE DRUGS

Resistance to drugs may be of different types:

1. Some strains of *M. tuberculosis* are naturally resistant to drugs. This is extremely rare.
2. **Primary drug resistance:** Bacilli which are initially resistant to drugs may be the infecting organism.
3. **Secondary drug resistance:** This is drug resistance acquired by initially sensitive bacilli, due to irregular and inadequate chemotherapy.
4. In some cases initial resistance may be *either primary or secondary*, especially when a patient conceals the history of earlier chemotherapy.
5. **Transient resistance:** This is a bacteriological phenomenon which occurs sometimes during successful chemotherapy. One or two cultures may be reported as resistant but later these cases may also become sensitive. This is not an indication to change the drugs.

Patients with cavitory lesion in which the bacterial population is very high, are more likely to develop drug resistance. Resistance should be suspected when a lesion fails to become sputum negative and heal, despite adequate chemotherapy.

Alternate drugs: These are used when the organisms are resistant to one or more of the standard drugs, or toxicity is severe. The regimen consists of 3 to 4 drugs administered for a period of 2 years or more. The drugs include rifampicin, ethambutol, pyrazinamide or morphazinamide, ethionamide or prothionamide, cycloserine, kanamycin, viomycin, and capreomycin. There should be at least two bactericidal drugs. Life-long follow-up is necessary in cases where reserve drugs have been used.

Multidrug resistant TB (MDRTB) is increasing due to noncompliance and poorly supervised treatment programmes. Resistance to INH and rifampicin in MDRTB is highly dangerous. In HIV –ve individuals it causes 22% mortality. In HIV +ve case it is about 50%. Concurrent MDRTB and HIV infection carries a high mortality. Early detection and treatment of this combination is needed for successful outcome. Prevalence of MDRTB in some surveys in India give the following figures

Mahjan et al Delhi 1996	Tiwari et al Pune 1994
Resistance against INH- 26-48%	Resistance to 1 drug-38%
Resistance to SM 18-63%	Resistance to 2 drugs-28%
	Resistance to 3 drugs-13%

MDR TB may be classified as **basic MDR TB** in which the resistance is only to INH and rifampicin and **MDR TB plus** in which there is resistance to several other drugs as well. The molecular basis for resistance has been

elucidated. Even with combination drug regimen the cure rates for MDR TB is only 50-60%.

Treatment of MDRTB

1. Start treatment with at least three drugs to which the organisms is sensitive *in vitro*.
2. Use bactericidal drugs as far as possible.
3. Avoid drugs that impair absorption of anti TB drugs e.g. antacids.
4. Never add a single agent to a failing regimen.
5. Malabsorption is common in AIDS and therefore check the serum levels.
6. Always use directly observed therapy.
7. Surgical measures should be considered early so as to eradicate infection.
8. Consider treatment as successful only if two sputum cultures done at least two weeks apart are negative.
9. Continue treatment for at least 18-24 month after bacteriological clearance.
10. Strict isolation of the patients.

X-DR tuberculosis: This newly coined term denotes extensive resistance to drugs in the first and second line also. X-DR tuberculosis is classified as cases resistant to three or more of the second line drugs. The reason for developing.

X-DR tuberculosis is misuse and mismanagement of second line drugs. This problem is widespread in many countries. In India also this is cropping up. The mortality is $\pm 80\%$.

Special Points in Anti-tuberculosis Treatment

1. **Pregnancy and lactation** are not contraindications to standard anti-tuberculosis treatment. The drugs are not embryotoxic. If a sputum-positive mother gives birth, the baby should be removed, given BCG and preferably brought back to the mother only after it becomes Mantoux-positive. The baby should be observed for the development of primary tuberculosis. INH therapy is advocated as prophylaxis after BCG vaccination has taken effect.
2. **Hepatic disease:** It is better to avoid rifampicin, INH and thiacetazone since these drugs are metabolized in the liver.
3. **Renal failure:** Streptomycin and ethambutol are to be avoided. Rifampicin, INH and pyrazinamide are well tolerated.

TREATMENT OF TUBERCULOSIS (TB) IN HIV POSITIVE PATIENTS

Co-infection with the two diseases presents special problems. Primarily the resistance against TB is considerably reduced. So also the progression of AIDS is

also accelerated. The special problems include drug-drug interactions, overlapping toxicities, additional pill burden, problems of compliance and development of immune reconstitution inflammatory syndrome (IRIS). All HIV-TB patients should be treated with standard four-drug anti-TB therapy. Intermittent (once a week or twice a week) therapies should be avoided. The exact duration of treatment is not well defined, but drug susceptible TB should be treated for 6 months. Those with slow response i.e. sputum cultures positive even at 2 months should receive treatment at least for 9 months. Tuberculosis involving the central nervous system should receive treatment at least for one year.

In those with HIV and TB, the treatment has to be instituted against both diseases simultaneously. Despite starting treatment for TB, the death in the subsequent one month may still be mostly attributable to TB, whereas deaths occurring later may be due to other causes as well.

When should anti-retroviral therapy (ART) be started along with anti-TB therapy?

The CD4 T cell count provides an answer. In those with CD4 counts > 200/cmm. ART can be delayed till anti TB treatment is completed. In those with CD4 T cell counts < 200/cmm, ART should be started concurrently since progression of AIDS may lead to death.

What drug regimen should be given to treat HIV in the presence of TB? Rifampicin causes enzyme induction in the liver and this may lead to reduction in the blood level of nevirapine and other anti-retroviral drugs. It also predisposes to nevirapine induced hepatitis, especially in women with CD4-T cell counts > 250/cmm. Therefore the treatment of HIV should consist of two non-nucleoside reverse transcriptase inhibitors (NNRTI) with efavirenz in a daily dose of 600-800 mg. After completion anti-TB therapy, a cheaper NNRTI drug like nevirapine can be substituted.

Immune Reconstitution Inflammatory Syndrome (IRIS)

This phenomenon is not uncommon. This condition arises when anti-retroviral therapy partially restores the immunosuppression in AIDS. This manifest as exacerbation of tuberculous lesion such as lymphadenopathy, hepatosplenomegaly, fever, aches and pains, granulomas, suppuration, necrosis of tissues, rise in intracranial tension, flare up of pulmonary lesions and several others. Similar exacerbation may occur in other. AIDS- related infections as well. This may mimic drug reactions and it may even be life threatening IRIS is more likely to occur in patients where CD4 T cell counts are < 100/ cmm and in whom HAART is started within the first 2 months of starting anti TB therapy. The usual time for manifestation is 3 months after starting the therapy.

Treatment

Some cases clear up spontaneously on continuing the combination therapy. At times if IRIS is life threatening, such as worsening of lesions, the HAART has to be temporally withdrawn. Non-steroidal anti inflammatory drugs and prednisolone in adequate doses may have to be used. In any case development of IRIS is not a reason for abandoning specific treatment for both conditions.

PREVENTION OF TUBERCULOSIS

Improvement in economic and social factors and education of the community are associated with reduction in incidence of tuberculosis. Specific immunization is by Bacillus Calmette Guerin (BCG) vaccination. BCG mounts up CD4 T cell mediated immunity. Recent trials conducted in south India have thrown doubts on the full efficacy of BCG vaccination. However, the World Health Organization still recommends BCG vaccination as a protective measure against tuberculosis especially in children. BCG vaccination prevents severe disease and reduces the mortality in children, but protection against the development of pulmonary tuberculosis in children and adults is doubtful. As at present it is included in the primary vaccination programme of infants. There are attempts to modify BCG vaccine to improve its immunogenicity.

The vaccination is given intradermally over the left shoulder just below the insertion of the deltoid with 0.1 mL of the liquid or reconstituted dry vaccine. For infants below 4 weeks 0.05 mL is the recommended dose. Ideal time is to give BCG at the third month of life but in practice the vaccine is given in the neonatal period in many centers, for administrative convenience. A nodule develops which ulcerates and heals in 8-12 weeks, leaving a scar. Though BCG was given only to tuberculin negative subjects previously, it is now given routinely even without routine tuberculin testing. Relative immunity starts to appear in 4-6 weeks which wears off with the passage of time and disappears in 5-7 years. In some countries revaccination is done at 7 years intervals in high risk groups till the age of 21 years. Rare complications include non-healing of the ulcer, abscess formation in the axillary lymph node, and keloid formation. Dissemination may occur in immunosuppressed individuals. Nonhealing ulcers or troublesome lymphadenopathy responds promptly to local or systemic isoniazid therapy, but chemotherapy also eliminates the protective role of the vaccine.

Chemoprophylaxis: INH has been found to offer effective prophylaxis against tuberculosis in high risk groups. Chemoprophylaxis may either be primary or secondary depending on whether prophylaxis is given to a person who is tuberculin negative or tuberculin positive

respectively. Primary prophylaxis is given to the contacts of sputum-positive tuberculosis patients, before they develop the disease, e.g., newborns of infective parents.

Secondary chemoprophylaxis is employed only rarely. When corticosteroids or immunosuppressants have to be administered, INH may be given to prevent exacerbation of healed tuberculous lesion.

Surveillance: Persons who are at high risk of developing tuberculosis occupationally (danger group) such as hospital staff, school teachers, bus conductors, barbers, hotel employees, and others should have periodic medical examination.

WHO has developed the stop TB strategy with the following targets: Year 2015—reduce prevalence of TB and deaths due to TB by 50% relative to the levels that existed in 1990.

Year 2050—eliminate TB as a public health problem that is < 1 case per million population.

24th March of every year is designated the **World TB day** by the WHO.

MILIARY TUBERCULOSIS

Syn: Acute hematogenous tuberculosis

Tubercle bacilli entering the bloodstream are diffusely disseminated and results in miliary tuberculosis. This is more common in young children in whom it is seen as a complication of primary tuberculosis. Post-primary tuberculosis may also lead to hematogenous spread when the general resistance is low.

Pathogenesis and Pathology

Entry of the bacilli into the blood stream is through lymphatics or by erosion of blood vessels by caseating lesions. Areas of caseous vasculitis (Weigert's foci) occurring in veins or arteries may result in the discharge of bacilli into the circulation. Numerous tubercles develop in the affected tissues. These coalesce to form multiple lesions of the size of millet seeds. All organs are affected, especially the lungs, liver, spleen, kidneys, meninges, brain, bones and joints, intestines, skin, choroid of the eye, and serous membranes. The lesions may become confluent with the progress of the disease.

Clinical Features and Diagnosis

Majority of cases present varying grades of pyrexia. Localizing signs may not be evident in the beginning. In some cases meningitis and in a few others pneumothorax or pneumomediastinum may be the presenting manifestation. About one-third of the cases show enlargement of the liver and spleen. Generalized lymphadenopathy may occur. The lymph nodes are small or moderately enlarged in size, and discrete. Choroid tubercles may occur rarely.

Evidence of an underlying tuberculous lesion may be present in a few cases, but this is more an exception than the rule.

Diagnosis

Clinically the diagnosis of miliary tuberculosis should be considered in the differential diagnosis of fevers, especially so in children. Skiagrams of the chest are most helpful. This shows numerous, small rounded shadows—the miliary mottling. The upper lobes are more affected and this helps to distinguish miliary tuberculosis from other conditions such as pulmonary hemosiderosis, eosinophilia, disseminated carcinoma, pneumoconiosis, sarcoidosis, and histoplasmosis in which mottling of the lungs is more prominent in the lower zones. There is no characteristic abnormality on blood examination. Sputum examination is often unrewarding. Tuberculin test may be positive only in some cases. Histologically, the diagnosis may be made through biopsy of tissues like the liver, lungs or bone marrow (trephine biopsy). Choroid tubercles are diagnostic if they occur, but in Indian subjects they are only rarely found.

Treatment

Standard chemotherapy has to be started early and in most cases the condition dramatically improves within weeks. Corticosteroids may be given along with full anti-tuberculosis treatment to reduce toxemia in severe cases. Results of treatment, if started early, are excellent and complete resolution is the rule.

TUBERCULOUS MENINGITIS

About 25 to 30% of the total number of cases of meningitis seen in many hospitals in India were presumed to be due to tuberculosis. Children suffer from this disease most, but all age groups can be affected. The proportion of tuberculous meningitis is coming down (See also Chapter 188).

Pathogenesis and Pathology

Tuberculous meningitis develops commonly as a complication of miliary tuberculosis. The organisms reach the central nervous system in the blood stream. The other source of infection is rupture of a subcortical caseous focus. Small granulomas are formed in the superficial layers of the brain (*'Rich foci'*). Bacilli reach the subarachnoid space from these lesions and set up leptomeningitis. Tubercles are formed most commonly at the base of the brain and along the cerebral vessels. There is increased production of CSF. Adhesions develop in the base of the brain and these block the foramina. The CSF pressure is increased. Autopsy reveals thickening and cloudiness of the pia and arachnoid. The surface shows a

creamy white exudate. In advanced disease the whole of the base of the brain may be covered by thick granulation tissue, which envelops the cranial nerves and the major arteries. The cerebral vessels may develop endarteritis obliterans and thrombosis. This may lead to cerebral infarcts. Surfaces of the cerebral hemispheres and the choroid plexuses may show tubercles. The inflammation spreads to the inner lining of the cerebral ventricles as well.

Clinical Features

The onset is generally insidious with vague ill-health. The child may show nonspecific symptoms like fever, restlessness, irritability, vomiting and loss of appetite. In others, the onset may be acute with convulsions, high fever and signs of intracranial tension. A few cases develop abnormality of behaviour which may progress to stupor and coma. Death occurs in 4 to 8 weeks in untreated cases.

Physical findings depend on the stage at which the patient is first seen. Signs of meningeal irritation may not be evident in very early stages, but soon these become obvious. Neck stiffness is less prominent in younger children. Complications such as cranial nerve palsies, hemiplegia or monoplegia may be evident. Papilledema may be present in some. An acute presentation resembling purulent or aseptic meningitis is not rare. In a few cases the onset may be with brainstem involvement and acute pulmonary edema. Other features of miliary tuberculosis may be evident, especially in children.

Complications

Complications are invariably present in those cases which are seen late in the disease. Acute complications include internal hydrocephalus, cerebral infarction, cranial nerve palsies, convulsions, fluid and electrolyte disturbances and bed sores. The chronic complications are obstructive hydrocephalus, optic atrophy, subdural effusions, diffuse or localized spinal arachnoiditis, spinal cord compression and the development of tuberculoma in the brain and spinal cord (Fig. 49.5). In cases where treatment is delayed for four weeks or more, focal paralysis, intellectual impairment, epilepsy, hypothalamic disturbances and intracranial calcification may persist as sequelae. The overall mortality in large series varies from 10-15%.

Diagnosis

Early diagnosis is possible only if the clinical suspicion is strong. History of contact with tuberculous cases, evidence of miliary tuberculosis and the presence of choroidal tubercles should suggest the underlying cause. The clinical picture of advanced disease is that of a child, dehydrated, lying in opisthotonus with the typical

meningitic cry. This picture is rarely seen now. Differential diagnosis includes other forms of meningitis, encephalitis, acute or subacute demyelinating lesions, cerebral space occupying lesions such as brain abscess, subdural hematoma or tumors, leukemic and carcinomatous meningitis, and all other conditions causing coma.

Meningitis is diagnosed by examination of the CSF. **Lumbar puncture** should be done as early as possible on suspecting the diagnosis. If lumbar puncture fails due to spinal block, CSF should be obtained by cisternal puncture or ventricular puncture. Examination of the CSF shows rise in pressure, turbidity, and a rise in lymphocytes upto 500-1000 cells/cmm. A mixed pleocytosis may occur in some rare cases. A Fine coagulum ('cobweb') forms in the CSF when kept at room temperature for 6-24 hrs. Though this is highly suggestive of tuberculous meningitis, it may rarely be seen in other types of meningitis as well. Proteins are moderately increased up to 200-300 mg/dL. Sugar is reduced to less than 50% of the blood sugar. In severe cases the depression of CSF sugar is even more marked. The chlorides are diminished, as a part of generalized hypochloremia due to electrolyte losses. With meticulous care, *M. tuberculosis* may be demonstrable by culture and animal inoculation in up to 50% of cases. Acid fast bacilli (AFB) may be demonstrable in the cobweb in about 15-20% of cases.

Tuberculous meningitis has to be distinguished from other forms of meningitis. In purulent meningitis the CSF shows neutrophil predominance and the organism may be demonstrable by Gram stain. Cryptococcal meningitis may closely resemble tuberculous meningitis. The fungus is demonstrable in CSF by India ink staining.

In partially-treated purulent meningitis the CSF picture shows mainly lymphocytes. This should not be mistaken for tuberculous meningitis. Leptospirae, viruses, leukemic infiltration and carcinomatosis may all give rise to CSF pleocytosis and biochemical abnormalities. These should be kept in mind.

Treatment

The most important factor deciding a favourable outcome is early institution of chemotherapy. General treatment includes the correction of dehydration and electrolyte imbalance, maintenance of nutrition, good nursing care with special attention to the skin, bladder and bowels, analgesics to relieve headache and anticonvulsants to stop convulsions.

Standard antituberculosis chemotherapy is instituted as early as possible. INH is administered at a higher dose of 12-15 mg per kg (600 mg for an average adult). **Systemic corticosteroids** help to reduce morbidity, especially those due to adhesions and fibrosis and speed up recovery. They are employed after establishing specific chemotherapy. Prednisolone is started at a dose of 0.5 to

Fig. 49.5: CT scan. Tuberculoma right parietal lobe (see arrowhead). Male aged 26 with epilepsy. Completely cleared with therapy

1 mg/kg and is tapered off in 4-8 weeks. In severe cases dexamethasone in doses of 4-8 mg should be given twice or thrice daily IM or IV till the patient can tolerate oral medication for children the dose is 200-500 mcg/kg bw daily.

The progress is monitored by clinical assessment and also repetition of CSF studies at weekly intervals. When the cell count reaches normal levels, dosage of INH is reduced to 6 mg/kg bw. Thereafter, standard chemotherapy is continued as for pulmonary tuberculosis. The sugar content of CSF is the last to return to normal. Ambulation should be permitted only after the CSF sugar returns to normal.

CT scanning is an excellent method to demonstrate meningitis, obstructive hydrocephalus, presence of tuberculomata and for excluding conditions such as subarachnoid or subdural hemorrhage and primary space occupying lesions. Wherever possible, this facility should be employed for diagnosis, as well as follow-up (Fig. 49.5).

Prognosis

Specific therapy given within two weeks of onset of symptoms gives complete recovery. If treatment is delayed for 4-6 weeks, complications and sequelae may develop. Treatment started beyond six weeks is unrewarding in many cases.

Points to remember

- 1. Despite prolonged efforts over half century, tuberculosis still continues as a major cause of death in India and several other developing countries.
- 2. The main reasons are the high infectivity of the organism, its capacity to remain dormant, need for prolonged multi-drug therapy and the development of drug resistance.

- 3. The HIV epidemic has caused a boost to the incidence and complications of TB all over the world.
- 4. Development of drug resistance is a serum problem which has to be avoided at all costs.
- 5. The government of India has accepted the Revised National Tuberculosis Control Programme (RNTCP) with collaboration from international agencies. The DOTS programme which was developed by WHO with active participation of Indian scientists is the mainstay of TB control.

Non-tuberculous Mycobacteria

Several mycobacteria other than *M. tuberculosis* affect man as opportunistic invaders. These are known by several names such as opportunist mycobacteria, atypical mycobacteria, anonymous mycobacteria and unclassified mycobacteria. Some of these cause pulmonary lesions indistinguishable from tuberculosis, while others involve the lymph nodes, skin or subcutaneous tissues. Superinfection in cystic fibrosis cases is more common

Non tuberculous mycobacteria (NTM) are free living organisms that are widespread in nature (Table 49.2).

Based on their rate of growth and pigment production they are divided into four groups.

Group I—Photochromogenic: The colonies produce a yellow or orange pigment on exposure to light, e.g., *M. kansasii*, *M. marinum*. These have been described from the USA and European countries.

Group II—Scotochromogenic: This group produces yellow, orange or reddish pigment in the dark, e.g., *M. scrofulaceum*. It may give rise to cervical lymphadenitis in children.

TABLE 49.2

Lesions caused by nontuberculous mycobacteria

<i>M. marinum</i> (swimming pool bacillus, fish tank bacillus)	Ulceration of skin
<i>M. ulcerans</i>	Extensive ulceration of skin and subcutaneous tissue (Buruli ulcer)
<i>M. kansasii</i>	Pulmonary disease, local abscesses
<i>M. scrofulaceum</i>	Bone and joint lesions, lymphadenopathy
<i>M. chelonae</i>	Pulmonary disease, local abscesses
<i>M. fortuitum</i>	Furunculosis
<i>M. avium intracellulare</i>	Lymphadenopathy, pulmonary lesions, AIDS related and non-AIDS related disseminated lesions

Group III—Nonchromogenic: This group does not produce pigment on exposure to light, e.g., *M. avium intracellulare*, *M. ulcerans*.

Group IV—Rapidly growing mycobacteria: These organisms grow rapidly at 25°C, e.g., *M. fortuitum*, *M. chelonae*.

***Mycobacterium avium intracellulare* complex** consists of two distinct, but closely related mycobacteria.

Mycobacterium avium was described in chickens in 1890 referred to as avium tubercle bacillus. *M. intracellulare* was first cultured in 1969 from the sputum of tuberculosis patients at the Battey state hospital in Rome, Georgia USA. *M. avium intracellulare* complex is ubiquitous, isolated from all parts of the world from soil, house dust, fresh water plants, animal foods, bedding, chickens and other birds. *M. avium* complex grows slowly. They are nonphotochromogenic, smooth, cream coloured colonies unlike *M. tuberculosis* which produces rough flat dry colonies. In AIDS patients, *M. avium* complex organisms may show plasmid induced virulence and the colonies may be rough.

Treatment

Mycobacterium avium complex are very common pathogens in advanced AIDS and they produce infection and bacteremia. Clarithromycin 500 mg b.d. oral is an excellent drug to treat *M. avium* complex.

A three drug combination using rifabutin 600 mg/day, ethambutol 15 mg/kg/bw/day and clarithromycin 1000 mg has been found to be effective in producing resolution of lesions in 70% of cases. Rifabutin produces uveitis in high doses. Adverse effects of clarithromycin include taste perversion and rectal problems. Clarithromycin is effective as prophylactic in AIDS patients with CD4+ below 50/cmm.

Infection by these bacteria also leads to tuberculin sensitivity. Person to person spread of organisms does not generally occur.

In immunocompromised subjects, these mycobacteria cause extensive disseminated lesions. Various regimens based on one or more of the following drugs have given fully or partly successful results. Treatment consists of a combination of a macrolide such as clarithromycin or azithromycin with ethambutol and rifabutin given for six months or longer.

Leprosy

K.V. Krishna Das, Usha Vaidhyathan

Syn: Hansen's disease

GENERAL CONSIDERATIONS

Leprosy is a chronic communicable disease caused by *Mycobacterium leprae*. Mainly the nerves and skin are

affected but it may also involve mucous membranes and other internal organs. Gerhard Henrik Armauer Hansen identified the organism in 1873 and so the disease is named after him.

Leprosy has been known to affect mankind from biblical times. At present it is common in tropical regions of Asia, Africa, and Central and South America. Low standards of living, poverty and overcrowding favor its transmission and prevalence. But the disease is not confined to this group. Persons belonging to all socioeconomic groups may be affected.

By global efforts initiated by WHO, the prevalence and incidence of leprosy has been brought down considerably. Whereas the WHO figures for leprosy patients worldwide was 10-12 million in 1985, it came down to 1.15 million in 1997 with an annual incidence of 5.6 lakhs. The incidence of childhood leprosy cases has not fallen proportional to that of adults. In India, the prevalence has fallen from 57/10000 population in 1981 to 5.8/10000 in 1997. Of the 408000 people diagnosed as leprosy globally, 2 60 000 cases are in India, in 2004. Now 9 countries including India and Nepal have prevalence of 1/10 000. The term elimination is defined as a prevalence of <1/10 000 population. WHO accepted eradication of leprosy by 2000 AD as possible goal which is not achieved yet.

The Organism

Mycobacterium leprae is a rod-shaped, gram-positive, acid-fast bacillus varying in size from 1.8 to 2.5 µm in length. It is less acid fast than *M. tuberculosis*. 5% sulphuric acid is used for decolorization and staining by Ziehl-Neelsen method. The bacterial morphology helps in assessing the viability and the effects of drug therapy. Viable bacilli appear as regular rods. Bacilli which appear irregular and granular are probably dead. *Mycobacterium leprae* is grown experimentally in the foot pads of mice and in the nine-banded armadillo. *M. leprae* multiplies maximally at a temperature of 27-30°C. Consequently, the infection is maximum in the cooler parts of the body (i.e.) 34-35°C. The organisms infect the skin, cutaneous nerves, peripheral and autonomic nerves.

Transmission

Portal of entry is through abrasions in the skin or mucous membranes of the upper respiratory tract. Untreated subjects with lepromatous leprosy shed numerous bacilli in nasal discharges and minor abrasions in the skin even before they are clinically detectable. Other possible sources of spread such as insect vectors have also been incriminated but not proved.

The incubation period is ordinarily 2-7 years, but this may vary from a few months to 30 years. The mean incubation period for tuberculoid leprosy is 4 years and

for lepromatous is about 10 years. Since man has natural immunity against lepra bacilli, lesions do not develop in the majority of cases, or they remain subclinical. The clinical disease manifests in 1/350 of those infected with the organisms in endemic areas. Adults are more resistant, but 30% of children living in intimate contact with infective cases develop early lesions. In most of them the lesions heal spontaneously. Chronic progressive disease develops only in about 8% cases. Majority of the patients initially present with the disease within the first three decades of life. In lepromatous leprosy, males are twice more commonly affected than women, but in tuberculoid leprosy such a predilection is not noted.

Irrespective of the virulence of the infecting organism, the clinical outcome is so varied, depending on the immune status of the individual which is the deciding factor in pathogenesis. Both cellular and humoral immune mechanisms operate. The cellular immunity is protective, whereas the humoral antibodies are not. Cell-mediated immunity (CMI) which develops against the lipid components of *M. leprae* determines the progress of the disease. Based on the immune response, a wide clinical spectrum varying from the well-localized tuberculoid leprosy to the generalized lepromatous leprosy may be encountered.

The two polar forms are the lepromatous and tuberculoid types. Borderline leprosy denotes the variable clinical patterns seen in between the two polar forms.

PATHOLOGY

During the early stages of infection the clinical and histological changes are non-specific. The dermal nerve twigs show infiltration with round cells and histiocytes. *M. leprae* has tropism for laminin 2, a component of Schwann's cells, which are present in peripheral nerves. Mycobacteria may be seen in nerves and muscles of the skin and this is diagnostic. This stage is known as the *indeterminate stage* since it is not possible to predict the clinical outcome at this stage. The lesion heals due to natural resistance in 75% of cases. In those with progression of lesions tuberculoid lesions develop in the presence of good immunity whereas lepromatous lesions develop in its absence.

Tuberculoid Leprosy

This type is characterized by well-localized granulomatous lesions in and around the nerves. The cells are derived by the mobilization of phagocytic macrophages which are transformed into epithelioid and giant cells. These are surrounded by lymphocytic infiltration. This granuloma extends into the epidermis. The dermal nerves are destroyed by the cellular infiltration. Caseation is rarely seen in the nerves. The bacilli are very few and are not

generally demonstrable in these lesions. Such patients are non-infective.

Lepromatous Leprosy

In contrast to tuberculoid leprosy, lepromatous lesions teem with organisms. Mononuclear phagocytes ingest the organisms which multiply within and fill them completely. These bacterial masses are called *globi* and such cells are called *lepra cells*. Their cytoplasm is foamy. Lymphocytes are only a few or absent. There is no attempt at tubercle formation. The dermis is infiltrated throughout its entire thickness. The nerves, erector pili muscles, and endothelial lining of blood vessels also show similar changes. The epidermis is spared and a clear cell-free zone exists below the epidermis. The organisms are disseminated through the blood stream to other parts of the skin and organs such as eyes, respiratory mucosa, testes, liver, kidneys and muscles of the hands, feet and face. As a late complication amyloidosis may develop.

Borderline Leprosy

When the immunity is variable, borderline leprosy develops in which the histological picture tends to vary. With good cell-mediated immunity, the picture resembles tuberculoid leprosy, and this is called '*borderline tuberculoid*' (BT). There is differentiation of mononuclear phagocytes into epithelioid cells, but giant cells are not common. Lymphocytes are usually present but do not show tubercle formation. The subepidermal zone is clear and nerves are infiltrated but are still recognizable.

When the immunity wanes the picture resembles that of lepromatous leprosy and this is called *borderline lepromatous* (BL).

In peripheral neuropathy occurring in leprosy, the nerves are damaged mainly by the cellular reaction to the components of dead bacilli.

The lepromin test: The lepromin skin test detects delayed hypersensitivity. It is positive in tuberculoid and negative in lepromatous type. This test was in vogue for diagnosis and prognosis. This is seldom used now.

CLINICAL FEATURES

Indeterminate Leprosy

The disease starts with a single lesion or a few multiple lesions which appear as small hypopigmented or erythematous macules. Careful testing may reveal hyperesthesia, paresthesia, hypoesthesia or hypoalgesia. At this stage nerve trunks are not thickened. Slit skin smears are usually negative for acid-fast bacilli. Lepromin reaction may be negative or doubtfully positive. Evolution into the polar forms takes a long time after infection. In the early stage, which is known as indeterminate leprosy,

the distinctive features are absent. Though diagnosis is possible, it is difficult to predict the clinical outcome and the type.

Tuberculoid Leprosy (TL)

In this form the skin lesions are only a few (3 or less) and they vary in size. They are hypopigmented or erythematous and the margins are well-defined. The lesions may be flat or raised. Either the entire lesion or only the margins may be elevated. The surface is dry, rough, and anhidrotic. By this time the temperature and pain sensations are impaired. Nerve trunks, especially in the vicinity of the raised lesions, are palpably thickened. Supraorbital and great auricular nerves in the head and neck, ulnar, cutaneous branch of radial, the main radial and median nerve in the upper limb, and lateral popliteal (common peroneal), posterior tibial, musculocutaneous and sural nerve in the lower limbs are the common nerves palpated. Facial palsy manifesting over parts of the face either on one or both sides may develop. Slit skin smear does not show acid-fast bacilli and lepromin test is positive. Early lesions may heal spontaneously without complications. More advanced lesions also heal ultimately, but residual damage to nerves may occur due to reactions, which complicate the illness (Figs 49.7 to 49.11).

Lepromatous Leprosy (LL)

In this form the bacilli spread rapidly from the skin, both by local extension and through the blood stream, to other parts of the body. Extensive involvement of nerves, mucosa of the upper respiratory tract and the internal

Fig. 49.7: Hansen's disease- borderline tuberculoid

Fig. 49.8: Nerve thickening in Hansen's- great auricular nerves

Fig. 49.6: Hansen's disease- Lepromatous leprosy

organs occurs. Eyes, testes, lymph nodes, marrow of the phalanges, superficially placed muscles, liver, spleen and kidney may all be affected in varying degrees.

The morphology of the skin lesions depends upon the stage of the disease. Early lesions are flat, smooth, shiny, hypopigmented or coppery red, with ill-defined margins (Fig. 49.6). Numerous small lesions are distributed symmetrically. The entire body surface may be involved except certain areas like the axilla, groin and the flexor aspects of the limbs. In dark subjects they may be inconspicuous and can be made out only by careful search. Early lesions do not show sensory loss. As the disease progresses, papules and nodules appear especially on the ears and face. The eyebrows are lost. The facies is described as leonine and this is caused by infiltration and thickening of skin of the face. The mucosal lesion leads to ulceration of the nose, mouth, trachea and larynx. Nasal

(Figs 49.6 to 49.10 were provided by Dr Pradeep S Nair, Assistant Professor, Dermatology, Medical College, Trivandrum)

Fig. 49.11: Ulnar palsy in Hansen's disease

discharge teems with the bacilli. Nasal bones may be destroyed resulting in deformity of the nose. Involvement of the premaxilla leads to loss of the upper incisors.

Clinical evidence of nerve damage occurs late in lepromatous leprosy. The nerve trunks are symmetrically enlarged and soft to feel. Dorsal aspects of the forearms and legs show anesthesia and anhidrosis. Gradually

anesthesia spreads over the whole body except the palms, soles, axillae and groins. Motor weakness follows further nerve damage. Tendon reflexes are preserved till late stages. Paradoxically, the wasted muscles may be hyper-reflexic. In addition to neural damage, muscular dysfunction may result from direct invasion of the muscles by the bacilli. Affection of the testes gives rise to impotence and enlargement of the breasts.

Ocular involvement may occur by extension from the skin or by hematogenous spread. Common lesions include miliary lepromata on the iris and superficial punctate keratitis. All parts of the eye except the retina may be affected.

Lepromatous leprosy progresses relentlessly if left untreated, crippling the victim further and leading to mutilation. Progression of the disease can be arrested with treatment, though complete clearance of bacilli is difficult to achieve.

Lucio Leprosy

This is a special type of diffuse lepromatous leprosy originally described from Mexico, but it is also seen in other areas. The whole skin becomes smooth and stiff with loss of body hair, especially on the eyebrows. Slit skin smears are always positive for the organisms.

Borderline Leprosy

In this form the clinical picture truly reflects the absence of localization seen in histology. Skin lesions are numerous, which are asymmetrical, varying in size and shape. The flat lesions are not as well-defined as in tuberculoid leprosy. The margins may be entire or deficient in places and they slope outwards to the periphery. Satellite lesions may be present. Papules and nodules form only rarely, and would show central dimpling when they occur. The involvement of nerves is more widespread than in tuberculoid disease. Nerve damage is earlier in onset than in lepromatous disease. Bacillary count and the lepromin test are variable. Spontaneous healing is uncommon except in the very early stage. Improvement in the immune status converts the disease into the tuberculoid form with tendency to heal. Loss of immunity downgrades the lesion to the lepromatous type with its characteristic features, but nerve damage is seen in addition. Borderline leprosy can be further subclassified into borderline tuberculoid (BT), mid-spectrum borderline (BB), and borderline lepromatous (BL) based on the bacterial index and lepromin test.

Pure Neuritic Leprosy

Though in all forms of leprosy the nerves are the first targets of attack, sooner or later the lesions extend into the skin. In some patients only nerve involvement is seen

without any perceptible skin lesions. This form is called pure neuritic leprosy. Clinically, the presentation is with the affection of single or multiple large nerve trunks. The nerves are enlarged, firm and tender. Both sensory and motor abnormalities are demonstrable. The affected parts are usually negative for bacilli. Lepromin test is generally positive but it may be doubtful or negative in some. Definite diagnosis of this stage can be made only by nerve biopsy. Autonomic nerves may be affected.

Main causes of tissue damage in leprosy

1. Bacillary infiltration—lepomatous leprosy
2. Peripheral neuritis—loss of sensory, motor and autonomic functions.
3. Reactions in leprosy.

REACTIONS IN LEPROSY (LEPRA REACTION)

Episodes of acute inflammation (called reactions) occur during the course of leprosy. In some patients occurrence of a reaction may be the precipitating event to seek medical help. Immune reactions may be caused either by delayed hypersensitivity (*Jopling type 1 reactions*) or to the formation of antigen antibody complexes—(*Jopling type 2 reactions, erythema nodosum leprosum*).

Type 1 reaction occurs in patients with borderline leprosy cases. There is a sudden change in cellular hypersensitivity. These reactions may be spontaneous or precipitated by therapy occurring within six months.

Existing lesions increase in size and severity and may become erythematous, edematous and tender. New lesions may develop. The nerves become swollen, painful and tender, and nerve abscesses may form. The neurological deficit may increase. Edema of feet, hands and face may occur. Constitutional symptoms like fever are rare.

Type 2 reaction is caused by vasculitis resulting from the deposition of immune complexes, without a shift along the immunological spectrum. This type of reaction is seen in about one half of the patients with lepomatous leprosy and one fourth with borderline leprosy. Commonly this reaction occurs during the second year of treatment. These reactions may be associated with the appearance of tender erythematous nodules, which are called *erythema nodosum leprosum* (ENL). Type 2 reactions are characterized by general inflammatory phenomena such as fever, rigor, pain and tenderness in the skin and nerves, arthritis, lymphadenopathy, iritis and keratitis. Further damage to nerves and eyes may develop and repeated reactions aggravate the disability.

Lucio Phenomenon

This is a severe form of type 2 reaction occurring in lucio leprosy. It is characterized by the formation of erythe-

matous macules which become purpuric or ulcerated. Later they heal with atrophic scarring.

DIAGNOSIS

The diagnosis of leprosy is based on clinical signs and symptoms. A case of leprosy is defined as a person having one or more of the following features, and who has yet to complete a full course of treatment.

1. Hypopigmented or reddish skin lesion(s) with definite loss of sensation.
2. Involvement of the peripheral nerves, as demonstrated by definite thickening with loss of sensation.
3. Demonstration of acid-fast bacilli in skin lesions by standard slit skin smears or histological diagnosis of granuloma affecting the nerves.

Demonstration of *M. leprae* in the skin is by preparing a slit skin smear from the ear lobe or other areas by scraping the subepidermal tissue through a small incision. The material is stained by modified *Ziehl-Neelsen method*. *The disease should not be diagnosed if only nerve thickening is present, without any other accompanying symptoms or signs.*

Quantitative estimation of the bacterial count is obtained by noting the density of the bacilli in the smear which is recorded as the *bacterial index*. Presence of many clumps of bacilli in an average field is recorded as 6+ whereas presence of 1 to 10 bacilli in hundred fields is recorded as 1+. In addition, the morphology of the bacilli enables the observer to assess their viability. This morphological index is used for recording progress with treatment. Nasal mucosa shows organisms and nasal smears give an idea of the infectivity of the patient. In borderline leprosy *M. leprae* are scanty and in tuberculoid leprosy they are not present in skin smears.

None of the cardinal diagnostic criteria like sensory changes, thickened nerves or organisms may be present in indeterminate leprosy. A high index of suspicion and familiarity with the early signs and symptoms are the only factors which help to diagnose this stage. Diagnosis has to be confirmed by the demonstration of *M. leprae* inside nerves or erector pili muscle.

Differential Diagnosis of the Skin Lesions

Many other common skin conditions give rise to macular lesions. These are pityriasis alba, tinea versicolor, nutritional dyschromias, birth marks and early vitiligo. Raised lesions or plaques have to be differentiated from fungus infections, cutaneous tuberculosis, lupus erythematosus, and lichen simplex. Psoriasis and lichen planus do not give rise to problems in diagnosis due to their distinctive features. Post kala-azar dermal leishmaniasis has to be distinguished from lepomatous leprosy. Reaction in leprosy may be mistaken for other

forms of vasculitis as in systemic lupus erythematosus or polyarteritis nodosa. Other conditions that produce localized sensory loss are entrapment neuropathies and injury to peripheral nerves. Rarely nerves may be thickened, in hypertrophic polyneuritis, Refsum's disease, amyloidosis, and traumatic neuromas.

MANAGEMENT

The clinical diagnosis of leprosy should always be confirmed by the laboratory tests, before starting treatment, in view of the socioeconomic and psychological implications. The lepromin test is seldom done for clinical purposes because clinical differentiation along with bacteriological and histological diagnosis is quite satisfactory for management. Education of the patient on the nature of the disease, outcome of treatment, and measures to avoid spread is absolutely essential for success.

General Treatment

This includes measures to improve general health and treatment of intercurrent illness.

Chemotherapy

At present six effective antileprosy drugs are available. Among these, dapsone, rifampicin and clofazimine are used in standard regimens. The others which are used in special situations include minocycline, ofloxacin and clarithromycin. None of these should be used as monotherapy.

Dapsone: The time honored and basic drug for the treatment is dapsone. The drug is inexpensive and relatively non-toxic in the doses used. Delayed hypersensitivity reactions and less commonly agranulocytosis have been reported. Mild hemolytic anemia is common, but severe anemia is rare except in glucose 6 phosphate dehydrogenase deficiency. The drug is cumulative in the system. Dapsone is weakly bactericidal in a dose of 100 mg daily. Dapsone in combination with clofazimine kills more than 99.999% of *M. leprae* within 3 months. This suggests that the rifampicin-resistant mutants in an untreated patient with LL are likely to be eliminated by 3-6 months of treatment with dapsone - clofazimine component of the standard MDT regimen.

Rifampicin: Rifampicin is the most powerful bactericidal drug against *M. leprae* and three monthly doses of 600 mg kills 99.999% of viable *M. leprae*. It is relatively nontoxic, although occasional cases of renal failure, thrombocytopenia, influenza-like syndrome and hepatitis have been reported.

Clofazimine: Clofazimine is bacteriostatic when given in a dose of 50 mg a day. It has also got anti-inflammatory

properties in high doses. Pigmentation of the skin is common but it clears completely after treatment is discontinued. Higher doses may cause gastrointestinal symptoms.

Though most of the patients are rendered non-infectious within a few weeks, clinical improvement may not be apparent for several months. Complete resolution may take a few years.

Clinical Classification for Control Programs

The WHO expert committee concluded that patients could be classified into three groups

Paucibacillary single lesion leprosy (one skin lesion)

Paucibacillary leprosy (2-5 skin lesions)

Multibacillary leprosy (more than five skin lesions)

When classification is in doubt, the patient should be treated as having multibacillary leprosy. All smear positive cases should be treated as multibacillary leprosy.

The bacillary load in paucibacillary cases is of the order of 6 logs whereas in multibacillary cases it is 11 logs or more.

Standard Multi Drug Therapy (MDT) regimens: (Seventh report of the WHO expert committee on leprosy- 1998)

Paucibacillary cases: (for adults)

Rifampicin 600 mg once a month, supervised,

Dapsone 100 mg daily, self administered.

Duration- 6 months

Multibacillary Cases: (for adults)

Rifampicin 600 mg once a month, supervised

Dapsone 100 mg daily self administered

Clofazimine 300 mg once a month, supervised and 50 mg daily self administered.

Duration - 24 months.

Children should receive appropriately reduced doses of the above drugs. Multibacillary patients should complete 24 monthly doses within a 36 month period and paucibacillary patients, 6 monthly doses within a 9-month period. Patients should receive their drugs in monthly, calendar blister packs.

The possibility of further shortening the duration of MDT is being evaluated. On the basis of many large trials, it is possible that the duration of the current MDT regimen for multibacillary leprosy could be further shortened to 12 months without increasing the risk of developing resistance to rifampicin.

A patient who relapses should be treated with a further course of MDT. A defaulter is a patient who started MDT but who has not received treatment for 12 months. If such a patient returns to the health center for treatment, and shows signs of active disease, he should be given a new

course of MDT. In the absence of activity, there is no need to re-start MDT and the patient should be educated to report promptly on the appearance of any of these signs.

Once treatment is started, there is rapid clearance of the organisms from the nose. Therefore isolation is not necessary. Rifampicin, dapsone and clofazimine are safe during pregnancy.

Alternative MDT Regimens

1. A single dose of rifampicin 600 mg, ofloxacin 400 mg and minocycline 100 mg (ROM) is an acceptable and cost effective alternative regimen for the treatment of patients with single lesion paucibacillary leprosy.
2. For patients who do not tolerate clofazimine, ofloxacin or minocycline could be used as substitutes for clofazimine. An alternative regimen is to give monthly doses of ROM for 24 months
3. Patients harbouring rifampicin resistant *M. leprae* are very often resistant to dapsone and their treatment depends on clofazimine. The recommended regimen for adults (multibacillary cases) is daily administration of 50 mg of clofazimine together with ofloxacin and minocycline for 6 months. For at least an additional 18 months, clofazimine with either minocycline or ofloxacin should be administered.

Treatment of Reactions

In reactions the specific anti-leprosy treatment is continued unchanged unless there are compelling reasons to discontinue it.

Because of the high-risk of permanent damage to the peripheral nerve trunks, *type 1 reaction* (reversal reaction) needs to be diagnosed as soon as possible and treated adequately. Prednisolone is the drug of choice. To begin with, 40-60 mg of prednisolone is given daily and gradually tapered (over 12 weeks) weekly or fortnightly and eventually stopped.

Type 2 reactions vary in severity, duration and organ involvement. Mild Erythema Nodosum Leprosum (ENL) can be treated with analgesic or antipyretic drugs such as aspirin, while severe reactions with neuritis should be treated with prednisolone. Thalidomide, 100 mg three to four times daily is also effective for the treatment of severe ENL. It should be used only in male or post menopausal female patients who have become dependent on corticosteroids and must be given only under close medical supervision.

Clofazimine in a dose of 300 mg daily in divided doses is also effective for ENL but is less potent than corticosteroids and often takes 4-6 weeks to develop its full effects. So it should never be started as the sole agent for the treatment of severe ENL. The total duration of high dose clofazimine therapy should not exceed 12 months.

Other Measures

Splinting and physiotherapy help to prevent nerve damage and its sequelae. Care of hands and feet, protective footwear, physiotherapy and rehabilitation are integral parts of patient care in subjects with sensory loss.

PREVENTION AND CONTROL

BCG offers variable protection against leprosy in different countries, ranging from 34-80%. The reliable way to control the spread of leprosy in contacts is regular 6 monthly examinations. Close contacts with high-risk of transmission can be given chemoprophylaxis with 15 mg/kg rifampicin once a month for 6 months.

Early diagnosis and treatment are the sure ways to arrest the disease, prevent spread and avoid disability. Educating the public, increasing the awareness of the problem and eliminating the social stigma through propaganda have helped to implement mass programs and prevent spread.

Rehabilitation of the disabled patient is to be undertaken along with curative measures. This includes surgical correction of deformities, plastic surgery especially of the hand to make the hands more functional, avoidance of burn injuries to hands and feet, protection of the eyes from exposure keratitis and other community measures needed to ensure social rehabilitation.

The national leprosy control program: This was launched in India in 1955. This program emphasized the need for health education. Centers were established for survey, education, and training (SET centers) in areas of high endemicity, for early detection and mass treatment. In addition, training and research centers for leprosy were established at different parts of the country. This program was redesignated *National leprosy eradication program* (NLEP) in 1982. More than 250 non-governmental organizations are active in India working for prevention of leprosy and offering other services to the victims.

Points to remember

1. India still harbours a large number of leprosy patients though, the incidence and prevalence have dropped considerably.
2. Infection is spread by nasal droplets and through cuts in skin and mucous membranes
3. Manifestation depends upon the degree of CMI.
4. Diagnosis is clinical and by demonstration of *M. leprae* by slit skin smears.
5. Treatment is with rifampicin, dapsone and clofazimine.
6. National and international programmes are afoot to eradicate the disease.

Psittacosis

K.V. Krishna Das

Chapter Summary

Chlamydia—General Considerations 296
Psittacosis 296

Chlamydia—General Considerations

Chlamydiae are small gram-ve organisms which remain intracellular. They have both DNA and RNA. They possess cell wall and divide by binary fission. They have a unique biphasic life cycle with dimorphic forms which are functionally and morphologically distinct.

Life Cycle

The elementary body (EB) is an infectious but metabolically inactive form which attaches to the epithelial cell surface and enters the cell by endocytosis. Once endocytosed it differentiates into a larger pleomorphic form called reticular body (RB) and remains inside a membrane bound vacuole thereby evading phagolysosomal fusion. Once inside the cell they interrupt the metabolic processes of the host cells and utilize them for their own metabolism and replication. These processes are not yet fully understood. Antigenically they are complex, possessing antigens of genus, species and serotype specificity.

The human pathogens include the species *Chlamydia trachomatis*, *Ch. pneumoniae* and *Ch. psittaci*.

Psittacosis

Syn: Parrot fever

Definition

Psittacosis is an infectious disease caused by the organism *Chlamydia psittaci* which is a primary pathogen of birds. *Chlamydia psittaci* is a gram-negative obligate intracellular parasite.

Epidemiology

The disease is present all over the world. Psittacine birds (parrots, parakeets, cockatoots) are commonly affected,

Spectrum of human diseases caused by Chlamydiae

	Acute lesions	Chronic lesions
<i>Chlamydia trachomatis</i> serovar A to C	Conjunctivitis	Trachoma
do—serovar D to K	Urethritis	Proctitis, pelvic inflammatory disease, urethritis, Reiter's syndrome, tubal obstruction epididymoorchitis
do—LGV serovars	Lymphogranuloma venereum	Multiple sinuses esthiomene
<i>C. pneumoniae</i>	Pharyngitis, sinusitis, bronchitis, community acquired pneumonia	Atherosclerosis asthma
<i>C. psittaci</i> derived from parrots, canaries, pigeons, turkeys, ducks chickens, cats, ewes	Atypical pneumonia, hepatic and renal dysfunction, endocarditis, conjunctivitis abortion	

but all types of birds may suffer. Infection in man results from close contact with birds. The organism is present in the feces of infected birds. Humans acquire the infection by inhalation of bird's feces or handling the tissues of infected birds.

Pathology

Chlamydia psittaci reaches the pulmonary alveoli and the reticuloendothelial cells of the spleen and the liver. In the lung patchy consolidation develops. Liver and spleen are enlarged due to congestion. The heart, meninges, and the brain also show congestion. The alveolar exudate is mainly mononuclear.

Clinical Features

The average incubation period is about ten days. The onset is sudden with fever, malaise, sore throat, and intense photophobia. Temperature ranges from 37-39°C. There is relative bradycardia. Tachypnea may occur. There may be cough with scanty mucopurulent sputum. Signs of pulmonary consolidation may be evident. After about 10 days of fever the temperature comes down by lysis. Mortality may reach 20%. Respiratory failure and toxemia are the usual causes of death.

Diagnosis

Psittacosis has to be differentiated from viral pneumonia, typhoid fever, influenza and Q fever. History of contact with birds is the most helpful clue to diagnosis.

In the first few days of the illness the organisms can be isolated from the sputum and blood by inoculation into

mice or into the yolk sac of embryonated eggs or into irradiated cell cultures. Diagnosis can be established by demonstrating antibodies by ELISA or microimmunofluorescence.

Treatment

Tetracycline is very effective. It is given in a dose of 4 g/day for 2 days and then 2 g daily till recovery is complete. Doxycycline 100 po bd up to 3 weeks is a convenient alternative.

Control

Quarantine of birds imported from other countries should be insisted upon and the infected birds should be killed. Carrier state among the birds is reduced by incorporating tetracycline in bird feeds.

51

Viral Infections

K.V. Krishna Das

Chapter Summary

General Considerations 297

Laboratory Diagnosis 298

Prevention of Viral Diseases 299

General Considerations

Most of the viruses are not visible under light microscope. They vary in size from 300 nm to 20 nm. Each virus contains a nucleic acid molecule with either RNA or DNA as its genome. A complete viral particle which contains the genetic material (genome) and the surrounding protective coat which serves as vehicle for its transmission from one cell to another is called a *virion*. Viruses lack enzymes required for the synthesis of their components and for energy metabolism. They are, therefore, dependent on the metabolic pathways and components of their host cells. They are obligate intracellular parasites. They cause lesions in several living organism such as animals, insects,

plants and bacteria. Many viruses may live in their host cells without producing disease but some are pathogenic.

Viral Multiplication

Multiplication of viruses is controlled by the genetic information contained in the viral nucleic acid. Viral multiplication involves six sequential steps. These are: (i) adsorption to the host cell, (ii) entry to the cell, (iii) release of viral nucleic acid into the cell contents, (iv) biosynthesis of viral components, (v) maturation of the virus particles, and (vi) release of numerous virus particles from the host cell.

Viral infection causes demonstrable changes in the host cell such as cytolysis and destruction of the cell. Sometimes the virus may become latent and persist within the cell to be reactivated later. Incorporation of viral nucleic acid into the genome of the host cell may result in malignant transformation. Several cells may fuse together to form giant cells. In the central nervous system demyelination may occur. Many tissues infected by virus

show inclusion bodies within the cytoplasm or the nucleus. These are made up of aggregates of virions at the site of synthesis or these may merely represent products of degeneration caused by virus infection.

Viral Spread

The mechanism of transmission and portal of entry of viruses vary.

Common Routes of Entry

1. Respiratory tract e.g., coryza, influenza, measles and smallpox.
2. Alimentary tract e.g., enteroviruses and hepatitis A and E.
3. Abrasions or wounds on the skin which may be due to animal bites (rabies), arthropod vectors (arboviruses), injection (virus B hepatitis) or abrasions of skin (papilloma virus).
4. Intact conjunctiva (adenovirus and measles).
5. From mother to fetus through the placenta (rubella cytomegalovirus, HIV).
6. From the genital tract, during birth (Herpes simplex virus type II, HIV).

The outcome of infection by a virus depends on its virulence and the resistance of the host. The effects on the host may be divided into specific and nonspecific. Specific response is the production of immunity, while the nonspecific response includes fever and production of interferons. Both humoral and cellular immune responses play their roles in viral infections.

Proteins of the viral capsid stimulate the formation of humoral antibodies which neutralize the virus. They also cause complement mediated lysis of the infected host cells. Although in many cases the antibodies are protective, sometimes these are harmful, causing immune complex type of tissue injury to the renal glomeruli, synovia of joints or the skin. IgA antibodies secreted into the respiratory tract protect against infection by other respiratory viruses. Humoral immunity is vital for recovery from many viral infections, e.g. enterovirus infections. Some viruses like herpes, rubeola and pox stimulate cell-mediated immunity which plays the major role in defence.

Interferons

Interferons are proteid substances produced by the host cells in the early phase of infection. Other stimuli also may stimulate the production of interferons and hence this response is not strictly specific. Interferon protects the cell against the virus by interfering with the translation of viral messenger and thereby inhibiting viral multiplication. The interferons are not virus specific, but they show species specificity. Only interferons produced in human or primate cells have protective effect against human infections.

Viruses show variation in their susceptibility to interferons. Interferons exert their protective role even before humoral antibodies develop. At present interferons are produced commercially by DNA technology.

Laboratory Diagnosis

1. **Isolation of the organism:** Viruses can be isolated by inoculating material removed from the subject at the optimum time, into suitable cell systems like tissue culture media, chick embryos or experimental animals. Specimens include throat swabs, sputum, rectal swabs, blood, urine, CSF or vesicle fluid. Since the virus is present in the host in the early part of illness, specimens have to be collected early to isolate the organism. They have to be transported in sterile screw-capped bottles containing Hank's balanced salt solution. Such specimens can be stored at -70°C without affecting the viability of the virus. These methods are mainly used for research purposes at present.
2. **Demonstration of viral inclusions, viruses and viral antigens:** Viral infection used to be diagnosed by the demonstration of inclusion bodies under light microscopy, e.g., rabies and smallpox. At present the viruses can be identified by electron microscopy, e.g., rotavirus in feces.

The presence of viruses or viral antigens in tissues can be demonstrated by immunofluorescence, immunodiffusion, immunoelectron microscopy, radioimmunoassay, countercurrent immunoelectrophoresis and enzyme-linked immunosorbent assay (ELISA) techniques. These methods are being employed increasingly when viral isolation is difficult or impossible.

3. **PCR and other techniques** employed in molecular biology are widely employed to make specific diagnosis. Apart from identifying the virus, these methods also help to quantitate the viral load.
4. **Antibodies against viruses:** These can be demonstrated in the serum of the patient. Paired samples of sera are collected, the first sample in the acute phase and the second sample after an interval of 12-14 days. Humoral antibodies can be demonstrated by techniques such as virus neutralization, complement fixation, hemagglutination inhibition, indirect hemagglutination, immunofluorescence, radioimmunoassay and ELISA. In the acute phase IgM antibodies are formed, which give place to IgG antibodies as the infection becomes chronic, or with the passage of time.

The diagnosis of the viral infection can be confirmed by isolating the virus and demonstrating a four-fold increase in the specific antibody titers in paired samples of serum.

Prevention of Viral Diseases

At present, protection against many viral infections is possible by specific immunization. Live vaccines or inactivated vaccines are used for this purpose. Live vaccines are used in the cases of poliomyelitis (*Sabin's oral vaccine*), yellow fever, measles, mumps and rubella. Killed virus vaccines are used for prevention of rabies (*human diploid cell vaccine and duck embryo vaccine*), poliomyelitis (*Salk vaccine*), Japanese encephalitis and several others.

Passive immunization against diseases such as measles, mumps, rabies and infective hepatitis can be conferred by the use of human gammaglobulin or convalescent sera, early during the incubation period. Hyperimmune serum, which gives better protection, is used for the prevention of rabies.

Specific identification of the viral infection is important since specific methods for prevention and specific antiviral drugs are available.

52

Viral Infections of the Respiratory Tract

Coryza, Influenza, Parainfluenza, RSV, SARS, Nipah Virus, Human Metapneumo Virus

K.V. Krishna Das

6

Chapter Summary

- Coryza 299
- Influenza 300
- Avian Flu 302
- Parainfluenza 302
- Respiratory Syncytial Virus Infection (RSV) 303
- Severe Acute Respiratory Syndrome (SARS) 303
- Other Paramyxoviruses 304
- Nipah Virus 304
- Human Metapneumo Virus 304

Coryza

Several viruses cause the clinical picture of coryza. Of these, *rhinoviruses* are the most important and common. The disease spreads by droplet infection and the portal of entry is the upper respiratory tract. Epidemics occur in early autumn, mid-winter and spring. Incubation period varies from a few hours to 3 to 4 days. Hyperemia and edema of the mucosa of the nose and rhinopharynx are the early lesions. Copious amounts of watery fluid rich in glycoproteins exude. After a short course the disease spontaneously subsides completely without any residual damage.

Clinical Features

Onset is abrupt with headache, nasal congestion and obstruction. It is followed by sneezing and watery discharge from the nose, which becomes mucopurulent and tenacious later on. Mild fever (37.5-38°C) and muscle pains set in within a few hours. The whole course lasts for 2-3 days. Coryza predisposes to the development of secondary bacterial infection. Physical examination is negative except for nasal congestion, conjunctival injection and pharyngitis. Complications are sinusitis, infection of the lower respiratory tract and otitis media.

Diagnosis

Clinical diagnosis is easy. Secondary bacterial infection should be looked for. Coryza has to be distinguished from allergic rhinitis in which nasal congestion may be prominent. In this, there may be other signs of allergy like pruritus and asthma extending for long periods. The causative organism of coryza can be cultured from throat washings or nasal swabs.

Treatment

Treatment is symptomatic. Confinement to home and avoidance of contact with others help to shorten the course of the illness and limit its spread. Paracetamol 0.5 g given thrice daily provides symptomatic relief of aches and

pains. Medicated inhalations, throat lozenges and decongestant nasal drops are all helpful. Specific protection using vaccines which contain a few strains of rhinoviruses has been attempted on a limited scale.

Influenza

Influenza is a common viral disease which presents as an acute febrile illness. It is caused by three groups of *myxoviruses*, important among them being *Influenza virus A, B and C* which are antigenically different. Influenza A has occurred in pandemics on several occasions. India experienced influenza pandemics in 1781, 1889, 1918, 1957, 1968 and 1977. The pandemic that took place in 1977 was due to H1N1. During these pandemics the antigenicity of the causative organisms has changed due to the development of new mutants. Influenza A, B and C consist of at least four subgroups each. The virus is spherical (80-120 nm in diameter) or filamentous in shape. The virus has a glycoprotein coat possessing hemagglutinin (H) and neuraminidase (N) activity. The subtypes of influenza viruses differ in their surface proteins-Hemagglutinins (H) and neuraminidase (N). The usual human subtypes are H1N1, H1N2 and H3N2. Influenza viruses undergo re-assortment of their genetic material between different influenza viruses and new strains emerge, so that existing vaccines may be ineffective to protect against newer strains.

During epidemics children and the elderly suffer more. Dissemination of the virus occurs more readily when people are crowded together. Infection is through the respiratory tract. Influenza can also occur as inter-pandemic illness. This takes the form of sporadic illness or local outbreaks.

Influenza B causes localized outbreaks in closed communities such as schools, military camps and dormitories. Influenza C leads to human disease only rarely.

Pathology

Virus spreads by the respiratory route. Viral multiplication reaches its peak in 24-72 hours after the onset of the clinical illness. The virus multiplies in cells lining the respiratory tract including the ciliated epithelium, alveolar cells, mucous gland cells and macrophages. The infected cells show degenerative changes like cytoplasmic granulation, vacuolation and swelling. Ultimately the cells undergo necrosis and they slough away. The mucosa is hyperemic and edematous. Focal hemorrhages are common in these sites. Pneumonia may occur primarily due to viral infection, though it is more common to get secondary bacterial pneumonia. In viral pneumonia intra-alveolar hemorrhage may occur. Secondary bacterial infection occurs in about 25% of cases and it gives rise to suppurative inflammation.

Fig. 52.1: X-ray chest pneumonia

Clinical Manifestations

The incubation period ranges from a few to 48 hours. Onset is sudden with fever, severe generalized myalgia and prostration. There is spasmodic non-productive cough. Conjunctiva is injected. Temperature varies from 38°C to 40°C and may last for 3-4 days. In the uncomplicated case there is relative bradycardia. Severe complications may occur in a few, especially at the extremes of age and in debilitated subjects. Mortality is higher in the age groups below 2 years and above 65 years.

Complications

Pulmonary Complications

These include primary influenza virus pneumonia, influenzal pneumonia with secondary bacterial infections, and bacterial pneumonia with multiple organisms (Fig. 52.1).

1. **Primary influenza virus pneumonia:** This is a serious condition associated with high mortality. These subjects present with high fever, cough with blood stained expectoration, dyspnea and cyanosis. Examination of the chest may reveal bilateral rhonchi and crepitations. Pulmonary involvement is diffuse. Fever and respiratory signs persist despite antibiotic therapy and other symptomatic measures. The course is more acute and serious in those cases with rheumatic heart disease, myocardial infarction, or chronic obstructive airway disease.
2. **Influenzal pneumonia with secondary bacterial infection:** In addition to viral pneumonia, localized consolidation may also develop.
3. **Bacterial pneumonia:** The condition is caused by multiple organisms such as *staphylococci*, *H.*

influenzae, group A streptococci, and pneumococci. This type of pneumonia carries a grave prognosis.

Cardiac Complications

Toxic myocarditis may occur. This gives rise to tachycardia and cardiac failure. The ECG may be abnormal.

Neurological Complications

These include febrile convulsions, meningitis, meningo-encephalitis and encephalitis. A rare complication is the development of Reye's syndrome, which is more frequently seen in children. It presents as hepatic failure with encephalopathy and rise in intracranial tension. Reye's syndrome is associated with ingestion of aspirin. Apart from influenza A and B other viruses may also lead to this syndrome, e.g. varicella. Reye's syndrome develops as a result of serious derangement of mitochondrial function.

Diagnosis

The diagnosis is not difficult during an epidemic. Coryza may be mistaken for a mild attack of influenza. Nasal symptoms predominate in coryza but are less marked in influenza.

Adenovirus infection, which may resemble influenza, can be diagnosed by the prominence of sore throat and pharyngitis. Primary atypical pneumonia has to be differentiated from influenza virus pneumonia. In primary atypical pneumonia the sputum is more purulent. It is of gradual onset and the clinical course is milder.

Streptococcal pharyngitis may present as a short duration fever with sore throat. Its incidence is higher in children. Cervical adenitis is present and blood shows neutrophil leucocytosis. The severe pain and bodyache of influenza may be mistaken for dengue fever and sandfly fever.

Specific diagnosis can be made by isolating the virus from throat washings or sputum and by demonstration of four-fold rise in titre of antibodies in paired sera by hemagglutination inhibition test.

Prognosis

The disease runs a benign course without complications in the majority of cases. Uncomplicated cases recover within a week or two. Complications increase the mortality. In many cases convalescence may be prolonged. Generalized vague ill-health may persist for several weeks.

Treatment

Bed rest is essential during the period of illness and during convalescence. If there is secondary bacterial infection, a course of appropriate antibiotics should be given.

Specific drugs include **amantadine**, **rimantadine**, **zanamivir** and **ostelamivir**. These drugs act on the virus in different ways.

Amantadine in a dose of 100 mg given twice daily for 10 to 14 days offers chemoprophylaxis against influenza A virus, but not B. It protects the host cell from virus invasion. These drugs interfere with viral uncoating within the cell. Amantadine and rimantidine reduce the duration of fever by 1-2 days. These are ineffective against avian influenza. Prolonged administration during outbreaks reduces the incidence of fresh infections by 50% and ameliorates the disease in 70-100% of clinical cases. Side effects of amantadine include nausea, headache and neurological features. **Rimantadine** which is an analogue of amantadine is also effective.

Neuraminidase Inhibitors

Neuraminidase promotes influenza virus release from infected cells and facilitates viral spread within the respiratory tract, two neuraminidase inhibitors have been licenced for human use—zanamivir and oseltamivir. Unlike amantadine and rimantadine that target M2 protein of influenza A virus, these inhibit the replication of both of influenza A and B viruses. Zanamivir is given by inhalation due to its low availability when given orally. Oseltamivir is active when given orally. Both the drugs are good for chemoprophylaxis. When given early during the disease they reduce the severity, complications and duration. Compared to amantadine and rimantidine, development of resistance is also less.

Dose: Zanamivir (manufacturers Biote/Glaxo)

Inhalation: 5 mg Zanamivir + (20 mg lactose). After a single inhalation the drug is detectable in sputum for 2-7 days.

Ostelamivir (Tamifin) given in dose of 75 to 150 mg bd orally early in the disease probably controls the infection. Success is directly correlated with earlier administration of the drug. In children the dose is 30 mg bd oral for 5 days. Resistance of the virus to ostelamivir is being reported.

Specific Prevention

Vaccines containing inactivated viruses are available for use during pandemics or epidemics and these offer 90% protection. Since the viral characteristics change from time to time the composition of the vaccine has also to be different at times.

The general direction for the vaccine is given by the WHO, taking into consideration the most prevalent viral strains. Usually the vaccine contains A and B strains. One dose in previously exposed individuals and two doses in unprimed subjects give a 90% protection rate. Mild local and general side effects may occur in a few. Sensitivity to egg protein is a contraindication for the vaccine. Pregnancy is not a contraindication.

AVIAN FLU (INFLUENZA GROUP A H5N1 VIRUS)

The Threat of a Pandemic by the Avian Influenza Virus

The subtype H5 N1 influenza virus is a natural pathogen of chicken, ducks, turkeys and others. Though it was thought to be pathogenic only to them, the subtype H5N1 has crossed over to infect humans and caused small outbreaks. Hong Kong (1977) Thailand, Cambodia, Indonesia and several other Asian countries have reported outbreaks in poultry by H5N1 virus. In India H5N1 virus has been identified in Nawapur and Jalagon in Maharashtra State. As on 26th April 2006 the WHO cases has reported the occurrence of 205 confirmed cases in humans, with 113 deaths (55%). If human to human transmission of the virus becomes efficient, devastating pandemic more severe than the previous ones is likely to breakout. *Hence this matter is of great concern to all nations.*

Pathologically the lesions resemble those of classic influenza, but hemophagocytic histiocytosis may also be seen.

Clinical Features

The incubation period for human influenza viruses is short-2 to 3 days (range 1-7 days). However with influenza A H5N1 the median time between exposure and onset of illness is 3 days (range 2 to 4 days). Most cases have occurred in previously healthy children and young adults. Symptoms of bird flu in humans include fever, cough, and sore throat, pneumonia, acute respiratory distress, and life-threatening complications. The symptoms of bird flu may vary depending on the type of virus. Primary viral pneumonia and multi-organ failure are common. In the present outbreak, more than half of those infected with the virus have died. Death is due to respiratory failure and multi-organ failure especially respiratory, renal and cardiac failure.

Case Definitions

Criteria for suspecting avian flu. Persons with illness characterized by fever, (temperature > 38°C), cough and/or sore throat, severe respiratory symptoms and one or more of the following:

1. contact with a confirmed case of influenza A H5N1 during the infectious period,
2. recent (less than 1 week) visit to a poultry farm in an area known to have outbreaks of HPAI (highly pathogenic avian influenza), or
3. worked in a laboratory that is processing samples from persons or animals suspected to be having HPAI infection.

Procedure to Establish the Diagnosis

1. Suspect the disease and start investigations. Virus can be isolated from pharyngeal secretions 2-15 days after the onset of illness. Nasal secretions, blood, CSF and feces also contain the virus. Children may continue to shed the virus in nasal discharges for over 2 weeks after recovering from the acute attack.
2. Positive immunofluorescence antibody (IFA) using H5N1 monoclonal antibodies can be demonstrated in serum.

Diagnosis is confirmed by the following tests:

1. positive viral culture for influenza A H5N1.
2. positive real time PCR for influenza A H5N1.
3. and/or four-fold rise in H5N1-specific antibody titer.

Management

Avian influenza virus is resistant to amantadine and rimantadine. Oseltamivir 75 mg orally twice daily for 5 days and zanamivir would probably be useful if started as early as possible. No vaccine is available now to protect against H5N1 virus for general use.

A 2 dose regimen of 90 µg of sub-virion influenza A (H5N1) given IM over the deltoid muscle at 28 days interval generates neutralizing antibody. This vaccine is under trial.

Infection Control Precautions for Hospital Staff

Patients who have visited endemic regions within 10 days and who present with severe febrile illness and respiratory symptoms should be observed for avian influenza, with isolation, barrier nursing and other precautions.

1. Proper hand washing before and after contact with the patient.
2. Use gloves and gowns for all patient contacts. Use separate equipment for individual patients.
3. Protection of the eyes with goggles or face shields.
4. Precautions against droplet infection: Patients should be isolated in monitored negative air pressure ventilation systems. Health care staff should use a fit-tested respirator, or approved N-95 filtering mask when entering the room.
5. Suspected poultry meat and eggs should be properly cooked so that the whole item reaches a minimum temperature 70°C which is needed to destroy the virus.

Parainfluenza

This is caused by para influenza viruses which belong to the group of paramyxoviruses. Other members of the group include mumps measles respiratory syncytial virus and human metapneumovirus. These viruses are 80-120 nm in size. They cause respiratory infection. Based on antigenic differences, para influenza viruses are divided

into four types. Para influenza has nothing in common with influenza virus. Para influenza viruses affect mostly children. Mainly the respiratory tract is involved.

Clinical Manifestations

After an incubation period of 5-6 days, it starts with fever which is a constant feature. Type I infection causes laryngotracheobronchitis or croup. Type II infection causes tracheobronchitis, bronchiolitis and bronchopneumonia in infants and children. Submandibular lymph nodes may become enlarged and tender. **Complications** include secondary bacterial infection leading to otitis media, sinusitis and bronchiectasis.

Treatment

There is no specific drug against this virus. Secondary bacterial infection has to be treated with antibiotics.

Respiratory Syncytial Virus Infection (RSV)

It is a major pathogen of the lower respiratory tract in infants and elderly persons, especially immunocompromised. It belongs to the family Paramyxovirus and the genus Pneumovirus. According to WHO data a third of the deaths in children below 5 years of age is due to respiratory tract infections caused mainly by *Str. pneumoniae*, *H. influenzae* and RSV. There is no clear data of the epidemiology of RSV infection in India. Still it is most likely that the infection is quite prevalent. Route of infection is the upper respiratory tract, especially the nasopharynx and the eyes. Incubation period is 3-5 days. Main pathological lesions are in the bronchiolar epithelial cells leading to inflammation and edema of the peribronchial region. Plugs containing mucus and epithelial debris lead to ball-valve obstruction of distal airways with air trapping. Cellular immunity plays a major role in the recovery from infection.

Clinical Features

Most common manifestations are rhinitis, cough and fever at times. Otitis media, bronchiolitis, pneumonia and croup are common in children. Severe bronchiolitis may lead to respiratory failure.

In adults RSV infection leads to exacerbation of chronic bronchitis and emphysema.

Diagnosis is established by demonstration of RSV antigens in nasopharyngeal washings, by ELISA.

Management

In many cases the disease is self limiting and only supportive measures are needed.

Ribavirin is probably effective as an antiviral agent and this should be employed in severe cases.

Prophylaxis

Vaccines are under trial. In immunocompromised infants a humanized monoclonal antibody may be tried with benefit during epidemics. While attending to cases, handwashing and avoiding contamination by oronasal discharges are important.

Severe Acute Respiratory Syndrome (SARS)

SARS is an emerging infectious disease caused by a novel corona virus first described from China and Hong Kong and reported in 2003, which threatened to assume pandemic dimensions. The disease spreads widely, probably by the respiratory route by droplet infection even by very short periods of exposure. Possibly the secretions from other sites and excreta are also infectious. Direct exposure, closed environment in aircrafts and air travel contributed to the dissemination of the virus in many parts of the world. The disease was effectively contained from spreading, by prompt action directed by the W.H.O and taken up internationally. India did not have proved cases of SARS during this period.

Clinical Features

The cases presented with fever initially with or without chills or rigor, influenza-like symptoms and radiological signs compatible with pneumonia. History of contact with established cases was present. The mean age of the patients were 35-40 years. Presenting symptoms include pyrexia (90%), chills or rigor (71%), cough (52%), vague symptoms (50-60%), dyspnea (30%) and diarrhea (25%).

Common laboratory findings include lymphopenia in 58%, thrombocytopenia in 40% and raised lactate dehydrogenase (LDH) in 70%. Viral RNA can be identified by real time PCR (RTPCR) from nasopharyngeal aspirate, stool and urine. Seroconversion occurs slowly and IgG might be detected by 8-10 weeks.

Radiological abnormalities were present in all cases on admission or follow up. In 70% they were bilateral. The abnormalities include subtle haziness (36%), mild infiltrates and ground glass appearance (57%), denser infiltrates and dense confluent opacities (7%).

The differential diagnosis includes atypical pneumonia, influenza, parainfluenza, respiratory syncytial virus and adenovirus infections, and pneumocystis pneumonia. The disease carries a high mortality exceeding 50%, if unrecognized.

Management

SARS should be suspected in acute febrile illnesses with moderate or severe respiratory embarrassment. Isolation of the patient and protection of health care staff should be instituted as described for avian flu (pp 302).

Environment and contaminated materials are disinfected by domestic bleach (1000 ppm hypochlorite

solution) for non-metallic articles and 70% alcohol for metallic objects.

Specific Therapy

1. Anti bacterial drugs: Treatment with levofloxacin 500 mg once a day IV or oral should be started without delay in patients above 18 years of age. In patients younger than 18 years, pregnant women and patients suspected to have tuberculosis clarithromycin 500 mg orally bd with co-amoxyclav (amoxycillin and clavulanic acid) 375 mg tds is the combination of choice.
2. If chest radiograph shows extensive lesions or clinical features are worsening the antiviral drug ribavarin should be started in doses of 400 mg 8 h (1200 mg/day) IV for 3 days or till the condition becomes stable, and thereafter 1200 mg oral bd (total 2400 mg/day) for 10-14 days.
3. Corticosteroids should be started along with ribavarin. The standard protocol consist of a 21 day regimen as follows:
 - a. Methyl prednisolone 1 mg/kg bw 8 h IV (total 3 mg/kg bw/ day) for 5 days
 - b. Methyl prednisolone 1 mg/kg bw/ day IV for 5 days
 - c. Prednisolone oral 0.5 mg/kg bw/bd daily for 5 days
 - d. Prednisolone oral 0.5 mg/kg bw od daily for 3 days, and
 - e. Prednisolone oral 0.25 mg/kg bw od for 3 days.Ventilation should be assisted in those having ventilatory problems. Success rate of treatment is high, if instituted early.

Points to remember

1. SARS is an emerging, serious life threatening infection by a corona virus which ushered in several parts of the world in 2003.
2. Prompt recognition of the mode of spread and International action helped to prevent the spread of the disease.
3. All health care professionals should be aware of such infections and early reporting to public health authorities is vital, to prevent devastating outbreaks.

Ref. Loletta K.Y.So Development of a standard treatment protocol for severe acute respiratory syndrome. The Lancet 2003, 361 1615-1617.

Other Paramyxoviruses

NIPAH VIRUS

Other paramyxovirus infections are being reported in recent times. Nipah virus is a member of this group which was identified to produce local outbreaks of encephalitis-like illness in persons working in pig farms and abattoir workers handling pigs in Singapore. Further reports are likely to follow.

HUMAN METAPNEUMO VIRUS

Human metapneumovirus is a common respiratory pathogen especially in children. It is a RNA virus. It causes bronchitis in 59%, pneumonia in 8% croup in 18% and exacerbation of asthma in 14%. Nasal wash specimen is used to isolate virus.

Measles

Syn: Rubeola

Measles or Rubeola (red spots-Arabic) is an acute exanthematous febrile illness caused by a specific virus of the paramyxovirus group affecting children more. It is an RNA virus varying in size from 150-300 nm.

The present day major killers of children globally are measles, diphtheria, whooping cough, tetanus, tuberculosis, polio-like paralysis and to some extent poliomyelitis.

In developing countries 10% of all deaths in children below 5 years of age are measles related.

Pathogenesis and Pathology

Man is the only natural host. The disease may occur in localized or wider outbreaks once in 2-3 years, especially during spring. The virus is present in the nasopharyngeal secretions, and infection is by droplets. Portals of entry are the respiratory mucous membrane and the conjunctiva. The period of infectivity starts 5 days after the exposure to the virus and lasts until 5 days after skin eruptions have appeared. Infants do not generally suffer, presumably because of the persistence of maternal antibodies in them.

The virus multiplies in the epithelium of the respiratory tract and then causes viremia. Hematogenous spread occurs to various tissues. The virus can be isolated from blood, conjunctiva, lymphoid tissues, and secretions of the respiratory tract for a few days before and for 1 or 2 days after the appearance of rashes and from the urine as long as 4 days after the rash. Following the viremic phase the virus localizes in the skin and respiratory tract in addition to several tissues. There is interaction between the virus and the T-cells.

The mucous membrane lesions (enanthem) known as *Koplik's spots* seen in the cheeks, consist of vesicles and necrotic epithelium. Microscopically the lesions show cytoplasmic and intranuclear inclusions, giant cells and intercellular edema. Aggregates of virions in the affected cells can be demonstrated by electron microscopy.

Multinucleated giant cells with acidophilic nuclear and cytoplasmic inclusions (*Warthin Finkelday cells*) may be found in the hyperplastic lymphoid tissues of lymph nodes, tonsils, spleen and thymus. Chromosomal breaks may be seen in leucocytes. Epithelium of the respiratory tract is disrupted and this favours secondary bacterial infection. Lungs show interstitial pneumonia with giant cell infiltration. In patients, who develop encephalomyelitis, the brain shows focal hemorrhage, congestion and perivenous demyelination.

Clinical Features

Incubation period is 9-11 days. The initial manifestations are malaise, irritability, high fever, conjunctivitis with

excessive lacrimation, edema of the eyelids, photophobia, hacking cough and nasal discharge. These symptoms last for 3-4 days (up to 8 days) and then the rashes start. Koplik's spots appear as small, red irregular lesions with bluish-white center on the mucous membrane of mouth 1-2 days before the skin rash. They are best seen in the buccal mucosa opposite the upper molar teeth. Lesions similar to them may occur in the conjunctiva and intestinal mucosa. The rashes are red and maculopapular, first appearing on the forehead and behind the pinna, later on spreading down to the face, neck, trunk and limbs. Maximum affection is on the face and shoulders. These rashes persist for about 3 days and disappear in the order in which they appeared. The disease becomes more severe in adults in whom complications are likely to be more. The general symptoms disappear 1-2 days after the appearance of skin rash. Cough may persist throughout the illness.

Complications

These are common, though in the majority the disease is self-limiting. Respiratory complications include croup, bronchitis, bronchiolitis and rarely interstitial giant cell pneumonia. These are more common in immunocompromised persons and malnourished children. The eye lesion may progress to corneal ulceration, keratitis and blindness. Myocarditis develops in 20% of cases and this causes transient ECG changes, but clinically this may remain silent. Acute abdominal pain may occur due to mesenteric lymphadenitis. In pregnant women, fetal loss may occur in 20% of cases.

Secondary bacterial pneumonia by *Staphylococcus*, *Streptococcus*, *Pneumococcus* and *H. influenzae* is common and may progress to lung abscess and empyema. Otitis media may develop commonly. Stomatitis may develop and progress to cancrum oris, especially in malnourished children. Quiescent tuberculous lesions may flare up or fresh tuberculous infection may develop. Diarrhea may occur as a complication and may prove troublesome.

Neurological complications of measles include;

Acute post infectious measles encephalitis caused by cell mediated autoimmune response to measles virus-frequency 1/1000 cases. *Encephalomyelitis*, another serious complication, occurs in 1/1000 patients, usually occurring 4-7 days after the appearance of the eruption. It is characterized by high fever, headache, drowsiness and coma ending fatally in 10% of cases.

Measles inclusion body encephalitis (MIBE) – This occurs only in immunocompromised subjects.

It is a subacute infection occurring 1-7 years after infection. Measles virus persists in the brain. It presents as alterations in cognition, convulsions and coma. This disease is invariably fatal.

Progressive encephalitis may develop in 1-6 months after measles in immunosuppressed children. Subacute sclerosing panencephalitis (SSPE) is a late complication of measles in which the virus persists in the brain, possibly with alteration of matrix proteins. It is characterized by progressive dementia and motor weakness. In this disorder the measles virus tends to persist for long in neural tissue and bring about slow degenerative lesions and a clinical picture similar to slow virus infections result. SSPE is estimated to occur with a frequency of 1/8000 in children infected with measles.

Laboratory Diagnosis

Laboratory investigations are essential to diagnose atypical cases and also for differentiating measles from rubella. Leucopenia is frequent in the early stages. Leucocytosis occurs with secondary bacterial infection. Cerebrospinal fluid shows raised protein and lymphocytosis in encephalomyelitis.

Demonstration of multinucleated giant cells in Giemsa stained smears of nasal secretions is a simple side room laboratory test. Virus antigen can be detected in the cells by immunofluorescence. Virus can be isolated in human embryonic kidney and amnion cells.

Demonstration of rising antibody levels by complement fixation test, hemagglutination inhibition test and neutralization test in paired sera help to make serological diagnosis.

Differential Diagnosis

Rubella has to be differentiated from measles. Rubella is a milder illness of short duration without significant respiratory complaints. Infectious mononucleosis, toxoplasmosis, secondary syphilis, adenovirus and enterovirus infections, scarlet fever and drug rashes have to be differentiated.

Treatment

There is no specific drug against the virus and, therefore, management is symptomatic. Bacterial infection has to be treated with antibiotics based on clinical and bacteriological findings. Children who continue to be ill after an attack of measles should be investigated for the presence of tuberculosis.

Prevention

Administration of gammaglobulin 0.25 mL/kg within 5 days of exposure effectively prevents or attenuates the attack. Children below three years, pregnant women, immunocompromised persons and those who suffer from tuberculosis should be given gammaglobulin for passive immunization.

Live attenuated measles vaccine, prepared from *Edmonston B strains of measles virus* is used for active immunization. Immunity lasts for a period of over 10 years. Vaccination after 12 months of age is more effective, though earlier vaccination can be done in measles prevalent areas. In those vaccinated before 12 months, a second dose should be given at the age of 15-18 months. The vaccine may be given alone or in combination with rubella and mumps vaccines. Vaccination is contraindicated in pregnancy, tuberculosis, leukemia, lymphoma and immunocompromised patients. Combined vaccines for measles, mumps and rubella are available (MMR vaccine). Adverse effects include fever in 5-15% and rashes. MMR vaccination 2 doses give seroconversion in 98% for measles and only 88% for mumps. So more among the vaccinated persons are susceptible to mumps than measles.

Measles vaccine is supplied free of cost along with the general immunization schedule. MMR vaccine is available at cost for those who prefer to take it. Several reports suggest that supplementation of vitamin A (400000 units or 20 mg once orally) to undernourished children help to reduce mortality during measles outbreaks.

Though the WHO recommended vaccination coverage of 90% of the children by 2000 AD, this target is still to be achieved. Vaccination is very effective in preventing measles and SSPE.

Aerosol vaccines using Schwartz or Edmonston-Zagreb strains of the virus have been compared with the standard subcutaneous injection. The antibody response at one month and one year are reported to be comparable.

Smallpox Syn. Variola

Smallpox is a natural infection in man caused by variola virus and the virus affects only humans. The virus is 200-250 nm in size and belongs to the group of pox viruses which are DNA viruses. The variants of variola virus – variola major and variola minor can be distinguished in the laboratory. Studies to sequence the genome of the virus are in progress.

The virus is transmitted from man-to-man by the respiratory route. There are no animal reservoirs or insect vectors in the transmission of this disease. The transmission may be direct from patient-to-patient or through fomites and other contaminated articles. Nasopharyngeal secretions, vesicle fluid, and dried scabs contain the virus. The virus can remain viable in dried scab for over one year. The patient is infective from the onset of early symptoms till the last scab has fallen off.

Though smallpox was one of the most dreaded diseases and outbreaks occurred in the tropics regularly, at present the disease has been eradicated by worldwide

efforts undertaken by the WHO from 1967 to 1977. The world was declared free of natural infection in October 1977. In India the last case was reported in 1976. Except for the stock cultures of the virus maintained in a few laboratories the virus is believed to have disappeared. This achievement was made possible by an intensive program of mass vaccination and early case reporting. Absence of any non-human reservoir and vector and the solid immunity produced by vaccination have contributed to the achievement. Variola virus proteins modulate the immune system. *Since the virus can be grown easily and modified genetically to evade the vaccination induced immunity, it is a good candidate for bio-terrorism and warfare.*

Pathology

After entry, the virus reaches the lymph nodes, where it multiplies and then enters the circulation. The skin and mucous membranes are affected thereafter. Cellular, humoral and innate immunity influence the course of small pox. The affected epithelial cells show acidophilic cytoplasmic inclusion bodies called *Guarnieri bodies*. These are aggregates of the virus particles which are called *Paschen bodies*.

CLINICAL MANIFESTATIONS

The incubation period is 12 days (8-16 days). Prodromal symptoms occur 2-4 days before the eruption starts. These consist of high fever, myalgia, headache, backache, delirium and abdominal pain. The rash starts on the third day and the fever subsides when the rash appears. Fever reappears after varying intervals, when the rash becomes pustular. The temperature comes down with scabbing. The rashes are characteristic. They are distributed in a centrifugal pattern. The face, arms and legs are more often and more heavily affected. Presence of vesicles in the palms and soles is characteristic (Fig. 53.1). Initial lesions are erythematous macules, which progress successively into papules, vesicles, pustules and scabs at 48-hour

intervals. The vesicles and pustules are deep-set in the skin, multiloculated and the center is umbilicated. Unlike as in chickenpox, all the vesicles are at the same stage of development. When the scab separates, pitted scars are left behind, which tend to remain permanent.

In vaccinated individuals who possess residual immunity, the clinical picture is modified and this is termed varioloid. This is abrupt in onset with the development of only a few rashes. The course is benign. Smallpox may occur without the characteristic rash “*variola sine eruption*”. A less virulent form of the virus capable of producing milder manifestations, “*variola minor*” (*alastrim*), has also been recognized.

Other serious clinical types may occur less commonly. These are hemorrhagic smallpox which is highly fatal, and the flat form in which the papules are velvety, which may become vesicular and lead to peeling off of the whole epidermis.

Complications

Secondary infection by staphylococci occurs during the stage of pustulation. This may lead to septicemia, pneumonia, osteomyelitis, septic arthritis, otitis media and pyelonephritis. Death is due to coagulopathy, hypotension and multi-organ failure. In the eye, vesicles in the cornea may suppurate and lead to panophthalmitis and blindness. Smallpox was a common cause of blindness in India till three decades ago. Neurological complications include demyelinating lesions such as encephalitis, encephalomyelitis and peripheral neuritis. Laryngeal edema may occur, leading to respiratory obstruction.

Osteomyelitis Variolosa

In this form of destructive osteomyelitis, the metaphyses are infected with the virus during the phase of viremia, but symptoms are late to develop. Destruction and detachment of the epiphyses lead to permanent bone and joint deformities which persist in later life (Fig. 53.2).

Fig. 53.1: Smallpox (1) Distribution of rash (2) Note the deep seated vessels, all at the same stage of development

Fig. 53.2: Osteomyelitis variolosa

6

Course and Prognosis

Till the middle of this century smallpox used to be a major killer among children with a mortality of 20-80% among unvaccinated subjects. Death is due to severe toxemia or secondary infection.

DIAGNOSIS

Clinically smallpox should be suspected when an unvaccinated person gets high fever with prodroma and rash occurring on the third day. The distribution and progress of the rash strengthens the diagnosis. Since the world has been declared free of smallpox, physicians have to be alert to detect initial cases and subject them to thorough laboratory investigations. By international agreement reporting of fresh cases to the health authorities carries a cash award. Chickenpox, drug rashes and erythema multiforme are to be differentiated from smallpox. Rickettsial pox and pustular syphilis may resemble mild cases of smallpox.

Laboratory Diagnosis

1. Demonstration of the virus in material from vesicles or crusts by electron microscopy. Characteristic brick-shaped virus can be identified. PCR assays confirm the presence of virus.
2. Identification of Guarnieri bodies from the vesicular material.
3. Isolation of the virus.

Treatment

The treatment is mainly supportive. Antibiotics are used when secondary bacterial infection occurs. After exposure, the attack can be prevented by administering methisazone in a dose of 1.5-3 g twice daily for four days. Methisazone offers protection in unvaccinated individuals but it has no curative effect when the disease is manifest. Vaccinia immunoglobulin can be administered and it has a protective role. Early notification of cases, strict barrier

nursing and large scale immunization of the surrounding population should be undertaken to prevent the spread of the disease. Since the vaccine is not at present available for regular use, vaccination programs have to be undertaken by the appropriate health authorities.

Prevention

Vaccination used to be the most effective method to prevent smallpox. It was introduced by Edward Jenner on May 14, 1796. Since the world is declared free of smallpox, regular vaccination of infants is not insisted upon at present. Several strains of vaccinia of low pathogenicity are used for the vaccine. Single clones are used for vaccine production. Attenuation is achieved by serial passage in non-human tissue. Third generation vaccines are under development. The immunity is solid, the exact duration is not clear. There is evidence that the conventional vaccine diluted ten times still maintains its immunogenicity. Vaccination done within 3-4 days of exposure will prevent or allay the disease manifestations. Due to the fear of bioterrorism, many countries are actively producing smallpox vaccine. Priority is to vaccinate health care workers.

The vaccine contains killed or freeze dried vaccinia virus. Though generally safe, rarely complications occur. These include generalized vaccinia, secondary infection, eczema vaccinatum, progressive vaccinia (vaccinia gangrenosa) and post-vaccinial encephalitis.

The doctor working in India has to keep smallpox in mind and report the first suspicious case to prevent the occurrence of a devastating epidemic in a non-immune population.

WHO website on additional information on small pox are available at <http://www.who.int/topics/smallpox>

Chickenpox

Syn: Varicella

Chickenpox is a common viral infection occurring frequently in children. The disease is highly contagious. It is characterized by fever and disseminated vesicular eruptions. Though in children the disease is benign and self-limiting, as age advances the disease becomes more serious and produces grave complications.

The etiological agents of varicella and herpes zoster are identical in all respects. The varicella zoster (V-Z) virus is a DNA virus measuring 100-150 nm in diameter. It multiplies in the nuclei of infected cells and produces intranuclear inclusions.

It is an exclusively human herpes virus that causes chickenpox (varicella), become latent in cranial nerves and dorsal root ganglia, to be reactivated later to produce shingles (zoster) and post-herpetic neuralgia.

Pathogenesis and Pathology

Cases of chickenpox are most infective in the early stages of illness and virus is present in the lesions and the respiratory discharges. Infection occurs by respiratory route, contacts or nosocomially. After entry there is a period of blood stream dissemination and widespread organ involvement demonstrable in autopsies. Vesicles develop in the skin and mucous membranes. The epidermis undergoes degeneration. The vesicles contain serum, polymorphs and multinucleated giant cells. Virus is present in vesicle fluid for 3-4 days, but not after the onset of crusting.

As a complication, pneumonia may occur. In varicella pneumonia the tracheobronchial mucosa, the alveolar septa and the interstitial tissues of the lungs are edematous and show mononuclear cells with intranuclear inclusions and giant cells. Pneumonia develops as nodular areas of consolidation in the lungs. Ultimately these lesions may become calcified. Encephalomyelitis which resembles that seen in measles may occur as a complication. During the acute phase of the disease infants and children may develop acute encephalopathy with fatty infiltration of the viscera (*Reye's syndrome*).

Epidemiology

The infectious period extends from a day or two before the onset of the rash to six days after the appearance of new skin lesions or until all vesicles have started crusting. Chickenpox develops commonly due to exposure to other cases of chickenpox and rarely in contacts of herpes zoster. Herpes zoster is mainly a disease of adults who have partial immunity to the virus. Though chickenpox produces good immunity, it wanes off after 10 years and second attacks may develop.

CLINICAL FEATURES

The rashes appear 14-16 days after exposure (range 10-23 days). Prodromal symptoms are mild in children, the first manifestation in whom is the appearance of vesicles. Early symptoms in adults include fever, headache, backache, sore throat and malaise which last for 2 or 3 days. Enanthem occurs over the palatal and pharyngeal mucosa even before the skin rash appears. The skin rashes (*exanthem*) come up in crops starting from the first day of fever and these continue for 3-4 days so that lesions at different stages—macule, papule, vesicle, pustule and scab—may be present simultaneously (*polymorphism*). The rashes are centripetal, maximally affecting the trunk and sparing the distal parts of the limbs. Face may be affected variably. The axillae are almost invariably affected. The vesicles are unilocular, *superficial, elliptical in shape and contain clear fluid in the beginning (tear drop vesicles)*. These become pustular in 24 hours. Intense

Fig. 53.3: Chickenpox. Note superficial vesicles; in different stages of development

pruritus may develop and scratching disrupts these vesicles. The pustules dry up to form scabs in a few days. When the scabs fall off, superficial scars are left behind which clear up in due course. Recovery is the rule in the vast majority of healthy subjects. Complications and death may occur in immunosuppressed persons and children receiving glucocorticoids. In them progressive varicella develops and organ involvement is more common (Fig. 53.3).

Complications

1. Thrombocytopenia may develop leading to hemorrhage into the vesicles, conjunctiva and intestines.
2. Staphylococcal infection may supervene leading to bacteremia and delayed healing.
3. Children with impetigo may develop bullous lesions.
4. Superinfection by hemolytic streptococci causes varicella gangrenosa.
5. Around 15% of adults with chickenpox may develop primary varicella pneumonia. This is manifested 1-6 days after the onset of the rash. This may be asymptomatic or it may present with high fever, tachypnea, cough, pleuritic chest pain, cyanosis and hemoptysis. Physical examination may not give evidence of extensive consolidation. It may show only a few rhonchi, scattered rales or rarely pleural effusion. Radiologically extensive nodular lesions are seen in both lungs. As the rashes subside and general condition improves the pulmonary lesions clear up.
6. *Neurological complications* develop more in immunocompromised individuals at all ages. In elderly persons these may occur in immunocompetent individuals as well. The central nervous systems lesions include myelitis, encephalitis, encephalomyelitis, ventriculitis and meningitis. The major pathological change in varicella zoster encephalopathy is a vasculitis affecting the small and large vessels. Clinically the presentations include transient

cerebellar ataxia, encephalomyelitis, polyneuritis cranialis, ascending paralysis, transverse myelitis and optic neuritis.

7. Other systemic complications that may develop rarely are myocarditis, keratitis, iritis, nephritis, arthritis, purpura, orchitis and appendicitis. Quiescent tuberculosis may be reactivated. Chickenpox occurring in the first two trimesters of pregnancy may give rise to congenital malformations in 9%.
8. Varicella during pregnancy: *Congenital varicella syndrome* in the fetus occurs in the 3rd trimester of pregnancy especially between 8-20 weeks. Clinical features include skin lesions, neurological and eye defects, limb hypoplasia, Intra uterine growth retardation (IUGR) and other manifestations due to direct viral invasion. Risk of developing this syndrome is 0.7% in first trimester and 2% in the second. Detailed ultrasound examination is diagnostic. Abnormalities include limb deformities microcephaly, hydrocephalus, polyhydramnios and soft tissue calcification. These are detectable at least 5 weeks after maternal varicella. If the mother develops the rash between four days prior to delivery and two days thereafter, it is highly probable that the newborn is infected. The disease is associated with high mortality in the neonate.

Diagnosis

Clinical diagnosis is not difficult in typical cases. Fever with vesicular rash occurring on the trunk and milder prodromata is suggestive of chickenpox. Smallpox used to be an important differential diagnosis. Though smallpox has been eradicated, it is extremely important to identify any similar illness and subject the patient to full investigation. The clinical differentiation between chickenpox

and smallpox is given in Table 53.1. When the disease is modified by immunization or immunosuppression laboratory confirmation becomes necessary.

Laboratory Diagnosis

Examination of material scraped from the vesicles (Tzanck smear) reveal eosinophilic intranuclear inclusion bodies within epithelial cells and multinucleated giant cells. Virus can be isolated from vesicular fluid. Serological diagnosis can be made by complement fixation, immunoadherence, hemagglutination, indirect immunofluorescent antibody detection tests or ELISA. Presence of the virus in blood vessels can be detected by PCR.

Treatment

In the majority of cases only symptomatic treatment is required, when the illness is mild. Paracetamol in a dose of 0.5 g given thrice daily serves to relieve pain. To prevent secondary infection, local antiseptics like chlorhexidine can be used. Pruritus can be reduced by local application of peanut oil containing 1 % phenol. Antiviral drugs such as acyclovir have to be given parenterally in complicated cases.

For normal hosts acyclovir 20 mg/kg bw orally as tablets up to a maximum of 800 mg 4-5 times a day for 5 days is effective.

In immunocompromised hosts and in normal hosts with pneumonia or meningoencephalitis the dose is 10 mg/kg IV 8 hourly for 7-10 days or more. If started early the results are excellent.

Prophylaxis

Spread of infection can be prevented by isolation of the patient and heat sterilization of contaminated articles.

TABLE 53.1

Clinical differentiation between chickenpox and smallpox		
Signs and symptoms	Chickenpox	Smallpox
1. Prodromal symptoms	Absent or mild	Prodromal symptoms more
2. Rash		
a. Appearance of vesicles	Within 24 hours of onset of fever	3rd or 4th day of illness
b. Distribution	Centripetal rash, i.e. more on the	Centrifugal, i.e. rash more on the face and body and less on the face and limbs extremities and less on the covered parts of the body
c. Nature of eruption	Superficial and more on flexor regions Axilla involved Rash appears in crops for 3-4 days	Deep-set in skin and more on extensor regions and bony prominences Axilla usually free Rash comes out as a single crop during 1-2 days
	Vesicles are oval or elliptical Rash in different stages occur simultaneously Unilocular vesicles without umbilication, which collapse on puncture Superficial scars which fade off	Vesicles are round Rash is in the same stage all over Multilocular and umbilicated vesicles, do not collapse on puncture Deep permanent scarring

Immunosuppressed children who are exposed to chickenpox should be given protective immunoglobulin. Varicella zoster immunoglobulin (VZIG) prepared from pooled human plasma contains antibodies against varicella, and when given in a dose of 12.5 units/kg body weight within 72 hours of exposure it gives passive immunity. Secondary bacterial infection should be treated with antibacterial agents.

Live attenuated varicella zoster virus vaccines are available for use in special situations. The vaccine is prepared by growing the attenuated virus in human diploid cells. It may be given to children after the age of 1 year.

Dose

1 year to 12 years	0.5 mL subcutaneous injection.
Above 12 years	0.5 mL two doses at an interval of 6-10 weeks in between vaccination is indicated for children who are likely to undergo immunosuppressive therapy.

Available commercially as varilrix C (Smith-Kline and Beecham). Vaccination should be avoided during pregnancy and within one month of measles vaccination. Pregnancy has to be avoided for three months after chickenpox vaccination. Immunity persists for two decades or more. A second dose of vaccine boosts up immunity.

Herpes Zoster

Syn: Shingles

Herpes zoster is an acute eruptive disorder characterized by painful radiculitis and vesicular eruptions in the corresponding dermatomes. It is seen more commonly in subjects above the age of forty years. Chickenpox and herpes zoster are caused by the same virus, the latter occurs in persons who have acquired partial immunity. Following the episode of chickenpox the varicella-zoster virus becomes latent in

ganglia along the entire neuraxis, particularly the trigeminal ganglia and the dorsal root ganglia, remaining mainly in the cytoplasm of the neurons. Later the perineural cells of the ganglia are also involved. The virus persists in noninfectious form with intermittent periods of reactivation and shedding. The exact factors leading to reactivation are not fully known. The virus can be isolated from these tissues by appropriate methods. Attacks of herpes zoster are often precipitated by immunodeficiency states, hematological or neurological malignancies or trauma. Involvement of the cerebral arteries by VZV produces unifocal or multifocal vasculopathy (i.e.) granulomatous arteritis. The localized form occurs in immunocompetent and the multifocal form occurs in immunocompromised subjects. This usually occurs after reactivation from the ganglia. This virus travels trans-axonally to involve the cerebral arteries. This leads to vascular occlusion and stroke. Intensive intravenous administration of acyclovir helps to resolve the lesion. When used along with other supportive measures.

CLINICAL FEATURES

The eruption has an abrupt onset after a prodromal illness characterized by malaise, fever and severe pain in the corresponding dermatomes lasting for 3-4 days. The pain may be lancinating, deep-boring, burning or vague, and in many cases it is unbearable. The common sites for the eruptions are the ophthalmic and maxillary divisions of the trigeminal nerve, geniculate ganglion of the facial nerve and thoracic and abdominal nerve roots. After a variable period of pre-eruptive neuralgia, the rash begins as reddish papules which soon develop central vesiculation. The vesicular fluid becomes turbid in three days and crust formation occurs after a week. The rash may involve a whole dermatome or only parts of it. The eruptions seldom cross the midline (Fig. 53.4).

With the formation of pustules the initial pain may subside, but in many elderly patients it may persist in the

Fig. 53.4: Herpes zoster

same form or in an altered form for months or even years. This is referred to as **post-herpetic neuralgia**. Vague paresthesiae, varying degrees of sensory loss and even lesser degree of motor loss may persist over the affected segments for considerable periods. In general the condition is benign, but the development of neuralgia may lead to severe distress and even suicidal tendencies in susceptible subjects. Incidence of post-herpetic neuralgia is more in elderly subjects (9-34%) with severe prodromal symptoms and painful confluent lesions. VZV involvement of CNS is accompanied by high leukocyte count in the CSF. Presence of virus in CSF detectable by PCR.

Complications

1. Secondary infection: The vesicles may be infected by bacteria, giving rise to fever. Deep scarring may occur.
2. Ophthalmic herpes: In herpes involving ophthalmic division of the trigeminal nerve keratitis may develop. Optic neuritis and oculomotor palsy may occur less commonly.
3. Herpes of the geniculate ganglion presents as facial nerve palsy and vesicles over the ipsilateral external auditory meatus (Ramsay-Hunt syndrome). Generally the facial nerve palsy tends to persist. Zoster occurring in the distribution of the maxillary and mandibular divisions of the trigeminal nerve may lead to osteonecrosis and spontaneous loss of the teeth.
4. Paralysis of muscles corresponding to the involved spinal segment is a rare sequel. Cervical herpes zoster may give rise to weakness of the arm. Encephalitis and myelitis have been reported rarely.
5. In leukemic subjects and those on immunosuppressant therapy extensive vesiculation may develop (generalized herpes).
6. Pregnancy: The fetus may be infected and this may lead to congenital malformations.
7. **Post-herpetic neuralgia.**
8. VZV vasculopathy and strokes.

Diagnosis and Differential Diagnosis

Once the eruption has occurred over the sensory root distribution, diagnosis becomes easy. Before the onset of the eruption, the pre-herpetic neuralgia may be mistaken for other serious conditions depending on its location. These include trigeminal neuralgia, vascular headache, painful ophthalmic problems, myocardial infarction, pleurisy, cholecystitis, appendicitis or any surgical abdominal emergency. Careful examination of the part in bright light may show at least erythematous rashes in many cases and this should suggest the diagnosis. Examination of the serum and CSF may reveal anti VZV IgG in serum and CSF, the levels being relatively higher in CSF. Even in cases with clear-cut diagnosis, an attempt

should be made to bring out an underlying malignancy like lymphoma or carcinoma, especially in the elderly subjects.

Specific Treatment

Immunocompetent individuals—Acyclovir 800 mg orally five times a day for 7-10 days. A new drug famcyclovir is a newer and more effective analogue given in a dose of 250mg t.i.d orally for 5-7 days. If started early it may even prevent the occurrence of post herpetic neuralgia.

Immunocompromised individuals: - Acyclovir 500 mg/m² IV eighth hourly for 7 days. Steroid should be given only under cover of acyclovir.

Local treatment consists of keeping the area dry and clean. Analgesics like aspirin and dextropropoxyphane are required in the eruptive stage. A short course of ACTH or prednisolone has been recommended in the elderly patients with a view to prevent post-herpetic neuralgia. Opinions are divided on this issue. The risk of dissemination of infection is a real danger.

The most troublesome complication of herpes zoster is post-herpetic neuralgia. Age is the most important single factor to predict its occurrence. There is no reliable method to prevent the neuralgia. Treatment consists of the administration of analgesics, tricyclic antidepressants and anticonvulsants. The pain is often refractory to analgesics. Diphenylhydantoin (300-400 mg/day), carbamazepine (200-1000 mg/day), and tricyclic compounds (amitriptyline, imipramine, doxepine) have been used with some benefit. Other therapeutic modalities like transcutaneous nerve stimulation (TNS) have benefitted some patients. Aspirin dissolved in chloroform and allowed to evaporate topically reduces pain. Capsaicin applied as ointment over the affected segment may bring about relief. Early specific treatment of herpes zoster reduced the chance for neuralgia.

Zoster Sine Herpete

1. This condition is characterized by recurrent severe shooting pains, but no vesicular eruptions. The diagnosis can only be made based on rising titers of antibody to V/Z virus.
2. Characteristic localization of pain to a dermatome with serologic evidence of herpes zoster, in the absence of skin lesion is diagnostic.

Pre-herpetic Neuralgia

This develops in herpes zoster before the appearance of the rash. This is due to ganglionitis. The area of pain and site of rash usually coincide in most of the cases, but not always so. Aseptic meningitis and acute meningo-encephalitis may occur with the occurrence of the rash.

Herpes Simplex

Syn: Herpes febrilis, Fever blister, Cold sore

Infection by *Herpes simplex virus (HSV)*, also known as *Herpes virus hominis (HVV)*, produces recurrent crops of vesicles over the mucocutaneous regions. The virus remains in the skin and nerve ganglia in the dormant form to be activated periodically to give rise to recurrent eruptions. Herpes viruses are DNA viruses and the pathogenic types are two different antigenic variants herpes simplex type 1 (HSV 1) and herpes simplex type 2 (HSV 2). The former causes lesions around the mouth, noses, cornea and conjunctiva and around the nails—(herpetic whitlows). This is a non-venereal infection. HSV 2 is a sexually transmitted disease which has assumed great importance since it leads to genital cancers in woman.

Fever, exposure to sunlight, physical or emotional stress, malignancy and immunosuppressant drugs lead to exacerbation. Fevers, especially pneumonia, malaria and meningitis are commonly associated with herpes labialis. Herpes simplex is rare in enteric fevers. A crop of vesicles develop following a short period of tingling pain and paresthesia over the affected region. The vesicles remain for 7-10 days after which they start to heal with the formation of crusts. Healing is complete in 21 days. When the crusts fall off, thin scars persist for some time. Common sites of eruption are around the mouth and external nares. Less commonly herpes simplex keratitis, recurrent gingivostomatitis and vulvovaginitis may occur. Herpes simplex virus can cause mild fever.

Serious complications may occur in susceptible persons and in immunosuppressed subjects. These include herpes simplex encephalitis and *Kaposi's varicelliform eruptions (eczema herpeticum)*. Herpes simplex encephalitis may lead to necrosis of the temporal lobe and rise in intracranial tension. Kaposi's varicelliform eruption develops in infants and adults with eczema. In such subjects the eruptions become generalized and this leads to excessive loss of fluid, electrolytes and proteins. Herpes tends to become generalized in subjects who have sustained burns. Generalized herpes simplex occurring in wrestlers is called *herpes gladiatorum*. Herpes simplex virus pneumonia occurs in immunocompromised hosts.

Diagnosis

Herpes simplex has to be differentiated from pustular or vesicular rashes and herpes zoster; the latter is nonrecurrent. Herpes simplex virus can be isolated from the vesicle fluid. Serological diagnosis is by demonstrating complement fixing antibodies. In herpes simplex encephalitis the virus can be demonstrated in CSF by PCR.

TREATMENT

Local lesions which are benign may be left alone with simple cleaning and application of gentian violet. Topical

idoxuridine (0.1% hourly as drops or 0.5% ointment) is effective in herpetic keratitis. Acyclovir ointment is available for local use over the vesicles. This gives relief of pain and prevents recurrence. In severe cases and complicated cases systemic therapy with acyclovir has to be given. Dose is 800 mg orally 5 times a day for 5 days. In case of HSV encephalitis, acyclovir should be given in a dose of 10 mg/kg bw IV 8 h for 10-14 days. For neonatal herpes simplex infections the dose is 10 mg/kg bw IV for 10-14 days. Fanciclovir 500 mg oral tds for 5 days is a suitable alternative.

Note: HSV2 infection (Genital herpes) is described along with sexually transmitted diseases in chapter 48

Rubella

Syn: German measles—Three days measles

Rubella is an exanthem caused by a RNA virus (50-85 nm in size) belonging to the family of togaviruses. The disease is characterized by mild constitutional symptoms and rash. Its importance is due to the risk of producing fetal abnormalities and abortion if it occurs in women during the early months of pregnancy.

Epidemiology

The infection spreads through droplets and entry is through the nasopharynx. Infective period starts one week before the onset of the rash and it lasts for one week after the rash fades. Virus is present in the nasopharyngeal secretion one week before the onset of the illness. In the early stage, viremia occurs. The virus reaches the fetus through the placenta and causes lesions in the fetus. The baby sheds the virus at birth and continues to be infective for 6 to 31 months. The disease is prevalent in the community and small epidemics may occur from time-to-time. Many cases may be subclinical. An attack confers life-long immunity. In western countries it is estimated that 10-15% of adult women are susceptible to infection. In India the disease is not infrequent, though reliable statistical figures are not available.

Pathogenesis

The virus is present in blood up to two days before the onset of the rash. Lymph nodes are moderately enlarged, showing edema and hyperplasia. When the fetus is affected, the virus multiplies in the liver, spleen, bone marrow and other tissues and leads to various structural malformations in the heart, nervous system, eyes and the limbs.

CLINICAL FEATURES

The incubation period is usually 2-3 weeks. The onset is sudden with malaise, fever, rashes and characteristic

TABLE 53.2

Differential diagnosis between measles and rubella		
	Measles	Rubella
Prodrome	Nasal congestion and cough more severe	Mild
Rash	Confluent reddish and pinkish maculopapular rash—slower progress and clearance	Discrete maculopapular—rapidly progressing and clearing
Temperature	Rises abruptly with rash	Does not rise abruptly with rash
Lymph nodes	Not characteristic	Retroauricular, posterior cervical or posterior occipital are characteristic
Koplik's spots	Pathognomonic	Nil

6

enlargement of the occipital, posterior auricular and posterior cervical lymph nodes.

The rash which resembles that of measles begins on the face and neck and spreads to the trunk and limbs, but the rash is less extensive. Enanthem may occur consisting of discrete rose colored spots on the palate and fauces. The rash becomes discrete by the second day and it disappears in 3-4 days.

Compared to measles, constitutional symptoms are mild in children. In addition to fever and malaise, arthralgia, joint stiffness and headache may occur. Rarely serious neurological complications like encephalitis, encephalomyelopathy or polyneuropathy develop 5-10 days after the onset. Thrombocytopenia may develop in a few (Table 53.2).

Diagnosis

Clinically the disease should be suspected when fever, posterior cervical lymphadenopathy and rash occur in a young subject. Rubella has to be distinguished from measles, secondary stage of syphilis, drug rashes, infectious mononucleosis and Echo, Coxsackie and

adenovirus infections. The leukocyte count is normal in rubella. Specific diagnosis is established by finding a four-fold increase in hemagglutination inhibition antibodies in paired sera or by isolating the virus.

Congenital Rubella

Rubella embryopathy results either from inhibition of cell growth or cellular necrosis. Fetal defects include retardation of growth, eye defects like cataract, glaucoma, or retinopathy, congenital heart defects, nerve deafness, mental retardation, hepatosplenomegaly and skeletal abnormalities. Rubella occurring in women in the first 16 weeks of pregnancy leads to fetal malformation in up to 50 to 80% of cases. Risk of fetal affection reduces if the infection is acquired later in pregnancy.

Treatment

As the disease is generally benign, it is desirable to acquire rubella before the child-bearing age. No specific treatment is indicated. Medical termination of pregnancy has to be considered if there is proof of rubella infection in early pregnancy.

Prevention

Vaccination using live attenuated virus confers immunity. Live attenuated rubella virus RA 27/3 grown in human diploid fibroblast cells is effective, when given in a dose of 0.5 ml as a single injection. Vaccination confers solid immunity over 10 years. If facilities are available, vaccination should be considered for girls in the age group of 11-13 years and women in the child-bearing age who are antibody-negative and are desirous of child-bearing. The vaccine virus passes into the fetus and so pregnancy should be avoided for eight weeks following vaccination. Gammaglobulin administered to the mother after exposure aborts an overt -attack, but safety of the fetus cannot be guaranteed. Ideal time for vaccination is after 12 months of age. The combined MMR vaccine takes care of rubella as well.

54

Mumps

K.V. Krishna Das

Chapter Summary

General Considerations 315

Clinical Features 315

Treatment 316

Prevention 316

General Considerations

This common childhood infection is caused by mumps virus which belongs to the group of paramyxoviruses. It is an RNA virus. The infection is worldwide in distribution and spreads through droplets. The disease runs a subclinical course in 30-40% of cases. Man is the only known host and the infection spreads directly from man-to-man. Infectivity rate among contacts is not high. Second attacks do not occur since mumps produces solid life-long immunity.

Pathology

Organisms enter through the respiratory tract. The virus is present in the saliva from 7 days before to 8 days after the onset of parotitis. In susceptible hosts viral multiplication leads to viremia. Thereafter the virus localizes in several organs such as the salivary glands, pancreas, central nervous system, testes, ovaries, thyroid gland and others. The salivary glands are enlarged and histology shows mononuclear infiltration. Neurological lesions take the form of meningoencephalitis or encephalomyelitis. Testicular lesions include intense interstitial edema, perivascular lymphocytic exudate, focal hemorrhages and destruction of germinal epithelium, which may be patchy or generalized.

Clinical Features

Incubation period is 18 days (range 12-21 days). Initial symptoms are fever, pain over the region of the parotid gland, especially on opening the jaw, trismus, dryness of the mouth and headache. Soon the parotids and less

Fig. 54.1: Female mumps

commonly the other salivary glands become tender and enlarged. Unlike suppurative parotitis, redness and edema are absent. Sialoadenitis is usually bilateral, but rarely it may be unilateral (Fig. 54.1).

After 5-7 days the fever and glandular enlargement subside. In the uncomplicated case, there is leukopenia with relative lymphocytosis. A few atypical lymphocytes may be present. When complications occur, neutrophil leukocytosis may develop. Around 50% of cases show CSF pleocytosis.

Complications

In the vast majority, the course is benign and uncomplicated. If the disease occurs in adult males 25% develop uni- or bilateral **orchitis**. The affected testis are red, swollen, tender and painful. Reactive hydrocele may develop. Sterility may follow bilateral involvement. **Oophoritis** may develop in women. Though parotitis is present in most of such cases, rarely gonadal lesions occur without obvious parotitis.

Pancreatitis should be suspected when patients with mumps complain of upper abdominal pain. In a few cases, serum amylase level may be increased. Pancreatitis usually subsides without sequel. Thyroiditis develops in some cases. The occurrence of **meningitis** is heralded by intense headache and signs of meningeal irritation. CSF shows

lymphocytic pleocytosis. Encephalomyelitis is a rare complication. Arthritis follows the acute illness after 2-3 weeks.

Diagnosis

Bilateral enlargement of the parotid and other salivary glands with mild constitutional disturbances should suggest the possibility of mumps. The diagnosis is easy, during outbreaks but it may be difficult when the presentation is atypical such as unilateral parotitis, or meningitis. Mumps virus can be isolated from throat washings obtained 48 hours before to 7 days after parotid swellings develop. Rise in antibody titer can be demonstrated in paired sera by complement fixation, hemagglutination inhibition or Elisa. PCR helps to identify the viral antigens.

Treatment

Symptomatic treatment consists of analgesics and antipyretics in addition to bed rest. This is all that is

required in most of the cases. Troublesome dryness of the mouth can be relieved by frequent sips of water.

When orchitis is present, local dressing with ichthyol glycerine and supportive bandage give relief. Prednisolone 40 mg daily for 4-7 days may help in reducing the inflammation. The meningitis also subsides with symptomatic measures. Corticosteroids produce early clinical improvement though there is no objective benefit demonstrated by controlled studies.

Prevention

Specific prophylactic measures are not generally required, since the infection runs a benign course and produces lasting immunity. A live attenuated vaccine (*Jeryl-Lynn strain*) is available for administration along with measles and rubella vaccines (MMR vaccines). This produces a noncommunicable subclinical infection. The vaccine is administered to children above the age of 13 months. Measles, mumps and rubella vaccines can be given together as a single injection safely between the age of 13-15 months. Booster doses are not required. Rarely fever, rashes and seizures may occur as adverse reactions.

Prophylaxis 326

GENERAL CONSIDERATIONS

Several viruses can cause the syndrome of acute viral hepatitis. This is characterized by diffuse inflammation of the liver as the predominant feature. Five viruses are mainly responsible for the vast majority of cases—Hepatitis A Virus (HAV), Hepatitis B Virus (HBV), Hepatitis C Virus (HCV), Delta Virus (HDV), and Hepatitis E Virus (HEV).

HAV and HEV are transmitted predominantly feco-orally through the enteric route. The others are transmitted parenterally. Viruses A and E produce acute hepatitis. Chronicity and delayed damage to the liver do not occur. On the other hand HBV and HCV cause both acute and chronic hepatitis, as in many cases the infection tends to persist and lead to chronic hepatitis, cirrhosis liver and carcinoma. HDV is exceptional in that it can exist only in the presence of HBV infection. It acts as a co-infecting agent and modifies the clinical picture and outcome in HBV hepatitis. Recently many workers described a sixth hepatotropic virus and independently named it hepatitis GV virus (HGV-C) and hepatitis GE virus (HGV). Probably they are the same, and are commonly referred to as HGV.

HCV, HEV and other viruses were previously known as non-A non-B viruses because diagnostic markers were not available. At present diagnostic serological markers are available for all hepatitis viruses.

Several other viruses cause hepatic lesions in addition to lesions in other parts of the body. These include cytomegalovirus, *Epstein-Barr virus*, herpes simplex, varicella zoster, dengue, yellow fever, rubella, hemorrhagic fever viruses, human immunodeficiency virus and others (Table 55.1).

Hepatitis A Virus (HAV)

It is a single stranded RNA virus belonging to the genus hepatovirus. There are four genotypes of the virus showing antigenic cross reactivity.

It is present in faeces of cases from 2 weeks before the onset of the symptoms. Infection is by the fecal-oral route. In tropical countries and in communities where food

hygiene is low, this infection is prevalent and the vast majority of sufferers are children. Contamination of drinking water supply with sewage is responsible for several outbreaks from time-to-time. Most of the adults acquire immunity due to subclinical infection or overt disease. They show the presence of specific antibody which is protective. With improvement in hygiene the disease becomes less common in children, and older age groups are affected more. Other methods of transmission include oral-anal sexual contact in homosexual men and rarely the parenteral route if the blood donor incubates the infection. The incubation period varies from 2-6 weeks. This virus has been grown in tissue culture. This infection does not become chronic. HAV used to be known as short-incubation hepatitis. HAV is relatively acid stable, it resists drying and can remain for at least a month under room temperature. The virus multiplies in the liver, and is passed into bile 2-3 weeks before the onset of jaundice, and the feces contains the virus. Maximal infectivity is during the later part of the incubation period. Once jaundice occurs infectivity comes down even though the virus is present in feces. The initial antibody response is IgM anti-HAV. This runs parallel to serum transaminase levels. After the eighth week the levels come down. IgG anti-HAV rises during recovery and this confers life-long immunity. RIA and ELISA tests are available for detecting these antibodies. PCR test can identify the virus specifically and distinguish between the different hepatotropic viruses.

Hepatitis B Virus (HBV)

HBV is the prototype member of the Hepadnaviridae (hepatotropic DNA virus). It is 42 nm in diameter. Chronic

TABLE 55.1 The important features of the viruses primarily causing hepatitis						
	HAV	HBV	HCV	HDV delta virus	HEV	HGV

Vaccination	Available	Available	No	—	No	No

hepatitis B affects 350 million people, approximately 5% of the world population. Carrier state of the virus ranges from 0.1-20 % in different parts of the world. Prevalence has been classified as high (> 8% of population affected), intermediate (2-7%) and low (< 2%). Prenatal transmission is high in high prevalence areas. In India the prevalence ranges from 1.2 to 12.2% the average carrier rate is 3.34%. Eight genotypes A-H have been identified and the prevalence in different geographical areas varies. In India A and D genotypes are more prevalent. The different genotypes vary in their pathogenicity, especially in severity, chronicity and oncogenic potential. Mothers who are chronic carriers of infection and those who develop acute hepatitis B in the last trimester transmit the disease to their babies in the perinatal period. If the HBsAg and HBeAg are positive the chances for transmission exceeds 90%. Infection is acquired by the infant during its passage through the vagina and inoculation of mother's blood and liquor amnii. Infection acquired during the neonatal period leads to chronicity in > 90% of cases, whereas infection acquired during adult life leads to chronicity only in 5-10% of cases.

HBV spreads by parenteral introduction of the infective agent along with blood or blood products or through needle pricks. In communities where the carrier rate is low (1 in 1000 or less) HBV infection is seen in special population groups such as newborns of carrier mothers, homosexuals, drug addicts and personnel working in dialysis units and laboratories. The virus can also spread by hetero-or homosexual intercourse. In homosexuals, the transmission rate is high. Risk factors include multiple casual sexual partners, anal intercourse, and a high carrier rate among these subjects. Oral-oral spread occurs by kissing, since the virus is present in saliva. Accidental contamination by infected blood can transmit the disease. In India the main mode of transmission is horizontal-from child to child or adult to adult. Other than the liver and plasma, it may be present in saliva, tears, vaginal secretions, semen, breast milk, sweat and urine. It is highly infectious. Infection is by parenteral route or contact with abraded skin, or mucosal surfaces. Risk of infection from needle stick injuries in health care workers is as high as 30%. This risk can be prevented by immunisation. Gastric acid and pancreatic enzymes destroy the virus. It is demonstrable in sera of patients many weeks before the acute illness, and it may be demonstrable for 3 months or more after clinical recovery.

Viral Morphology

The virus consists of a central core consisting of core antigen (HBcAg), e-antigen (HBeAg), a specific DNA polymerase and a circular DNA (HBV-DNA). Under electron microscope the virus is seen as spherical particles

called Dane particles. The virus consists of a lipoprotein outer coat which is secreted in excess by hepatocytes and released into serum. Presence of excess of envelope antigen HBsAg is a special feature of HBV. This surface antigen circulates in the plasma in the form of rods or spheres with a diameter of 22 nm. This is detectable as hepatitis B surface antigen (HBsAg) 1-10 weeks after infection and 2-8 weeks before onset of symptoms. This is diagnostic of the presence of infection. Some cases of HBV hepatitis do not show HBsAg in blood, even though the viral genome may be demonstrable. HBsAg is itself not infective to others. HBsAg was described in 1965 first by Blumberg in the blood of an Australian aboriginal and was hence termed Australia antigen. HBsAg can be detected by RIA or ELISA tests. Its presence is pathognomonic of recent or chronic HBV infection. With the onset of clinically detectable hepatitis and jaundice, the level of HBsAg falls. Clearance of HBsAg indicates resolution of infection.

Immune Markers of HBV Infection

Antibodies to HBsAg develop (anti-HBs) and these may be IgM and IgG in serum and IgA in secretions. These antibodies provide immunity to future infection by HBV. IgM is short lived, whereas IgG antibody persists. Anti-HBs antibody (anti-HBs Ab) can be estimated to detect protective immunity. These are detectable in patients who recover from the disease and in these who are successfully vaccinated. Antibody levels above 10 m IU/mL are protective.

Antibodies to other HBV components develop in due course. HBcAg (Hepatitis-B core antigen) is not detectable in serum, but with the onset of clinical illness anti-HBc IgM (IgM antibody to core antigen) appears and remains elevated throughout the course of the disease. Detection of anti-HBc IgM is diagnostic of HBV hepatitis. This also helps to rule out superinfection in an HBV carrier by other hepatitis viruses. Anti-HBc IgM is the only serological marker of HBV infection when HBsAg has disappeared and anti-HBsAg has not reached detectable levels. Anti-HBcAb is not a neutralizing antibody and therefore it is not protective. Initial antibody is IgM type later it is replaced by IgG type. Persistence of anti-HBc IgG in high titer indicates continuing infection.

HBe antigen is a circulating peptide derived from the core genome and transported from liver cells. HBe positive mothers transmit the disease more readily to their infants (73%) than HBe negative mothers (13%).

Detection of hepatitis-e antigen (HBeAg) indicates active replication of the virus and presence of infective agent in the liver. HBeAg appears within 1 week of appearance of HBsAg and disappears within 4 weeks of onset of symptoms. Persistence of HBeAg beyond 10 weeks should suggest progression to a carrier state and it

may also portend the development of chronic hepatitis. In those who overcome the infection antibody to HBe- (anti HBe) appears within 4 weeks of onset of symptoms. Presence of anti-HBe suggests good immunological response and chance of recovery.

Presence of virus in blood is demonstrable directly by the presence of circulating viral DNA (HBV-DNA). In India about 25% of HBsAg + subjects show also HCV positivity. Coexistent hepatitis C infection suppresses markers of HBV replication.

HBV DNA and DNA polymerase appear in the serum at the same time as HBeAg. These also are markers of HBV replication and potential infectivity. HBV DNA is detected by polymerase chain reaction (PCR). Levels of HBV DNA correlate with transaminase levels and HBsAg in the serum.

HBV infection is tolerated by the body and once infection occurs, 5-10% become chronic carriers. *Younger the age of getting the infection, greater is the chance of developing carrier state. In vertical transmission from mother to newborn the carrier state may develop in 80-90%, whereas in transmission in adult life the chances are less.* Most of the carriers tolerate the virus which replicates in the liver. They show HBsAg positivity and viremia, but at the same time do not suffer from the disease. They are the main source of spread to others. This state may persist lifelong. Risk of primary carcinoma of the liver is high in them and many of the cases of liver cell cancer occurring in young adults, especially in India and other neighbouring countries are attributable to HBV.

The life cycle of HBV can be divided into four stages:

- Stage 1** Immune tolerance occurs. Viral replication occurs even without elevation of hepatic SGPT. This is the incubation period. HBeAg and HBV DNA levels in serum are high.
- Stage 2** Immunological response develops leading to production of cytokines, direct cell lysis and the inflammatory process. Secretion of HBsAg continues. This is the stage of active sympto-

matic hepatitis. This may last for 2-4 weeks. In those with chronic hepatitis this stage may extend to several years, leading to cirrhosis and its complications. If the host is able to mount an immune response that eliminates the infected hepatocytes, active viral replication ends and this marks the onset of the third stage.

Stage 3 This is the stage at which the bulk of the virus infected cells have been cleared. At this stage HBeAg is no longer detectable but anti-HBeAb becomes demonstrable. Viral DNA levels drop even through PCR may still be able to detect it. In most cases the infection is cleared and the SGPT levels become normal. However HBs positivity may still persist, presumably because of the integration of the viral genome with that of the hepatocyte.

Stage 4 At this stage the virus is cleared and protective antibody is abundant. Most patients eventually become negative for HBsAg and positive for anti-HBsAg (HBsAb). HBV DNA is no longer detectable and the patient is immune to further infection.

The factors affecting the stagewise progression of the infection and the ultimate outcome include.

- 1. genetic predisposition of the host
- 2. co-infection with other virus (hepatitis C and D)
- 3. treatment with immunosuppressant drugs, and
- 4. the appearance of HBV mutants (Table 55.2).

Hepatitis C Virus (HCV)

This was first identified in 1989. It is an RNA virus belonging to the family flaviviridae. At least six genotypes, HCV 1 to HCV 6 are identified and subtypes are denoted by letters a, b, etc. In India HCV3 is more prevalent. In voluntary blood donors in West Bengal the prevalence rate was 1.8%, in Chandigarh it was 2.8% and in Delhi it was 1.85%. The genotypes determine the response to treatment. Types 2 and 3 are more responsive

TABLE 55.2				
The four stages of hepatitis B infections				
	Replicative phase		Integrative phase	
Disease marker	Stage 1	Stage 2	Stage 1	Stage 2
HBsAg	Positive	Positive	Positive	Negative
Antibody to HBsAg	Negative	Negative	Negative	Positive
HBV DNA	Strongly positive	Positive	Negative	Negative
Antibody HBcAg	Positive	Positive	Positive	Positive
HBeAg	Positive	Positive	Negative	Negative
Antibody to HBeAg	Negative	Negative	Positive	Positive
Asparate and alanine aminotransferase levels	Normal	Elevated	Normal	Normal

to pegylated interferon and ribavirin (85%) whereas the others are less so (48%). Genotype 1b is most aggressive in course and least amenable to drugs.

The virus is present in blood, tissue fluids, saliva, vaginal secretions and semen of infected persons. Infection is acquired mainly by parenteral route. Transfusion of blood and blood products and sharing of contaminated needles for injection account for more than 85% of cases. Sexual transmission occurs from unprotected sexual intercourse. Male to female transmission by the sexual route is more efficient and infection rate is 1.6% among sexual partners. Co-infection with HIV enhances the rate of sexual transmission. Health care staff gets infection by entry of the virus through contamination by blood and body fluids coming into contact with cuts and wounds or needle stick injuries. Infection rates among health care workers are 0.6-4.5%. Hemodialysis patients have infection rates ranging from 0.6-4.5%. Perinatal transmission rate is 2-3%. In general HCV is less infectious compared to HBV.

The course of HCV is progressive if untreated. Unlike HBV 50-70% of cases develop chronic hepatitis. Of these 20-50% develops cirrhosis over a period of 10-20 years. Twenty five percent among these cirrhotic patients may develop hepatocellular carcinoma. In contrast to HBV, infection HCV acquired during childhood: runs a more benign course than that in adults. Older age, alcoholism and coinfection with HBV and HIV increase the risk of diseases progression and chance of developing decompensated cirrhosis. In thalassemic children with iron overload HCV runs a more aggressive course.

After infection by HCV, the viral RNA becomes detectable in serum within 1-2 weeks. Thirty percent of cases are anicteric. Eighty-five percent go into chronicity. The natural history of HCV infection is variable. In more than 60%, the infection persists and the virus is demonstrable in blood for over 5 years. Ten percent may recover completely.

Hepatitis Delta Virus (HDV)

Syn: Delta Agent

This is an RNA virus which is incomplete, and therefore, requires prior infection by HBV for establishing and replicating in the host. HDV is transmitted parenterally and sexually. Vertical transmission from mother to offspring is rare. HBV and HDV may enter together or separately and cause co-infection of the recipient or HDV may cause super-infection on a person already suffering from HBV.

HEPATITIS E VIRUS (HEV)

This is an RNA virus transmitted mainly by the enteral route, and is associated with poor sanitation. It can occur

in small or large outbreaks. The virus is shed in feces and so fecal-oral route of infection accounts for most of the cases. HEV antigen has been identified in the cytoplasm of hepatocytes in patients suffering from the disease.

Waterborne outbreaks of HEV hepatitis have been described from several parts of India—Ahmedabad, Kohlapur, Srinagar and others. HEV RNA or anti HEV antibodies have been reported from swine, cows, goats and rodents. Infection by consuming uncooked deer meat has been recorded.

(S. Tei et al. The Lancet 2003. 362. 371-373).

HEPATITIS G VIRUS (HGV)

Two groups of investigators detected a new hepatitis virus independently named hepatitis GB virus (HGBV-C) and hepatitis G virus (HGV). The letter GB stands for the initials of the patient from whom the virus was isolated first. Three viral agents have been identified HGBV-A, HGBV-B and HGBV-C. They belong to the group of tamarin viruses which cause hepatitis in tamarin monkeys.

HGV was cloned from a patient who developed community acquired chronic hepatitis.

Molecular characterization of both HGBV-C and HGV has shown an almost identical pattern. They are single stranded RNA viruses belonging to the family flaviviridae. HGBV-C and HGV share 80% of this nucleotides and 86% of their amino acid sequences. HGV viremia is highly prevalent in persons undergoing hemodialysis and is correlated with the number of transfusions and duration of hemodialysis. In reports from India HGV and HBV coinfection occurred is 6-17% where as HCV and HGV coinfection occurred in 11-19%. GBV closely resembles HCV, but unlike HCV, it does not replicate in the liver cells. It does not cause hepatitis. It replicates in vitro in peripheral blood mononuclear cells, CD4 and CD8 T lymphocytes and also B lymphocytes. Human infection by GBV occurs in 1-8% of blood donations. Clinical significance of HGV still remains uncertain. Its role in the pathogenesis of hepatic lesions remains unsettled. At present it is not found to worsen the course of HCV. Though HGV responds to interferon, at present this treatment is not recommended.

PATHOGENESIS AND PATHOLOGY

Under most circumstances HBV and other viruses by themselves do not kill the hepatocytes. An intact immune system is necessary to cause cell injury as well as ultimate clearance of the virus. For practical purposes the severity of hepatocyte injury also reflects the vigour of the immune response. The most complete immune response is also associated with the chance of viral clearance and full recovery.

The hepatitis viruses cause injury to liver cells by direct invasion and immunological processes. Immune

complexes appear in blood prior to the onset of liver injury. They may account for the serum sickness like syndrome observed in the early phase. Cellular immunity also plays a role in altering the host's response to the virus and the progression to the chronic carrier state.

Pathology

The lesions caused by viruses A, B and others are all similar. In uncomplicated hepatitis the essential lesions are ballooning of hepatocytes, acidophilic degeneration leading to the presence of **Councilman's bodies** and focal necrosis or cell dropouts. Changes are more pronounced in the centrilobular regions. There is infiltration by small lymphocytes, plasma cells and eosinophils, most marked in the portal regions. Kupffer cells undergo hyperplasia. Many large multinucleated hepatocytes are formed. There is also a variable degree of cholestasis. The pathological changes are seen diffusely involving all the lobules.

Necrosis of liver cells is a prominent feature in severe cases. Necrosis involving many adjacent hepatocytes is described as *confluent necrosis*. The term "*submassive*" *necrosis* is used to denote necrosis involving several adjacent lobules. The necrosis may extend between adjacent central zones, portal zones or between adjacent central and portal zones. If the reticulum is intact, full regeneration is possible and recovery is complete. If the reticulum collapses, collagenous tissue is laid down and this leads to fibrosis, which bridges adjacent zones. These cases have a more unfavourable prognosis and many of them progress to subacute necrosis or to chronic hepatitis and cirrhosis. When necrosis is submassive or massive and fulminant, the liver shrinks in size and this carries a grave prognosis. With the onset of recovery, regenerative changes and Kupffer cell activity become evident.

HBV and HCV predispose to cirrhosis and carcinoma. In India post-hepatitic cirrhosis is caused mainly by HBV and also by HCV. In endemic areas with a high carrier rate and chance for vertical transmission of the virus from mother to child, primary carcinoma of the liver occurring in young adults may be a late sequel to these infections.

GENERAL CLINICAL FEATURES

Hepatitis presents a clinical spectrum ranging from mild and inapparent infection to the most serious, fulminant and rarely fatal acute hepatic failure. Subclinical infection is recognized by the rise in antibody titer during epidemics. In many others, clinical illness without jaundice may develop. In these cases of anicteric hepatitis, prodromal symptoms and biochemical abnormalities may develop but jaundice may not occur. Such anicteric cases far outnumber the icteric cases during epidemics. As a general rule the onset of HAV hepatitis is more acute than that of HBV. The onset of the other viral infections is

generally similar, but variable in intensity. The clinical picture is similar, but HBV and HDV hepatitis tends to be more severe.

Prodromal Symptoms

The classic attack of viral hepatitis is heralded by a prodromal phase which lasts for three to five days or longer, before the onset of jaundice.

The prodrome consists of general malaise, headache, fatigue, nausea, vomiting and mild pyrexia. Severe anorexia and aversion for smoking and alcohol are characteristic. Symmetrical non-migrating polyarthritides with or without effusions may occur in 15% of cases. Features like anosmia, dysosmia, hypageusia or dysgeusia, urticaria, maculopapular rashes, polyarteritis and thrombophlebitis may occur less commonly.

The Icteric Phase

The prodromal phase is followed by the icteric phase. Urine becomes deep yellow and the stools pale in colour with the appearance of jaundice. Nausea and vomiting subside and appetite returns. The patient becomes afebrile and feels better. Transient pruritus might appear. Discomfort in the right hypochondrium may be felt. Liver may be moderately enlarged and mildly tender. Spleen is enlarged in 20% of cases. The jaundice deepens over the first one or two weeks, after which it gradually subsides to clear up in three to four weeks. Initially the jaundice is hepatocellular in type, later it becomes obstructive. Convalescence may be prolonged in many cases. HBV and HCV may produce symptoms related to other systems such as arthralgia and arthritis, lymph node enlargement and skin rashes, glomerulonephritis, keratoconjunctivitis and others (Fig. 55.1).

Stage of Recovery

In most of the cases clinical and biochemical recovery is complete within four to six months of the onset of

Fig. 55.1: Obstructive jaundice in viral hepatitis

jaundice. Loss of weight, general weakness and vague illhealth may persist for varying periods in many.

SPECIAL CHARACTERISTICS OF HCV, HDV AND HEV

Hepatitis C

The three types of clinical presentation are:

1. Florid stage with high viremia
2. Symptomless carriage with low viremia
3. Recovery without viremia — this occurs only in a few.

In contrast to HBV—there is no state of immune tolerance. Liver shows subacute or chronic lesions varying in severity. Hepatitis C is a common cause for hepatic transplantation. In many cases, the graft also gets infected by hepatitis C.

Acute HCV infection is asymptomatic in many, except for the presence of elevated transaminase levels in serum within 2-26 weeks (15 times the normal levels). 30% have symptoms such as anorexia, weight loss abdominal pain, myalgia and mild jaundice. These resolve in 1-3 months-PCR detects the virus in serum within a week of exposure. Antibody response occurs in 4-8 weeks and this can be demonstrated by ELISA tests.

Chronic HCV Infection: 60-70% of cases go into chronicity; among which a third are symptomatic. Clinical features include fatigue, right hypochondrial pain, hepatomegaly in 30-70%, splenomegaly in 15% and cirrhosis in a few. Carrier state with normal transaminase levels occur in 70% and with elevated transaminase levels in 30%. Those with elevated transaminase levels follow an unpredictable course. Transition from hepatitis to cirrhosis may take 3-30 years-Hepatocellular carcinoma develops in 20-30 years, the annual risk being 1.4%. Male gender, alcoholism, age above 45 years, host immune factors, viral genotype 1b and co-infection with HIV are adverse prognostic factors.

Extra hepatic manifestations of HCV: These are common in HCV infections. 45-65% show antinuclear antibodies (ANAs), smooth muscle antibodies and antithyroid antibodies is serum as epiphenomena.

Essential mixed cryoglobulinemia is associated with the presence of HCV RNA in serum in up to 84% of cases. The clinical features include the triad of palpable purpura, arthralgias and weakness. The various mixed cryoglobulinemia-related extra hepatic manifestations of HCV infection include the following

1. **Cutaneous leukoclastic vasculitis** This manifests as palpable purpura in the lower limbs, which ulcerate due to plugging of the dermal capillaries by precipitated cryoglobulins containing the virus. Severity of manifestations directly correlates with the viral load. Interferon treatment allays the lesions.

2. **Renal disease:** Membranoproliferative glomerulonephritis (MPGN) is associated with cryoglobulinemia in 20% of cases. The renal lesions confer poorer prognosis.

3. **Locomotor system:** 50% have one or other musculoskeletal manifestations. These include arthralgia, myalgia, polymyositis dermatomyositis Behcet's syndrome, antiphospholipid antibody syndrome, fibromyalgia and others. Joints affected include ankles, wrists, elbows, hands and toes. Response to antiviral therapy is good.

Nervous system—Neuropathies occur in 10-20% of cases. Lesions include cerebral infarction, stupor, mononeuritis multiplex and cranial nerve palsies.

4. **Miscellaneous conditions**

- a. Pulmonary vasculitis and respiratory distress syndrome
- b. **Sjögren's syndrome**
- c. **Porphyria cutanea tarda** (20-50% of cases)
- d. **Lichen planus, polyarteritis nodosa, prurigo, erythema nodosum and immune thrombocytopenic purpura.**

Hepatitis D (HDV)

HDV can lead to acute or chronic liver disease when co-infecting with HBV. This combination is more severe than simple HBV. Clinical presentation of HDV ranges from asymptomatic carrier state, acute and chronic hepatitis, cirrhosis and liver failure. Direct response to interferon, ribavirin and lamivudine is minimal if any. Control of HBV indirectly controls HDV as well.

Hepatitis E (HEV)

Volunteer self-inoculation study published from PGI Chandigarh revealed the following:

Incubation period was 15-20 days. Initial symptoms include anorexia, epigastric pain and high coloured urine. All these were well-established by 30 days post-inoculation. Icteric phase started from day 38 and lasted till day 120 associated with rise in serum bilirubin and transaminases.

HEV was first identified in blood on day 22 and could be detected till day 46. HEV antibodies appeared on day 41 and persisted beyond 2 years. Recovery was complete and follow up for 2 years did not reveal any sequel. Since HAV and HEV appear in blood before the onset of jaundice, there is risk of transmission by blood transfusion during the window period.

Clinical features are similar to those of HAV—jaundice, anorexia, hepatomegaly abdominal pain, nausea, vomiting and fever. Mortality in the general population is 0.5-4%, but in pregnant women the disease is more serious and mortality may go up to 20%. HEV is being reported from developed countries as well. At present there is no vaccine to protect against HEV.

Hepatitis G

The exact pathogenesis role of HGV is yet to be established.

INVESTIGATIONS

Urine

Bilirubin is present early in the disease. This is followed by the appearance of urobilinogen. With the onset of the obstructive phase, urobilinogen temporarily disappears from the urine to reappear during recovery. The feces is clay-coloured during the obstructive phase.

Blood

Initially there is leukopenia with relative lymphocytosis which reverts to normal with the onset of jaundice. Atypical lymphocytes may be present in small numbers. The erythrocyte sedimentation rate is mildly elevated in the pre-icteric phase returning to normal as jaundice appears.

Biochemical Tests

These depend upon the severity of hepatic functional impairment. The prothrombin time may be prolonged. Serum bilirubin increases in the first two weeks to reach levels of 10-15 mg/dL or more. This is a mixture of conjugated and unconjugated pigment, the former predominating. Serum bilirubin levels return to normal in 3 to 4 weeks. Serum transaminase values-alanine and aspartate transaminases (SGPT and SGOT) increase considerably to reach peak levels just before or after the onset of jaundice. In the majority of cases the enzyme levels are in the range of 200-600 IU/L. Raised levels may persist even for a few months after apparent clinical recovery. In some cases the enzyme levels reach much higher values. Apart from the transaminases, alkaline phosphatase, 5-nucleotidase, gamma glutamyl transpeptidase and serum LDH are moderately elevated. Serum alkaline phosphatase level rarely goes above twice the normal value and this helps in differentiating viral hepatitis from extrahepatic obstructive jaundice. Persistent elevation of the enzymes beyond six months would point to the development of chronic liver disease.

Serological markers are diagnostic for the different viruses. Second and third generation ELISA help to demonstrate viral antibodies. Recombinant immunoblot assay detects antibody to HCV and qualitative PCR measures the viral RNA.

Serological Markers for Diagnosis

Hepatitis B virus: Acute hepatitis due to HBV may be associated with HBsAg and IgM HBc. If IgM HBc is negative the hepatitis may be due to other causes as well.

Presence of HBsAg alone indicates the carrier state. Modern tests can detect HBsAg levels as low as 1ng/mL. The usual values in acute hepatitis vary from 10,000 to 100,000 ng/mL.

Presence of HBeAg indicates infectivity. Generally HBsAg and HBeAg are positive in most cases. Routine testing of HBeAg is not indicated. In chronic cases presence of HBeAg is an indication for starting treatment. Favourable response results in the production of antibody to HBeAg. Anti-HBe antibody (anti-HBe ab) appears in the serum and this indicates resolution and success of therapy.

Anti-HBe is found in both acute and resolved cases of HBV hepatitis. In acute hepatitis IgM anti-HBe is elevated in all cases and its presence is diagnostic. In chronic infections it is the IgG antibody.

Anti HBs antibody is not a reliable test to determine the prevalence of HBV infection in the population, but it is a good test to determine the success of vaccination against HBV.

Hepatitis C is diagnosed by demonstrating anti HCV antibodies and PCR tests to detect the viral RNA. Genotyping helps to characterize the virus, assess the prognosis and plan treatment.

Liver biopsy: Liver biopsy is not indicated in the ordinary case. Biopsy is indicated to differentiate viral hepatitis from extra hepatic obstruction and confirm the presence of chronic hepatitis if the condition does not resolve and diagnostic parameters are not clearcut. It is advisable to have biopsy confirmation of the persistent hepatic lesion before starting on interferon therapy.

COMPLICATIONS AND SEQUELAE

Complications occur in a small proportion of cases whereas the vast majority of cases recover uneventfully.

1. **Relapse:** About 15% of patients may get relapse after initial clearance of jaundice. Premature resumption of physical activity favours relapse. With proper management this also subsides completely.
2. **Prolonged cholestasis:** Cholestasis may persist due to the development of intrahepatic obstruction. This is more frequently seen with acute HAV and HEV infections. With rest and supportive measures these patients usually recover completely within weeks or months.
3. **Fulminant hepatitis:** This is a serious complication occurring in 1 to 2% of patients, more so in type B hepatitis. Hepatic function deteriorates rapidly with the onset of hepatocellular failure. When hepatic encephalopathy occurs within 8 weeks of onset of jaundice it is called fulminant hepatic failure. If this occurs between 8 weeks and 28 weeks it is called subacute hepatic failure. Hepatitis B is responsible for 30-60% of cases of acute hepatic failure. The liver

shrinks progressively. The condition is fatal in 80% of patients, irrespective of the treatment. Death is due to cerebral edema, brainstem damage, gastrointestinal hemorrhage, infections or renal failure. The overall mortality is 2% in HBV infections, but 10% or more in post-transfusion hepatitis, since the infecting dose is high in the latter.

Chronic hepatitis: This is defined as continuing inflammation of the liver persisting for more than six months. HBV is responsible for chronic hepatitis in 30-50%. Chronic hepatitis may take the form of chronic persistent hepatitis which is benign and self-limiting or chronic active hepatitis which is more sinister and often ends up in hepatic failure or cirrhosis.

Cirrhosis: HBV and HCV can progress to cirrhosis directly or passing through a stage of chronic active hepatitis. HCV relentlessly progresses to chronic liver failure and it is a frequent cause for hepatic transplantation. Median time from infection to cirrhosis is $\pm$ 30 years.

Hepatocellular carcinoma: Both HBV and HCV are oncogenic. Persistence of the virus in the system for 25 years or more predisposes to carcinoma. The risk of developing hepatocellular carcinoma is high in HBV carriers. The incidence of cancer in a community correlates directly with the HBV carrier rate. In areas where HBV carrier rate is very high (15%), the mean age for carcinoma is 25 years, since a good number of subjects get infected perinatally. In areas where the HBV carrier rate is low (1% or less), the mean age for cancer is 50 years or more, since the main source of infection is parenteral or sexual route. Malignancy may follow hepatitis directly or through a phase of cirrhosis. HCV is also carcinogenic.

Post-hepatitis syndrome: Sometimes symptoms of illhealth persist for many months after apparent recovery. The liver may remain slightly enlarged with evidence of mild or moderate dysfunction. Such persons generally show anxiety and loss of morale which aggravate the disability. If followed up, many recover. Only reassurance is needed.

Extrahepatic manifestations: Patients with HBV or HCV infection have circulating immune complexes, which lead to the development of serum sickness-like picture early in the disease. These are more prominent in the case of HCV.

Aplastic anemia: Aplastic anemia may follow HAV and HCV infection rarely. This is an immune mediated process.

Differential diagnosis: Drug-induced hepatitis, intra-hepatic cholestasis due to other causes and cholangitis present with jaundice, and these have to be differentiated.

Though hepatic amebiasis is not generally associated with jaundice, in a few cases it may create problems when mild or moderate jaundice occurs. Hepatic amebiasis presents with tender hepatomegaly, moderate leukocytosis, no impairment of hepatocellular function and recovery with anti-amebic drugs. Outbreaks of liver damage resulting from toxic products (e.g., veno-occlusive disease and aflatoxicosis) may be initially mistaken for viral hepatitis. Falciparum malaria should be excluded in all cases. Leptospirosis is a common cause for acute hepatitis at present.

Differential Diagnosis of Viral Hepatitis

Drug induced hepatitis	Rise of ALT is only moderate – compared to the rise in bilirubin
Alcoholic hepatitis	
Falciparum malaria	This should be considered in all cases and excluded by repeated examination of blood smear.
Gallstone disease with acute biliary obstruction	The transaminases may rise abruptly to high levels and fall soon. Serum bilirubin and alkaline phosphatase may rise later. Ultrasonography is most often diagnostic.
Acute anoxic damage to liver	This occurs in passive venous congestion occurring abruptly. This may lead to abrupt rise of SGPT to very high levels even 10000 IU/L, but unlike as in viral hepatitis where LDH level is only moderately increased, here LDH is also very much raised.
Leptospirosis	This presents with acute hepatitis and jaundice, proteinuria, hemorrhagic manifestations and neutrophil leucocytosis. Leptospira antibodies are demonstrable.

PROGNOSIS

Virus A hepatitis is a benign disorder which recovers uneventfully in most of the cases with mortality below 2%. In children the disease runs a milder course whereas in the elderly patients complications occur. Fulminant hepatitis carries a grave prognosis. During pregnancy viral hepatitis carries a higher risk of mortality and morbidity, especially in the malnourished subjects. The prognosis of HBV is more serious, mortality and morbidity being higher. Though the vast majority recover, 1-2% go on to chronic hepatitis and carcinoma. In 5-10% of cases the carrier state persists and such people can be infective to others.

HCV follows the same long-term behaviour as HBV. Unlike HBV which can exist in a carrier state with no lesion in the liver, HCV tends to produce chronic lesions in the liver in most cases.

HDV aggravates the clinical picture of HBV and leads to greater incidence of acute hepatic failure. HDV gets eradicated when HBV disappears.

HEV is more benign, except when it occurs in pregnant women in whom the mortality may reach up to 40%.

MANAGEMENT

Bed rest: All patients with acute viral hepatitis should be put to bed since this helps in speeding up recovery and avoiding complications. Heavy physical exertion is better avoided for a period of six months.

Diet: It is customary to recommend a low fat diet in the early stage of viral hepatitis so as to reduce nausea and abdominal discomfort. A normal diet can be resumed as the appetite returns.

Specific therapy: Drugs which are effective against HBV include ribavirin, lamivudine, adefovir, tenofovir, entecovir and interferon alfa (IFN α).

Ribavirin is an antiviral antibiotic given in a dose of 1000-1200 mg/ day oral for long periods. It is effective against HBV.

Lamivudine (Zeffix Glaxo SmithKline) It is a nucleoside analogue which inhibits DNA chain synthesis. The dose is 100 mg to 300 mg oral/daily. The drug is effective against HBV. It is also effective against HIV. Resistance to lamivudine therapy may develop and this is a major disadvantage. Main adverse side effects include anemia and teratogenic potential.

Adefovir dipovaxil (Hepsera-Gilead): This is an inhibitor of reverse transcriptase, effective against HBV. The dose is 10 mg/ day. It is indicated when the virus develops resistance against lamivudine. Doses above 30 mg/day may lead to nephrotoxicity.

Tenofovir (Viread-Gilead): This is also an analogue of adefovir and is a reverse transcriptase inhibitor. The dose is up to 300 mg per day oral. In cases resistant to adefovir, tenofovir may still be effective.

Entecovir is a newer analogue where is reported to be safe and effective.

The viruses may become resistant to all these drugs. The exact duration of therapy has not been conclusively determined. In those with favorable response the treatment has to be continued for several years (4 or more).

Indigenous drugs have been introduced from time to time. Though many of them have not undergone rigorous

clinical trials, some of them especially extracts of *Phyllanthus niruri* have shown benefit and seroconversion in a small proportion of cases.

Interferon Alpha (IFN- α)

This is used for hepatitis B, hepatitis C and also hepatitis D infections. This treatment is effective.

Interferon therapy is started when there is no further chance of natural cure and if the abnormal liver functions and liver biopsy findings persist after six months of clinical remission.

Combination of ribavirin 1000 mg oral bd and interferon 2-3 million units IM daily gives better results than either drug given alone. With higher doses of interferon the cure rate may go up to 60%.

Side effects of interferon include malaise, fever, shivering and 'flu' like symptoms within a few hours of injection. With successive injections the side effects came down. These side effects can be controlled by paracetamol 500 mg given orally. Other side effects include anorexia, hair loss, depression weight loss, marrow suppression, seizures and susceptibility to bacterial infection. Beneficial effects are monitored by the level of transaminases and clinical improvement. Majority of the cases that improve do so within 2 months. Maintenance of normal transaminase levels for six months or more after cessation of therapy indicates cure.

- Cure rates in HBV on interferon are 25-40%
- In HCV 6-12 months therapy gives cure rates of up to 40%.
- In HDV the remission rate is up to 25%.

Earlier the treatment is started, better is the response. Absence of cirrhosis, absence of high levels of hepatic iron in biopsy before therapy and HCV genotypes 2 and 3 indicate favourable prognosis.

Pegylated interferon (interferon attached to polyethylene glycol) which has longer duration of action gives better cure rates with less of side effect. The drug is more expensive.

Indications for Specific Therapy in HBV Infections

1. Presence of HBeAg with raised transaminase
2. HBe negative, but HBV DNA+, with raised transaminase
3. and HBe + cirrhosis

Treatment is by suitable combination of ribavirin, lamivudine, adefovir and interferon α . Dose of IFN for hepatitis B is 2-5 million units daily or 10 million units three times a week for 16 weeks or longer. The response to IFN varies with the type of virus. In HBV 30-40% respond with disappearance of hepatitis B antigen and HBV DNA from serum. There is an initial transient

exacerbation of hepatitis, followed by eventual recovery. The serum transaminases return to normal and HBsAg is also cleared gradually in 60% of cases or more. Recurrence is unusual. Alpha interferon is available as Roferon and Viraferon.

Duration of therapy should be from 1 year or more. Up to 30% develop resistance to the drugs and alternate drugs may be required. On stopping therapy HBV DNA may reappear. When HBV coexists with HIV, the dose of lamivudine has to be increased to 300 mg / day. It is likely that prolonged lamivudine therapy delays the onset of cirrhosis and carcinoma.

Results of therapy: Seroconversion rate is up to 32%, disappearance of HBsAg in < 1%, and normalization of transaminases in 41-72%. Histological improvement occurs in up to 50%.

6

Treatment of HCV

Acute HCV infection: IFN α 2b, 5 million units/day IM injection for 4 weeks and thereafter 3 times a week for 20 weeks. In chronic hepatitis C the pattern is different. Hepatitis C is more susceptible to interferon and smaller doses (3 million units given thrice a week for 6 months) are sufficient. Patients without cirrhosis do better than those with cirrhosis. In 50% of cases the transaminases fall to normal level and HCV RNA disappears from serum by the end of therapy. Relapses are more common and only 20-25% get permanent cure.

Chronic hepatitis C standard treatment Peginterferon + Ribavirin. Two formulations of peginterferon are available to treat HCV: The recommended dose for peginterferon alpha-2a is 180 μ g per week and that of peginterferon alpha 2b is 1.5 μ g/kg bw weekly. Ribavirin is also given in daily doses of 1000 mg oral for those <75 kg bw, and 1200 mg for those >75 kg bw. Duration of treatment for HCV genotype 1 is 48 weeks. For genotypes 2 and 3 the duration of treatment is only for 24 weeks with a dose of ribavirin of only 800 mg daily. For genotype 4, 5 and 6, the regimen for genotype 1 is given. Cost of treatment for 48 weeks is \$ 30-40,000. Persons with HCV above the age of 18 years should be treated if HCV-RNA is detectable in serum and evidence of chronic hepatitis such as elevation of SGPT and necroinflammatory changes are present in liver biopsy.

Follow-up: Prolonged follow-up is necessary in cases which have developed complications.

PROPHYLAXIS

HAV and HEV infections can be prevented by boiling drinking water for 10 min during the epidemics. General precautions to prevent fecal-oral spread should be instituted. These include personal hygiene, disposal of excreta and control of flies.

Passive immunization: Immune serum globulin (ISG or pooled human gammaglobulin) prevents or modifies virus A infection. The dose is 0.02 to 0.12 mL/kg given intramuscularly within 14 days of exposure. Passive immunisation is indicated in contacts of HAV hepatitis, pregnant women at risk, travellers to endemic areas and those who have received probably infected blood. The protection lasts for 4- to 5 months, therefore, the dose has to be repeated at 5 month intervals. Sexual and familial contacts of cases of HAV hepatitis during the incubation period should be given gamma globulin.

Active Immunization

Hepatitis A be prevented by vaccination. The vaccine is effective in 94-100% of the vaccinees. Formalized inactivated HAV virus vaccine is available.

Dose 2-18 years of age— 2 doses of 0.5mL at intervals 6-18 months.

Above 18 years of age— 2 doses of 1 mL. 6-18 months apart.

HAV vaccine is indicated for children in endemic areas, high risk groups such as hospital staff and travellers into endemic areas. Immunity against HAV lasts for several years (> 6). Further prolonged follow up is needed to assess the exact period of immunity. The vaccines costs about Rs.700/ dose adverse effects include local pain and mild general symptoms.

Combined HBV and HAV vaccines (TWINRIX) is available. Schedule is the same as for HBV (i.e.) 1mL each at 0, 1 and 6 months. The immunity agent HBV is strong for 10 years after which it may wane.

At present vaccines against HEV are not commercially available.

Hepatitis B: Avoidance of professional blood donors, avoidance of pooled blood products and screening of all blood donors for HBV and HCV help to minimize the risk of transmission. Boiling all equipment for ten minutes or autoclaving will destroy the virus. Those who have had jaundice during the past six months and those who are known to have caused post-transfusion hepatitis should be rejected as blood donors. Use of disposable needles and syringes for injections helps to safeguard against hepatitis.

Passive immunization: Passive immunization is required for those who have no demonstrable antibody against HBsAg. Hepatitis B immune globulin (HBIG) contains a high titer of anti-HBs and affords passive protection for three months if given within two days of exposure. The initial dose is 0.05 to 0.07 mL/kg body weight intramuscularly. A second dose is given 25 to 30 days later. The immunity lasts for a period of six months.

Indications for HBIG

1. Needle prick injury.
2. Spouses and sexual partners of acute HBV hepatitis patients.

- 3. Accidental transfusion of HBsAg +ve blood or blood product.
- 4. Mucosal contact with HBsAg +ve blood or other infective material in laboratory workers.
- 5. Babies born to HBsAg +ve mothers.

Babies born to mothers who develop hepatitis B during the third trimester or who are positive for HBsAg at the time of delivery should be given 5 mL HBIG on the day of birth and then every five weeks for six months till the baby is actively immunized. HBIG is available in India, but the cost is high. Immunization against HBV also protects against HDV.

Active Immunization

Effective vaccines are available widely for immunization. Commercial vaccines are prepared from two sources mainly.

- 1. Vaccine prepared by HBsAg of carriers— This plasma vaccine is cheaper and still used widely in many countries (Heptavac). Cost/dose around Rs. 50. Side effects include local soreness and mild febrile reactions.
- 2. Vaccine produced by recombinant DNA technology in yeast. This vaccine is more expensive costing about Rs. 400/- per mL. Each mL contains 20 mg of the material.

Vaccination is given to children after the first year of life by which time the maternal antibodies would have disappeared.

Dose children

2-18 years 0.5 ml (720 ELISA units) at 0, 6 and 12 months by IM injection

Adults

above 18 years 1 ml (1440 ELISA units) at 0, 6 and 12 months.
Antibodies start appearing by 3 weeks after vaccination. Immunity lasts for 10 years. The vaccine should not be frozen.

Side effects are few and it is one of the safe vaccines.

Indications for Vaccination

- 1. High risk groups—medical students, medical and paramedical personnel.
Those receiving hemodialysis, peritoneal dialysis, repeated doses of blood and blood products, babies born to HBsAg +ve mothers, spouses and sexual contacts of HBsAg +ve subjects.
- 2. Elective—Since the best method to reduce carrier state is to prevent the spread of infection, vaccination is indicated to all persons (irrespective of the age at onset of vaccinating schedule), if facilities permit.

In many countries, hepatitis vaccine has been included in the schedule for vaccination of infants, along with the DPT, polio and measles vaccines.

Schedule for vaccination

	1st dose	2nd dose after one month	3rd dose after six months
Adults	1 mL	1 mL	1 mL
Infants and newborns	0.5 mL	0.5 mL	0.5 mL
Booster at 5 years			

For infants of HBsAg +ve mothers HBIG and vaccine are given within 12 hours of birth and thereafter at 1, and 6 months. Protective titer of antibodies are not impaired by concurrent administration of HBIG and vaccine. The protective antibody level is 10 µIU/mL.

Immunity starts in about 1 month of first dose, and is strong by the third month. By six months more than 90% are immune. When the protection is desired early, accelerated course of vaccination can be given. This consists of 3 doses given at 1 month intervals and a booster at 12 months. Immunogenicity is more if IM injections are given over the deltoid region than over the gluteal region and therefore the former site should be chosen.

Intradermal injection of 0.1 ml of vaccine is also effective, but the immunization rates are lower.

Procedure to be followed if health care personnel get needle stick injuries with HBsAg positive blood contamination.: - Passive, immunization should be given with 3 mL HBIG (1 mL = 200 units) as early as possible and active immunization should be started simultaneously. Extensive vaccine coverage over the previous three decades have significantly reduced the incidence of hepatic cirrhosis and carcinoma in young adults in several countries.

Vaccine Against Hepatitis E Virus

A recombinant anti HEV vaccine has been tried in Nepal. 3 doses were given IM at 0, 1 and 6 months. Compared to placebo it gave 95.5% protection. Further trials are in progress.

Ref: Sreshta MP, et al. N Engl J Med 2007;356:895-903.

Points to remember

- 1. Hepatitis viruses belong to six different families
- 2. Infection is very common
- 3. Viruses A and E are feco-orally transmitted
- 4. Virus B, C and D are transmitted by parenteral inoculation
- 5. Viruses B and C lead to cirrhosis and carcinoma of the liver
- 6. Effective preventive measures are available for HAV and HBV.

Chapter Summary**Poliomyelitis 328****Echo Viruses 330**

Aseptic Meningitis 331

Acute Hemorrhagic Conjunctivitis (AHC) 331

Coxsackie Virus Infections 331

Hand-Foot-and-Mouth Disease 332

These are viruses which are found in the alimentary tract of man. These include poliomyelitis, Coxsackie, echo and several other viruses. They are isolated from the feces of healthy and sick individuals. Most of them are host specific and antigenically distinct.

Poliomyelitis*Syn: Heine Medin Disease, Infantile paralysis*

Poliomyelitis is an acute contagious disease producing a wide clinical spectrum ranging from a non-paralytic illness in which the patient develops symptoms and signs of meningeal involvement without paralysis to a severe paralytic form in which flaccid paralysis results from affliction of spinal motor neurons and brainstem nuclei. Poliomyelitis viruses belong to the group of *picorna viruses*. Three types are pathogenic—types 1, 2 and 3. Type 1 is most common and is responsible for the majority of paralytic cases. Types 1, 2 and 3 do not show cross-immunity.

Epidemiology

The disease is worldwide in distribution, spread by the feco-oral route. The virus is eliminated in feces by cases and carriers. The disease may occur sporadically or in outbreaks. Majority of cases of infection are inapparent with only transient nonspecific symptoms and a rise in antibody levels. Classic paralytic polio develops only rarely. Poliomyelitis used to be common in India with an incidence of 20-30/100,000 of the population. About 90% of children aged 5 years and above showed the presence

of neutralizing antibodies to all the three types of polio viruses acquired naturally, during the 1980s. Worldwide efforts to contain poliomyelitis started in 1988 with the aim of eradicating poliomyelitis from the world. Only humans act as reservoir of the virus and therefore it may lend itself to eradication by eliminating the human reservoir by vaccination coverage. By intensive and extensive mass vaccination programmes conducted nation wide, the incidence of poliomyelitis has been considerably reduced, though India is still not polio-free. With the decrease in incidence of paralytic poliomyelitis the relative frequency of non-polio paralytic lesions have increased.

Pathogenesis and Pathology

The virus enters the system by ingestion. It proliferates in the cervical and mesenteric lymph nodes and Peyer's patches. At this stage the virus may be present in the oropharyngeal secretions and feces. The next stage is one of viremia. The virulence of the virus and immune status of the host determine the localization of the virus to the central nervous system. Even a genetic predisposition to paralytic polio has been postulated. Physical exhaustion, intramuscular injections, tonsillectomy and local injury have all been known to be associated with paralysis localized to the affected part.

In the paralytic cases, the anterior horn cells of the spinal cord and the medullary nuclei are, swollen and congested. As the condition proceeds chromatolysis and pericellular infiltration occurs. The neurons are totally destroyed. Occasionally other parts of the CNS such as roof of the fourth ventricle and vermis, midbrain, substantia nigra, thalamus, globus pallidus and hypothalamus may be involved. In the early stages, the CSF shows increase in cells, mainly polymorphs, but this gives way to lymphocytic increase with the passage of time. Protein level may be moderately increased (up to 150 mg/dL) and the sugar level is normal.

CLINICAL FEATURES

The incubation period is 7-14 days. The disease manifests a bimodal pattern, the initial features are due to viremia

and the second one is due to neurological damage. Initial symptoms are nonspecific such as fever, headache, muscle pain and diarrhea. The second phase, which sets in after a period of three to four days, is characterized by paralysis. In many the infection may be subclinical.

Nonparalytic polio: Features of meningitis develop in nonparalytic polio. These include fever, headache, neck rigidity and muscle pains. Physical examination may reveal signs of meningeal irritation. The condition subsides without further events within a week.

Paralytic polio: In paralytic polio, paralysis may involve the spinal group of muscles, bulbar muscles or a combination of both.

Spinal form: The initial manifestations in this form are followed by diffuse muscle twitching and cramps. The muscles may be tender. Transient fasciculations may be noted. Paralysis of muscles sets in rapidly by the third or fourth day of illness. The spectrum ranges from mild weakness of a limb or a part thereof to extensive flaccid quadriplegia. Paralysis usually takes place within hours in the majority of cases, rarely it may take four to five days or more. There seems to be a predilection for the cervical and lumbar segments of the spinal cord. The tendon jerks are abolished. Objective sensory changes do not occur. The paralysis is asymmetrical, maximal in the beginning and tends to recover with time. Total destruction of neurons leaves behind complete paralysis, partially affected groups recover to varying degrees. The final picture is one of different combinations of muscle paralysis. Often part of a muscle is affected, leaving the remaining part unaffected. Ventilatory insufficiency may develop, if the diaphragm and intercostals are paralyzed. Respiratory failure manifests as restlessness and tachypnea, with shallow irregular respiration.

Bulbar form: Affection of the lower cranial nerves occurs early in this form. It may precede or follow the spinal involvement. Dysphagia, dysarthria and dysphonia occur commonly. Facial palsy may develop less commonly.

Involvement of the nuclei of the medullary reticular formation results in dysfunction of the vital areas such as the respiratory and vasomotor centers. These manifest as irregularity of respiration with apnoeic spells, vasomotor collapse, transient hypertension, and acute pulmonary edema.

Polioencephalitis: This form is unusual and is characterized by alteration in the level of consciousness, convulsions, signs of brainstem involvement and varying combinations of spastic or flaccid paralysis. This condition may mimic other forms of encephalitis.

Diagnosis: Poliomyelitis should be diagnosed clinically in any unimmunized child who develops an initial febrile illness and proceeds to acute paralysis within a few days. The clinical features and the CSF findings help to make a bedside diagnosis in almost all cases. Rarely Coxsackie

and Echo viruses are also capable of producing paralytic disease. There are reports of increasing incidence of Japanese encephalitis virus causing polio like presentation with asymmetric flaccid paralysis of limbs, meningism and lymphocyte pleocytosis in the CSF.

Laboratory Investigations

The virus can be grown in tissue culture from specimens such as feces, rectal swab and CSF. PCR studies help to identify the virus and distinguish it from other wild polio viruses. CSF shows moderate lymphocytic pleocytosis (100-200 cells/cmm) and mild elevation of proteins (40-50 mg/dL). These changes occur in several other conditions and therefore may not help in specific diagnosis. Serological diagnosis is established by demonstrating rising titers of neutralizing and complement fixing antibodies in the serum.

Differential Diagnosis

Nonparalytic poliomyelitis has to be differentiated from other conditions causing aseptic meningitis. *Acute motor polyneuropathy* occurring in nutritional and toxic neuropathies, viral encephalitis and Guillain-Barré syndrome may cause difficulty in diagnosis. In *Guillain-Barré syndrome* there is considerable rise in CSF proteins without rise in cells (albuminocytological dissociation), whereas in polio the cellular response occurring before the rise in proteins is marked. Nerve conduction studies also help in diagnosis. Slowing of the velocity of nerve conduction in the peripheral nerves and nerve roots is suggestive of Guillain-Barré syndrome. *Acute intermittent porphyria* may present rarely with motor paralysis. Other features of the disease such as psychiatric disturbances, abdominal pain and hypertension may be evident. Demonstration of excess of porphobilinogen in the urine supports the diagnosis. Sometimes painful conditions near the joints result in restriction of movement of the part. Such *pseudoparalysis* may occur in osteomyelitis, periosteitis, arthritis, hemophilia, scurvy with subperiosteal bleeding, syphilitic epiphysitis, etc. These have to be carefully looked for and excluded by local examination. Rarely hysterical paralysis may be mistaken for poliomyelitis. This has to be borne in mind when other features of hysteria are suggestive.

Prognosis

In the spinal form of paralytic poliomyelitis in children, mortality is 2-5%. Morbidity is variable. In adults mortality may go up to 15-30%, reaching 75% in bulbar polio. Death is due to respiratory paralysis, autonomic disturbances and encephalitis syndrome.

Treatment

Complete bed rest, analgesics and local heat to sore muscles give symptomatic relief. Since there is no specific

treatment, supportive measures are all important. The tendency to tire out muscles which are in a state of partial paresis should be avoided. The respiratory rate, deglutition and blood pressure should be closely monitored to detect complications early. In cases with bulbar polio, feeding by nasogastric tube and parenteral administration of nutrients and fluids may be required. Cases showing signs of respiratory embarrassment should be nursed in a respiratory intensive care unit. When the vital capacity drops to 25-30% of normal, endotracheal intubation and artificial respiration are called for. Normal vital capacity (VC) for adults = $25 \times \text{height in cm}$; VC for children is $200 \times \text{age in years}$. If ventilatory failure tends to persist, tracheostomy is indicated.

Once the acute phase is over, the muscle strength returns to varying degrees. This improvement is brought about by the recovery of partially damaged neurons, compensatory hypertrophy of the remaining motor units and sprouting of the peripheral nerve endings. In most cases considerable improvement in function is evident in 3-4 months. Further improvement is facilitated by active physiotherapy which is intended to prevent wasting and contractures and stimulate and restore function in partially paralysed muscles.

Deformities of the axial skeleton develop in severely paralysed patients. The affected limb fails to grow whereas the normal one undergoes compensatory hypertrophy. Contractures may result in further loss of function of the limbs. Planned orthopedic surgery and rehabilitation help to relieve functional and cosmetic disability in such cases.

Post-polio syndrome (PPS): This is progressive muscular atrophy and muscle weakness occurring several years after apparent recovery from poliomyelitis with residual paralysis. The distinctive features include weakness, pain, fasciculations and atrophy of muscles. Muscles supplied by bulbar nuclei, and diaphragm may be affected. Sleep apnea may develop. The exact pathogenesis is not clear. The severity of PPS before some relation to the severity of the original attack of polio.

The possibilities include:

1. Progressive attrition of surviving motor neurons and eventual loss of the axonal terminals, and
2. Following paralytic polio some of the surviving neurones sprout new endings in an attempt to restore muscle function. This may account of the partial recovery of strength for several years following the acute attack. It is likely the metabolic function of these neurones deteriorate and this leads to PPS.

The CSF shows elevation of IgM and interleukin-2 which point to an immunological basis for this syndrome.

PREVENTION

By and large poliomyelitis is a preventable disease. Prophylactic vaccination has significantly reduced the

occurrence of polio epidemics. Two types of vaccines are available-live vaccine (Sabin) which is given orally and the killed vaccine (Salk) which is given subcutaneously. The live vaccine is more widely used. The vaccines contain all the three viruses. The trivalent vaccine is given in three doses in the second, fourth and sixth months of age. The immediate response is the formation of IgM antibodies, to be followed later by the appearance of IgG antibodies in 90-99% of cases. In addition, the live attenuated vaccine also stimulates the formation of local IgA which gives immunity in the gut also. Booster doses are given at the age of 1½ and 5 years. Clinical trials conducted in several parts of India have suggested that the standard course of oral vaccination gives protective levels of antibody only in 60-70% cases. Therefore, five doses are recommended at monthly intervals (2,3,4,5 and 6 months) for better protective levels.

The vaccines are generally safe. Oral vaccine has produced limited outbreaks of minor paralytic disease, but with the present vaccines this risk is very low. While immunising children in closed community like a slum or a hostel, it is advisable to cover all the eligible children (up to the age of ten years if they have not been previously vaccinated). The killed vaccine may produce trivial adverse effects like pain at the site of injection and fever.

Eradication of poliomyelitis can be achieved by full coverage of the population by vaccination, provision of protected water supply and general improvement in hygiene. Continued surveillance is absolutely essential to prevent outbreaks. In several countries occurrence of fresh cases has been arrested. India has not achieved this goal yet.

As part of a strategy to eradicate the major infectious diseases of childhood, especially poliomyelitis, the Indian Medical Association (IMA) has recommended the following regime for immunization,

Contact	Age of child	Vaccine	Other care
1	At birth	BCG, OPV	
2	6 weeks	DPT, OPV	
3	10 weeks	DPT, OPV	
4	14 weeks	DPT, OPV	
5	9 months	Measles	Vit. A
6	16 months (Booster)	DPT, OPV	Vit. A

At present Indian Medical Association (IMA) is the main agency working with governmental institutions in giving effect to the pulse polio programmes.

Echo Viruses

Syn: Enteric cytopathogenic human orphan viruses

These are RNA viruses ranging in size from 20-30 nm which produce a spectrum of diseases ranging from mild upper respiratory infection, fever with rash, aseptic

meningitis to acute hemorrhagic conjunctivitis. Over 30 serotypes have been identified by using virus neutralization tests.

Pathogenesis

The virus gets in by ingestion and the mode of spread is feco-oral. After an initial period of viral multiplication in the epithelium of the intestines and respiratory tract, they enter the bloodstream to produce viremia. The organisms reach the various target organs from the bloodstream.

Clinical Features

The incubation period is generally 2-5 days but for hemorrhagic conjunctivitis it is shorter (12-72 hours).

The clinical manifestations include nonspecific fever, upper respiratory tract infections, exanthems, diarrheas, pneumonia, myopericarditis and serious neurological involvement.

Aseptic Meningitis

Aseptic meningitis may occur as a result of infection by several strains of echo viruses. Signs of meningeal irritation or rise in intracranial tension may be evident. The acute phase may last for 4-7 days.

The CSF shows lymphocytic pleocytosis usually less than 500/cmm. Mixed pleocytosis may occur in some cases. Complete recovery is the rule, but rarely complications such as transverse myelitis, bulbar paralysis, Guillain-Barré syndrome, cerebellar lesions and coma may develop.

Treatment

There is no specific treatment and, therefore, treatment is symptomatic and supportive. Prophylactic measures include improvement of environmental sanitation, provision of protected water supply and elimination of flies. Vaccines are not available for general use.

Acute Hemorrhagic Conjunctivitis (AHC)

This disease occurs in pandemics from time to time (1971, 1981). Most of the cases are caused by the *enterovirus EV 70*. All age groups are affected, children being more. The age group of 21-40 are more prone to develop neurologic complications. Infection is acquired by direct spread to the eyes from contaminated fingers, or by fomites. Incubation period is 12-72 hours. Initial symptoms are bilateral conjunctivitis with irritation of the eyes and watery discharge. The conjunctiva may show blotchy hemorrhage. In the vast majority of cases the symptoms subside without other local complications within 7-10 days. Secondary bacterial infection and keratitis may develop. The virus can be isolated from the

conjunctival secretions. In a small proportion constitutional symptoms such as fever, malaise and limb pains may occur.

Neurological complications may develop in a few, usually within 2-3 weeks (even upto four months). Adult males are affected more. These may take one of three forms—spinal, cranial or combined.

Spinal form: Asymmetric flaccid paralysis of the proximal muscles of the lower limbs, associated with backache and followed by muscular wasting.

Cranial form: Isolated or combined cranial nerve palsies.

Combined form: A variable combination of both. Sensory symptoms are absent or minimal. Examination of the cerebrospinal fluid (CSF) during the early stages may reveal mild lymphocytosis and moderate rise in proteins. Neutralizing antibodies against EV70 can be demonstrated in the majority of cases, in the serum as well as CSF. Treatment is symptomatic.

Coxsackie Virus Infections

Coxsackie viruses are picorna viruses which can be grouped into A and B. They were first isolated from the village of Coxsackie in New York by Dalldorf in 1948 and the name is derived therefrom. About 30 immunological types have been isolated. Many strains are commensals in the alimentary and respiratory tract of man. Spread is by the feco-oral route and small outbreaks occur especially in summer. The causative role of these viruses in any specific illness can be established only by isolating it from specific lesions in the affected organs, or tissue fluids.

Pathogenicity

Several lesions are produced by these viruses group A and B. These include (1) neurological lesions, (2) respiratory disorders, (3) carditis, (4) hand-foot and mouth disease and others. The incubation period is 2-14 days.

CLINICAL FEATURES

Neurological lesions: The clinical syndromes include polio-like paralysis, meningoencephalitis and aseptic meningitis. The pathological lesions are:

- Neuronophagia of the anterior horn cells of the spinal cord and perivascular infiltration, by lymphocytes,
- Meningoencephalitis, and
- Scattered foci of degeneration in the spinal cord, cerebral hemispheres, pons and cerebellum.

Respiratory lesions: Pleura is most characteristically involved. The syndrome of pleurodynia (*devil's grip*, *Bornholm's disease*, *epidemic myalgia*) is caused by Coxsackie B group viruses.

Severe pain develops in the chest and upper abdomen, after a prodromal febrile illness. Breathing becomes painful, short, shallow and rapid. Physical examination may reveal

pleural rub, pleural effusion, pneumonia, myocarditis, pericarditis, hepatitis or orchitis. The acute phase subsides in 2-3 days but mild fever and pain may persist for a longer period. Pleurodynia has to be distinguished from acute myocardial infarction, other forms of pleurisy and surgical abdominal emergencies. Symptomatic treatment with rest and analgesics gives relief.

Cardiovascular lesions: The heart is affected by both groups of Coxsackie viruses, but group B is more common to produce acute myocarditis and pericarditis. Infection acquired congenitally or neonatally tends to be serious and rapidly fatal. This may be associated with encephalitis or adrenal necrosis. Pericarditis is more common in older children and adults. Myocarditis may lead to cardiac failure, arrhythmias or the late development of chronic cardiomyopathy and calcific or constrictive pericarditis. Electrocardiographic changes may occur. Congenital heart disease is associated with Coxsackie B types 3 and 4 infection acquired *in utero*.

Hand-Foot-and-Mouth Disease

Infections caused by Coxsackie viruses types A-4, 5, 7, 9, 10 and 16 give rise to a febrile illness followed by superficial vesicular eruptions inside the mouth, fingers, palms and soles. Occasionally small outbreaks may occur. The whole course lasts for 4-8 days after which the vesicles develop into shallow ulcers which heal completely without leaving behind any scar.

Diagnosis

Hand-foot-and-mouth disease may be mistaken for chickenpox, aphthous stomatitis or herpangina. In chickenpox the vesicles are more widely distributed, multiple crops occur and pustulation and scab formation are seen. These are absent in hand-foot-and-mouth disease. The virus can be isolated from the vesicle fluid. Neutralizing and complement fixing antibodies are also demonstrable. Treatment is essentially symptomatic.

Other Manifestations

Coxsackie viruses have been implicated in the production of herpangina (painful vesicles in the throat and pharynx), lymphonodular pharyngitis, hepatitis, exanthematous fevers and pancreatitis.

Laboratory Diagnosis

It is aimed at isolation of the virus and demonstration of rising titers of antibodies.

Treatment

There is no specific therapy. Majority of the cases recover completely in one to six weeks. Absolute bed rest and symptomatic treatment should be continued till the ECG becomes normal.

57

Adenovirus Infections

K.V. Krishna Das

Chapter Summary

Acute Febrile Respiratory Illness	333
Acute Pharyngoconjunctival Fever	333
Epidemic Keratoconjunctivitis	333

Adenoviruses are a group of DNA viruses which cause a range of febrile disorders characterized by inflammation

of the respiratory tract and conjunctiva and accompanied by submucous and regional lymphadenopathy. The name is derived from the fact that these viruses were first isolated from adenoid tissue removed surgically.

The virus is 60-90 nm in size. Several serotypes are known. Adenoviruses are implicated in the production of acute respiratory disease, intestinal infections and mesenteric adenitis. Adenovirus is a common cause of respiratory disease especially in children below 15 years

of age. The disease spreads by droplet infection. Oronasal secretions of infected persons contain about 10^6 - 10^7 virus particles/mL. Even as low as 5 viral particles can result in infection and therefore the infection spreads fast. The incubation period varies between 3 and 14 days.

Clinical Features

Several clinical disorders are caused by these viruses.

1. **Acute febrile respiratory illness** occurs more frequently in children. Paroxysms of cough may occur. X-ray shows patchy lobular pneumonia. Encephalitis may develop as a complication.
2. **Acute pharyngoconjunctival fever** produces the classical triad of fever, pharyngitis and conjunctivitis. The disease subsides in 1-2 weeks. Unilateral or bilateral simple conjunctivitis may develop in some.

3. **Epidemic keratoconjunctivitis** may occur in outbreaks, affecting particularly shipyard workers and in harbour personnel. The onset is sudden with unilateral edema, conjunctivitis, superficial corneal opacities and lymphadenopathy. Later the other eye is also involved. The course is for 3-4 weeks. The majority recover completely, though in a small proportion blindness may result from corneal lesions.

Diagnosis

Specific diagnosis is established by isolation of the virus or demonstration of viral DNA by PCR.

Treatment

It is symptomatic and supportive. Severe pneumonia in infants and epidemic keratoconjunctivitis require special management.

58

Arena Virus Infections and Hemorrhagic Fevers

K.V. Krishna Das

Chapter Summary

General Considerations	333
Lymphocytic Choriomeningitis	334
Lassa Fever	334
South American Hemorrhagic Fevers	334

General Considerations

Since 1930 several viruses especially arena viruses are known to produce hemorrhagic manifestations, though other groups of viruses can also cause the same. The hemorrhagic fevers can be grouped under three headings depending upon the virus and the vector. Localized or generalized hemorrhage may occur as alarming symptoms in infections by dengue, yellow fever, chikungunya, Kyasanur forest disease and arena virus infections.

1. **Mosquito-borne hemorrhagic fevers** e.g. Dengue types 1, 2, 3 and 4, Chikungunya, yellow fever virus.

2. **Zoonotic viruses which may be transmitted to man**, e.g. Korean hemorrhagic fever, Argentinian hemorrhagic fever and Lassa fever (Lassa virus).
3. **Tick-borne hemorrhagic fevers**, e.g. Kyasanur forest disease. Omsk hemorrhagic fever and Crimean congo hemorrhagic fever group. The vectors in some hemorrhagic fevers have not been identified yet.

Newer and newer viruses capable of producing this syndrome are being added to the list even now. Small outbreaks of hemorrhagic fevers caused by dengue and chikungunya viruses have occurred in several parts of India, particularly W. Bengal.

Hemorrhagic fevers of South Asia: Viral hemorrhagic fevers occurring in Philippines, Malaysia, Vietnam and eastern parts of India are collectively referred to as hemorrhagic fevers of south east Asia." These are all transmitted by *Aedes aegypti* mosquitoes. All types of dengue viruses (especially type 2) and chikungunya virus are responsible for most of the cases.

Diseases Caused by Infections

Arena viruses are RNA viruses belonging to three families. They may be round, oval or pleomorphic, ranging in size from 110 to 130 nm. Under the electron microscope they resemble grains of sand and hence the name arena viruses (Latin-arenosus means sandy)

They all occur as natural inhabitants in rodents.

Except Machupo virus the others exist without producing diseases in them. The infection is transmitted from parent to offspring in utero and thus a reservoir of infection is maintained. Man may get the infection directly through cuts and wounds. Lymphocytic choriomeningitis, Lassa fever and viruses causing hemorrhagic fevers come under this group.

Lymphocytic Choriomeningitis

LCM virus (LCMV) was one of the earliest viruses to be isolated in the mid 1930s. It belongs to the family, arenaviridae which contains, about 20 known viruses affecting different rodents which shed the virus without themselves suffering from disease.

LCMV has assumed importance with the infection occurring more commonly in transplant recipients. Most of the cases are subclinical with < 1% developing meningitis and with mortality < 1% LCMV infection may be transmitted by donors who themselves do not show signs of overt disease.

Incubation is one week. Disease starts with prodrome and fever. Meningitis occurs by about 15-20 days. CSF shows moderate lymphocytosis, up to 700/cmm. LCM occurring in transplant recipients is generally obscure and fatal if, on detected.

Another pattern of LCMV infection is that of a fatal hemorrhagic fever typical of that of Lassa fever which is also an arena virus.

Ribavirin is effective against the virus. LCMV infection occurring in pregnant women may lead to hydrocephalus, mental retardation and chorioretinitis in the newborns.

Lassa Fever

This occurs mainly in Africa. Majority of infections are subclinical. Symptomatic cases may present with chest pain, sore throat, cough, abdominal pain, vomiting, diarrhea, facial puffiness, myocarditis and conjunctivitis. Minor hemorrhagic manifestations may develop due to increase in capillary leak. Nerve deafness may occur as a complication.

Treatment is symptomatic. Ribavirin given orally in dose of 1000-1200 mg/day may be beneficial.

South American Hemorrhagic Fevers

Important in this group are *Argentine and Bolivian hemorrhagic fevers* and *Venezuelan hemorrhagic fever*. The general symptoms include fever, malaise, myalgia, hypotension, petechiae, capillary leak syndrome and neurological complications including convulsions and coma.

Serological tests may show antibody by ELISA. Virus can be isolated from blood and other tissues by cell-culture. Mortality ranges from 10-20%. Mainstay of treatment is intensive care with correction of fluid and electrolytes and symptomatic management of hemorrhagic manifestations. Vaccines against Argentine hemorrhagic fever and Lassa fever are under trial in endemic areas.

General Considerations

Syn: Hydrophobia, Lyssa

Definition

Rabies is an acute viral disease, primarily of animals, clinically characterized by rapidly progressive and fatal encephalitis, acquired by man through the bites or licks of infected animals.

Etiology

The etiological agent is an RNA virus belonging to the group of rhabdo viruses. The rhabdoviridae consists of five genera each of which has several species. Rabies virus is a species of (sero type1) of the genus Lyssa virus of the family rhabdoviridae. It is a rod shaped virus approximately 180 by 75 nm. When isolated first from animals, it was called “*street virus*”. This has a long incubation period and the virus multiplies in the salivary glands and the central nervous system. By repeated intracerebral passage in laboratory animals, it adapts to them. At this stage it is called “*fixed virus*”. It has a uniformly shortened incubation period (4 to 6 days) and it loses its ability to multiply in the salivary glands. It has reduced pathogenicity and is used in vaccine production. Rabies virus is rapidly inactivated by heat. At 56° C, the virus dies in less than a minute, whereas at 37°C, it survives for several hours under moist environment. The virus is also inactivated by ultraviolet light, detergents and soap solution, ethanol, iodine and quaternary ammonium compounds.

Distribution and Incidence

Rabies is enzootic worldwide except in a few countries. Rabies is widely prevalent in India, but human rabies is generally underreported. *In India, 30,000 deaths were reported to the WHO in 1998.* Other countries reporting high incidence of human rabies are Bangladesh, Nepal, Sri Lanka, Pakistan, Vietnam, Philippines, Indonesia, Mexico and Ethiopia.

All warm-blooded animals are susceptible to rabies. Dogs are most important in transmitting the disease to man. Among mammals, different animals differ in their susceptibility to infection. Very highly susceptible animals include wolves, foxes, jackals, kangaroo rats and cotton rats. Highly susceptible animals include hamsters, skunks, raccoons, domestic cats, rabbits, bats and cattle. Dogs and primates are moderately susceptible. Opossums have low susceptibility. ***Dogs and other animals may or may not succumb to the infection.***

Transmission and Epidemiology

Virus enters through cuts or wounds caused by bites, scratches or licks of rabid animals, which contain virus

in their saliva. Rare modes of transmission include inhalation of virus aerosols. When dogs bark the saliva may be sprayed to a distance of up to 2 meters. Inhalations of aerosols created in caves inhabited by vampire bats, which suck blood from animals and man, have also resulted in rabies. Laboratory accidents of rabies following inhaled aerosols of fixed virus also been reported. Less commonly injury from cats, jackals, mongoose, wolves and other canines may transmit the disease. Rabies following accidental injection of vaccines containing live rabies virus are also reported.

Human-to-Human Transmission

Man to man transmission from contact with human saliva is extremely rare, though theoretically possible. Transmission has occurred through grafting of infected corneas and organ transplantation.

Pathogenesis

After entering a susceptible host, the rabies surface glycoprotein attaches to a cell and enters it by endocytosis. The surface envelope of the virus fuses with the vesicle membrane and the ribonucleoprotein enters the cytoplasm. Local replication may occur in striated muscle near the site of the bite, but there may also be direct invasion of nerve cells. Postsynaptic nicotinic acetylcholine receptors at neuromuscular junctions are important binding sites. Once inside the peripheral nerves, the virus is carried in the flow of axoplasm at the rate of about 3mm/hr to the dorsal root ganglia where replication occurs. This may give rise to prodromal paresthesia at the site of the bite. In the central nervous system, there is massive replication with viral budding from intracellular membranes of neurons and trans-synaptic transmission of virus from cell to cell. Passive centrifugal spread of virus from the CNS in the axoplasm of many efferent nerves including those of the autonomic nervous system occurs. By this route the virus spreads to the salivary glands and to lachrymal glands and several other tissues.

Pathology

The white and the grey matter of the cerebrum show severe congestion. Perivascular and perineuronal infiltration with mononuclear cells occur. Intracytoplasmic inclusion bodies (Negri bodies) are formed and these are demonstrable in 80% of the cases. Negri bodies are seen in large numbers in the hippocampal gyrus, Purkinje cells of the cerebellum, and the pyramidal cells. They are also seen in the basal ganglia and the cranial nerve nuclei and spinal cord. While their presence is diagnostic of rabies, their absence does not exclude the diagnosis. Extra neural changes include focal degeneration of salivary and lachrymal glands, pancreas, adrenal medulla and lymph

nodes. Interstitial myocarditis with round cell infiltration may occur.

Immune Responses

The immune response to natural rabies infection is insufficient to prevent rabies. Rabies can produce immunosuppression and only a minority of unvaccinated patients develops a measurable antibody response. Patients developing a cellular immune response tend to have the furious form rather than the paralytic form and die faster than those who do not mount such a response. The virus may persist in macrophages and may later emerge to produce disease. This may explain some cases with very long incubation periods.

6

CLINICAL FEATURES AND COMPLICATIONS

In Animals: In dogs the incubation period is usually between 2 weeks and 4 months (extreme range, 5 days to 14 months). The illness may start with 2 to 3 days of prodromal symptoms. e.g.: A change in behavior, fever and intense irritation. Dogs with the less common but more familiar, furious form of the disease become aggressive wander away from home and may develop convulsion, dysphagia, pharyngeal paralysis causing an altered bark, and hyper salivation. Those with paralytic or “dumb” rabies hide themselves and develop paralysis of the jaw, neck and hind limbs. Dysphagia and drooling of saliva may raise the suspicion of a foreign body stuck in the throat. Virus may be excreted in the saliva for 2 or 3 days before there are signs of rabies and the animal usually dies within the next 7 days. A small proportion of infected animals recover and may continue to excrete virus for long periods. Horses and cats usually exhibit furious symptoms whereas paralytic disease is the rule in foxes and bovines. Hydrophobia is not seen in animals but inability to drink is a common symptom of rabies.

Clinical Features

The incubation period is usually between 20 and 90 days (extreme range, 4 days to >19 years). Relatively short incubation periods are observed after facial and severe multiple bites. Bites from stray wild animals are more risky and dangerous. The disease manifests with prodromal symptoms like excitement, fever, malaise, anorexia, nausea and headache and nonspecific upper respiratory tract symptoms. Attention to the site of bite may be drawn by the tingling pain and paresthesia especially itching, which develops before the appearance of spasms. Psychotic behaviour with irrational and violent spells with intervening periods of calm may develop.

Neurological involvement may present as (1) the spastic (furious) form and (2) the paralytic form. In the former the lesions are more marked in the brain stem,

cranial nerves, limbic system and higher centres. In the paralytic form the lesions are mostly in the medulla, spinal cord and the spinal nerves.

The spastic form sets in at various intervals (hours to a day or so) after the prodromal symptoms. Sensory stimuli, which may be tactile, auditory or photic, provoke painful spasms. These are most marked and characteristic in the oropharynx. Swallowing liquid and later on a spray of water, its sight or even thought of it produces painful oropharyngeal spasms with respiratory distress. This symptom is called **hydrophobia**. Though not pathognomonic, this is almost confirmatory of the diagnosis. Aerophobic spasms caused by a draught of air on the face or switching on the fan are also diagnostic. The whole course extends to less than 5 days in almost all cases. The patient becomes comatose and death is due to respiratory paralysis resulting from bulbar involvement.

Paralytic form – This is characterized by ascending paralysis. It may start as monoplegia or paraplegia. Spasms are not prominent. Paralytic form is known to occur more often after vampire bat bites. Hydrophobia is rare. Patients may survive for a month even without intensive care. In India, the primary paralytic form occurs only in less than 20% of cases.

Complications: Neurologic, cardiac and pulmonary complications may develop.

- a. **Neurological:** Cerebral edema, generalized convulsions, polyneuropathy, severe autonomic dysfunction and inappropriate secretion of anti-diuretic hormone.
- b. **Cardiac:** Tachy- or brady-arrhythmias, hypotension, myocarditis with congestive cardiac failure.
- c. **Pulmonary:** Hyperventilation, respiratory alkalosis, hypoxia, aspiration pneumonia, pneumothorax, pulmonary edema, respiratory failure and respiratory arrest.
- d. **GIT:** Hematemesis due to ulceration or tears in the mucosa of the upper gastrointestinal tract.

Diagnosis

Development of mental excitement, hydrophobia and spasm or paralysis in persons who have sustained bites or licks from any warm-blooded animal within 6 months should suggest the possibility of rabies. A bite by an unusually excitable or partially paralyzed mammal indicates high risk of exposure to rabies. However in up to 16% of cases no history of exposure can be elicited. In the initial stages the diagnosis of rabies may be difficult.

Differential Diagnosis

Rabies has to be differentiated from encephalitis and other neurological disorders leading to paralysis. Paralytic rabies may be mistaken for adverse reaction to vaccination in

persons receiving anti-rabies vaccination. The spasms of tetanus may resemble hydrophobia especially if they involve the pharyngeal muscles (hydrophobic tetanus). Psychiatric conditions, such as maniac excitement and hysteria and drug reactions such as akathisia have to be differentiated at times. Hysterical subjects adopt hydrophobic manifestations, but absence of aerophobia excludes this condition.

Laboratory Diagnosis

In practice, diagnosis of rabies is primarily clinical. Where laboratory facilities exist tests are available for confirmation of diagnosis. The virus can be isolated in saliva or CSF for the initial 2 weeks of the illness, but this takes about 3 weeks and hence is not a practicable method for day-to-day use.

Neutralizing antibodies against rabies virus can be demonstrated after the initial 10 days of onset. Levels of antibody are much higher in CSF, compared to serum. Vaccinated individuals develop antibodies by 8 days after vaccination, but the titers are much higher in the patients who develop clinical rabies.

Antigen Detection

Rapid rabies diagnosis by PCR tests on saliva –CSF and skin biopsy are available in a few reference laboratories. A *direct immunofluorescent antibody* (IFA) test also rapidly identifies antigen in frozen sections of the skin biopsies taken from a hairy area, usually nape of the neck. Rabies- specific immunofluorescence appears in nerve twigs around the base of hair follicles. This test is 60-100% sensitive. False positives have not been reported.

Prognosis

In the ordinary settings rabies is invariably fatal. This underscores the need for preventing the development of rabies in persons exposed to the risk either by animal bites or by occupation. Recent reports of stray survivors by intensive and continuous prolonged life support measures are available.

Treatment

Once the disease is manifested treatment is only symptomatic. There is no specific treatment. Treatment aims at controlling spasms with muscle relaxants, maintenance of hydration by intravenous fluids, and assistance to ventilation. Those who attend on the patients should use gloves, masks, and protective goggles. Though the virus eliminated in human saliva is not very virulent, as a matter of abundant caution, attendants who have been inadvertently exposed to very close contact with rabies

may be advised to take a course of prophylactic inoculation.

Prophylaxis

Local treatment of bites, scratches, and licks: Thorough cleaning of the wound by washing with soap and water repeatedly and then by 40-70% alcohol or 0.1% quaternary ammonium compounds (*Cetavlon*) eliminates the virus present superficially. Bite wounds should not be sutured straight away. In severe bites local injection of antirabies serum or hyperimmune globulin helps in reducing the risk further.

Assessment of the risk: Animals incubating the disease may be apparently normal for five days before becoming symptomatic. Once they develop the disease, majority of them die within 5 days. Therefore, the animal should be observed for 10 days, to decide on the need for vaccination. If the animal is obviously rabid or it is not traceable vaccination is started straightaway without any delay. If the risk is only class I or II, vaccination can be undertaken after observing the animal. In class III risk, vaccination is started, but if the animal is normal, it can be stopped. A rabid dog shows features like recent change in behaviour, aggressiveness, characteristic howl, tendency to bite objects indiscriminately, ataxia, paralysis and excessive salivation. Paralysis of bulbar muscles may be mistaken for impaction of foreign bodies in the throat.

Post-exposure prophylaxis: The risk of developing infection can be estimated from the nature of initial injury.

Active immunization: This is achieved by antirabies vaccination (ARV). Vaccination affords considerable degree of protection, though this is not absolute. Immunity is established after 10-14 days of starting the course and it lasts up to 1 year. Antirabies vaccine was originally introduced by Louis Pasteur in 1885. *All the vaccines used for anti-rabies prophylaxis are killed vaccines.* The original vaccines were nerve tissue vaccines in which the fixed virus grown in the nervous tissue of sheep was killed by phenol or beta propiolactone. The course of injections used to be long, injections were painful and about 6 to 10% of patients used to get minor or moderate complications. A smaller number used to get serious neuro-paralytic and encephalitic complications. These vaccines are practically never given now due to this risk and the availability of safer and more effective cell culture vaccines.

Avian embryo vaccines: These are produced in chick (Flury) or duck embryos. Though allergic reactions may occur, neuroparalytic accidents are much less common with this vaccine. The vaccines are used mainly for active immunization of dogs and other pets.

TABLE 59.1

Classification of risk

Class I (Light risk)

1. Licks except on face and fingers.
2. Licks on intact mucous membranes.
3. Light bites and scratches over parts of the body except head, neck, face and fingers.
4. Consumption of unboiled milk or handling raw flesh of rabid animal.

Class II (Moderate risk)

1. Licks on fresh wounds and cuts and abrasions on fingers.
2. Scratches on fingers.

Class III (Great risk)

1. Licks on fresh cuts, scratches and bites on head, neck or face.
2. Bites on fingers and all lacerated wounds.
3. Jackal and wolf bites.
4. Any class II patient who has not received ARV within 2 weeks.

Cell Culture Vaccines

The available popular vaccines are

1. Monkey kidney cell vaccine marketed as Vero-rab
2. Purified chick embryo cell vaccine marketed as Rabipur
3. Human diploid cell vaccine (HDCV). The human cell derived vaccine costs about Rs. 750/dose whereas the other two cost about Rs. 250.

All are equally antigenic. Dose of monkey kidney cell vaccine is 0.5 mL, that of human diploid cell vaccine (HDCV) is 1 mL each time. All these vaccines are safe, painless and free from permanent neuroparalytic accidents. At present all these vaccines are imported. Immunity starts by the seventh day after the first dose. It lasts for 3 years.

Five injections of the vaccine on day 0, 3, 7, 14 and 28 given intramuscularly give rise to sufficient protection. A booster dose of 1 mL is given on day 90, if antibody level is not adequate. Injections over the deltoid are more immunogenic than gluteal injections (Table 59.1).

The course of cell culture vaccine is the same for all classes of bites, and the classification of the risk is only

to decide the need and timing of vaccination. Being a killed vaccine there is no contraindication for antirabic vaccination during pregnancy.

Passive immunization: If the risk is class III or even II, passive immunization should be given as early as possible, since active immunization will not be completed within the incubation period. Antirabic serum prepared in humans (*human rabies immunoglobulin HRIG*) should be given in a dose of 20 units/kg IM at a site away from the vaccine dose. If there is a lacerated wound, 50% of the dose should be infiltrated around it and the remainder should be given intramuscularly. The half-life of HRIG is for 21 days and this is probably the duration of passive immunity.

Antirabic serum (ARS) produced in horses is also used in a dose 40 u/kg bw IM. If horse serum is used the risk of anaphylaxis is higher. The equine antiserum is much cheaper than the human immunoglobulin. Both are effective. When the former is used, prior skin testing should be done to avoid anaphylactic reactions.

Pre-exposure immunization: Personnel who have occupational risk of rabies, e.g., veterinary surgeons, and kennel trainers can be actively immunized with HDCV. When an immunized person is exposed to the risk of rabies, he should receive booster doses of the vaccine.

Three doses of cell culture vaccines given as IM injections on day 0, 7, 21 or 28 give adequate antibody levels for up to 2 years. If facilities permit, antibody levels should be estimated and if the titer is inadequate a booster dose of 1 mL should be given. It is better to administer booster doses only when indicated, since over-immunization can be associated with serum sickness-like reaction in up to 6% of cases.

An alternate method is to give HDCV in a dose of 0.1 mL intradermally on days 1, 7, 21 or 28. Protection starts after four weeks. The intradermal route is inadequate for post-exposure prophylaxis. In persons who have received pre-exposure prophylaxis, if risk of infection occurs two booster doses of the vaccine should be given on days 0 and 3. Local washing of the wound and wound toilet are absolutely necessary to reduce the risk.

General Considerations

Arthropod borne (ARBO) viruses are a group of viruses with complex transmission cycles involving arthropods. These viruses have diverse physical and chemical properties and are classified into several virus families.

The arboviruses are transmitted by blood sucking arthropods from one vertebrate host to another. The vector acquires a lifelong infection through the ingestion of blood from a viremic vertebrate. The viruses multiply in the tissues of the vector without evidence of disease or damage. Some arboviruses are maintained in nature by transovarian transmission in the vector. The main pathogenic arboviruses includes members of the flavivirus, togavirus and bunyavirus families.

The major arbovirus diseases world wide are, dengue fever, yellow fever, sandfly fever, Kyasanur Forest Disease, chikungunya fever, West Nile fever and various forms of encephalitis like Japanese encephalitis, St.Louis encephalitis, Western equine encephalitis, Eastern equine

encephalitis, Russian spring-summer encephalitis and others.

The diseases with public health importance in India are dengue fever, chikungunya fever, sandfly fever, West Nile fever, Kyasanur Forest Disease, yellow fever and Japanese encephalitis.

Dengue Fever (DF)**Syn. Break bone fever, Dandy fever**

Dengue is an acute febrile illness, characterized by high fever, severe pain of bones and joints, lymphadenopathy and a characteristic rash.

History

Benjamin Rush in Philadelphia first described the clinical syndrome in 1789. Viral etiology and mode of transmission by mosquitoes were established in early 20th century. DF is found mostly during and shortly after the rainy season in tropical and subtropical areas of India Africa, Southeast Asia, China, Middle East, Carribean islands and Central and South America. In 1954 dengue became epidemic in many areas of tropical Asia. Large outbreaks of DF have occurred in many areas of India after 2000 and in Kerala particularly during July –August 2003. At present sporadic cases occur all over the country.

Etiology

Dengue is caused by four distinct serotypes of dengue viruses (Type DEN-1 to DEN 4) within the *flavivirus* genus of the family *Flaviviridae*. Dengue viruses are small 40-50 nm spherical particles composed of a lipoprotein envelope and nucleocapsid of single strand RNA genome. The major envelope glycoprotein E which is exposed on the virion surface contains type-specific and group specific antigens. There are genetic variations within serotypes. Some genetic variants within each serotype appear to be more virulent or have more epidemic potential. After primary infection each serotype provides specific lifetime immunity and short term cross-immunity.

Fig. 60.1: Aedes mosquito vector

6

Transmission

Man is the usual reservoir of infection. The main vectors are *Aedes aegypti*, *Aedes albopictus* and to a lesser extent *Aedes polynesiensis*. These are fresh water breeders existing in domestic surroundings and which bite frequently several persons during all times of the day. The bites may be painless and they do not fly long distances. The extrinsic incubation period in the mosquito is 8-14 days by which time the mosquito becomes infective and it remains so for the rest of its life (15-65 days). There is transovarian transmission of the dengue virus with the *A. albopictus* mosquito (Fig. 60.1).

Pathogenesis and Pathology

First attack of dengue: After the bite of an infected mosquito, the virus replicates in regional lymph nodes and is disseminated via the lymphatics and the blood to other tissues. Replication in the reticuloendothelial system and skin produces viremia, which begins 3-7 days after infection. Viremia is present for the first 3 days early in the illness. After the clearance of the viremia the virus persists in the infected mononuclear cells. In the majority of dengue infections the disease is self-limited.

Subsequent attacks of dengue: Though immunity in dengue is solid for the particular serotype, there is no cross immunity between the different species. Therefore re-infection with different serotypes can occur. The speed and extent of viral spread is much higher in subsequent infections by different serotypes of dengue viruses compared to the first attack. In this group, some develop severe complications such as dengue hemorrhagic fever (DHF) and dengue shock syndrome (DSS). Infection by DEN-2 following DEN-1 infection is likely to be more serious in this regard.

The hallmarks of DHF-DSS are increase in the permeability and fragility of the capillaries and abnormalities

of hemostasis. Ninety percent of cases of DHF-DSS occur during subsequent infections. Less commonly, infants born to mothers who transmit dengue antibodies transplacentally and are sensitized to the dengue virus may develop DHF-DSS in the first attack itself.

The immune status of the host plays an important role in determining the course of dengue infection and subsequent complications. The presence of non-neutralizing antibodies to a heterologous dengue virus may form virus-antibody complexes and facilitate the entry of dengue virus into the mononuclear cells and viral multiplication (antibody-dependent enhancement). The increased numbers of infected cells (monocytes and lymphocytes) with the release of cytokines like $\text{TNF-}\alpha$ and complement activation leads to endothelial swelling of small blood vessels, peri-vascular edema and mononuclear cell infiltration. The pathologic changes in complicated cases and DHF include arrest of megakaryocyte multiplication in the bone marrow and thrombocytopenia. Hemorrhages occur due to thrombocytopenia, platelet dysfunction and coagulopathy. There is also generalized abnormality of the vascular endothelium resulting in extensive leakage of fluid from the intravascular compartment.

In DHF there is widespread dissemination of the virus into several organs including liver, spleen, heart, bone marrow and rarely the brain. Liver shows focal midzonal necrosis, fatty changes and hyaline necrosis of hepatocytes.

CLINICAL FEATURES

Dengue fever is an acute febrile disease with headache, musculoskeletal pain, and rash, but the severity of illness and clinical manifestations vary with age. All age groups are affected.

Dengue can present in the following clinical syndromes.

1. Undifferentiated fever, particularly in children
2. Classic dengue fever
3. Dengue hemorrhagic fever and
4. Dengue shock syndrome.

Undifferentiated fever: Infection is asymptomatic in 80% of infants and children. In the ordinary case the illness presents as fever, malaise or irritability, pharyngeal injection, upper respiratory symptoms and rash. This resembles other common childhood infections.

Classic dengue fever: This is most common in adults and older children. The incubation period is 3-8 days. It starts abruptly with fever, headache, pain in the muscle, bone and joints, retro-orbital region and lumbosacral ache. A transient generalized macular rash may be present during the first 24 to 48 hours. Generalized myalgia increase in severity. Other symptoms such as anorexia, nausea,

vomiting, marked lassitude, cutaneous hyperaesthesia and dysgeusia appear on the second to the fourth day. Orbital pain may develop and movements of the eyeball may be painful. The temperature rises up to 40-41.5°C with relative bradycardia. Conjunctival congestion is common. Posterior cervical, epitrochlear and inguinal lymph nodes are enlarged, but non-tender.

The fever usually subsides after three days. A second bout of fever may occur after two days. This is milder than the first and lasting for 2-3 days (saddle back pattern). The second episode of fever comes down by lysis.

A maculo-papular rash occurs with the second bout of fever on the trunk, limbs and face. It disappears as the temperature falls. Mild hemorrhagic phenomena such as petechial hemorrhages, ecchymoses at injection sites, epistaxis and menorrhagia may occur during the course of the illness, even in uncomplicated cases.

DENGUE HEMORRHAGIC FEVER

This syndrome, characterized by increased capillary permeability and hemostatic derangements, occur more frequently in children. Based on the severity, cases of DHF can be categorized into four grades (WHO guidelines).

Grading Severity of Dengue Hemorrhagic Fever (DHF)

DHF is classified into four grades of severity, where grades III and IV are considered to be DSS. The presence of thrombocytopenia with concurrent hemoconcentration differentiates grades I and II DHF from DF.

Grade I: Fever accompanied by non-specific constitutional symptoms; the only haemorrhagic manifestation is a positive tourniquet test and/or easy bruising.

Grade II: Spontaneous bleeding, in addition to the manifestations of Grade I patients, usually in the forms of skin or other hemorrhages.

Grade III: Circulatory failure manifested by a rapid, weak pulse and narrowing of pulse pressure or hypotension, with the presence of cold, clammy skin and restlessness.

Grade IV: Profound shock with undetectable blood pressure or pulse

The minimum diagnostic criteria for DHF are a positive tourniquet test or spontaneous hemorrhages from multiple sites, thrombocytopenia ($<100,000$ /cmm), and evidence of plasma leakage as shown by increase in hematocrit by 20% or more from baseline, ascites or pleural effusion.

Early in the illness these children are clinically identical to those with classical dengue. But around the time of defervescence, a second phase of illness develops. This is characterized by petechiae, ecchymoses, epistaxis

and other spontaneous hemorrhages including gastrointestinal hemorrhage and menorrhagia. Variable ascites, or pleural effusion more common on the right side may develop. Liver may be enlarged and tender.

DENGUE SHOCK SYNDROME (DSS)

Dengue shock syndrome is the most serious complication of dengue hemorrhagic fever, seen widely in Asia and South America. It is seen in all hospitals in India, though infrequently. Some patients manifest signs of restlessness, abdominal pain and shock with cold and clammy extremities, diaphoresis, circum-oral cyanosis, irritability, or change in mental status. Hypotension with narrowing of pulse pressure below 20 mm Hg, severe shock and rapid deterioration, typically occurs on the second to fifth day of illness. Untreated, 50% of such patients may die. Patients with less severe illness or those successfully treated recover rapidly after a 1-2 day period of acute illness.

Other manifestations: Less commonly dengue may present with encephalopathy, intracranial bleed, renal failure, fulminant hepatitis and acute respiratory distress syndrome.

Course and Prognosis

Diagnosis

Dengue should be suspected when fever with severe body pain and rash occurs. In the initial stage it should be differentiated from Influenza, leptospirosis, malaria, and typhoid fever. In endemic areas sand fly fever and chikungunya have to be kept in mind.

Investigations

Usually there is leukopenia, mainly neutropenia and mild thrombocytopenia. Severe thrombocytopenia may occur in DHF. S. bilirubin is usually normal unless there is hepatic involvement. Serum transaminases show mild elevation even in uncomplicated cases.

Blood urea and creatinine are elevated in complicated cases. X-ray chest may show pleural effusion. Ultrasonogram of abdomen may reveal serous effusions.

Virological Diagnosis

Virus isolation is by cell cultures, done with blood culture within the first week of illness in specialized laboratories for special purposes. Viral RNA can be identified by is done by reverse transcriptase PCR (RT-PCR).

Serology

Virus can be isolated by blood culture within the first week. Complement fixation and neutralizing antibody titers can be demonstrated in paired sera drawn at intervals of 7 to 14 days.

Diseases Caused by Infections

The IgM Antibody capture ELISA has improved the serodiagnosis of dengue. By the end of first week IgM antibodies are detectable. They rise rapidly and by 2-3 months they become undetectable. A very high rise of IgG antibodies early in the disease indicates a second dengue infection. IgM antibodies are relatively specific for dengue without cross-reaction with other heterologous flaviviruses, but IgM antibodies do not distinguish individual dengue serotypes.

TREATMENT

Vast majority of patients can be managed as outpatients with paracetamol for fever, anti-emetics, oral fluids, reassurance and rest. Indications for inpatient treatment are fever above 40.5°C, prostration, severe vomiting requiring IV fluids and other complications.

Treatment of Complicated DF, DHF and DSS

The treatment is mainly supportive. Patient has to be treated in an intensive care facility with proper monitoring of vital parameters, attention to nutrition and fluid and electrolyte balance. The blood pressure, hematocrit, platelet count, bleeding manifestations, urinary output and level of consciousness should be monitored systematically to identify complications.

Hypotension, signs of increased capillary fragility and toxemia are indications for IV fluids. Normal saline, 5% dextrose saline, Ringer lactate, colloid plasma expanders and plasma have to be given with proper monitoring to maintain the blood pressure and vital functions. It is important to correct fluid and electrolyte balance early in the disease in order to prevent irreversible changes.

Indications for Blood Components/ Blood Transfusion

Platelet counts <25000/cmm with bleeding is an indication for platelet rich plasma or platelet concentrates.

In massive bleeding give blood transfusion.

IV fluid therapy should be properly monitored and stopped at the appropriate time so as to avoid fluid overload.

There is no specific antiviral therapy. Secondary bacterial infections and concurrent infections like malaria should be looked for and treated appropriately.

Prevention

General measures include anti-mosquito operations and personal protection using nets or mosquito repellants. Live attenuated vaccines against all 4 serotypes are currently under development.

Points to remember

1. Dengue, which was considered to be a mild infection is emerging as a serious problem
2. Four distinct viruses can cause the disease. No cross protection is present. But may produce DHF and DSS in subsequent attacks.
3. Main cause of death: DHF and DSS –increased capillary permeability
4. Early fluid replacement and supportive measures save life.

Sandfly Fever

Syn: Phlebotomus fever, Papatasii fever, 3 days fever.

It is a short, self-limited, undifferentiated febrile illness caused by sandfly-borne viruses.

Etiology

The disease is caused by members of phlebovirus subgroup of the family Bunyaviridae.

The disease is present in India mainly northern states and Himalayan areas. It is prevalent in other tropical countries, Middle East and Mediterranean countries.

It is transmitted by the sandfly *Phlebotomus papatasii*. Female phlebotomus sucks blood. It becomes infective 6-7 days after an infective feed and remains infective for the rest of its life. Sand fly fever viruses are trans-ovarially transmitted in their vector species. In the tropical environment sand flies are active throughout the year. In temperate climates they are seen only in summer. They are small (2-3 mm) and readily pass through bed nets and screens. They are nocturnal biters.

Clinical Features

Incubation period is 2-6 days. The illness starts abruptly with fever and rigor. The temperature rises rapidly to 40°C with headache, malaise, retro-orbital pain, photophobia, myalgia, nausea and vomiting. The absence of rash, lymphadenopathy, and respiratory symptoms may help in differentiating the illness from other viral syndromes. The acute febrile illness lasts approximately 3 days. This may be followed by a period of weakness, fatigue and depression lasting 1-2 weeks. Aseptic meningitis can occur in 12% of cases. There is associated neck rigidity, changes in mental status and sometimes convulsions. There is CSF pleocytosis with predominant mononuclear cells. The disease resolves without sequel.

Diagnosis

The diagnosis is mainly clinical. There is leucopenia. The diagnosis is established by culture of the virus, PCR test or serological assays. The most commonly used test is IgM capture ELISA. This is to be done 4-5 days after onset of

symptoms. It gives only a probable diagnosis. By 7-10 days IgG antibodies develop in the majority.

Prognosis and Treatment

The disease is self-limiting, benign and non-fatal. Treatment is symptomatic with analgesics and supportive measures. Prevention and control.

No vaccine has been developed. Spraying residual insecticides can control sand flies. Personal protection is achieved by using insect repellants. A new strategy tried in Vietnam against *Aedes aegypti* is to grow predator copepods in domestic water collecting vessels and tanks.

Yellow Fever

Yellow fever is an acute mosquito-borne infection of varying severity characterized by the triad of hepatitis, hemorrhagic diathesis and proteinuria.

Etiology

The causative virus is an arbo virus belonging to the genus *Flavivirus*, in the family *Flaviviridae*.

Distribution and Incidence

Yellow fever is prevalent in many parts of Africa, tropical parts of South America and Panama. The disease has not been reported in India. The presence of the efficient vector *Aedes aegypti* mosquitoes and the non-immune population pose a threat of the disease spreading in India, if the virus is introduced. Hence, this disease is of importance to India.

Yellow fever is notifiable under the International Health Regulations.

Transmission and Epidemiology

Epidemic (urban) yellow fever is transmitted from human to human by *Aedes aegypti* mosquitoes. Infected monkeys and the vector mosquitoes maintain the reservoir of infection in the jungle. These act as a source of infection when the humans intrude into endemic areas.

Pathology and Pathogenesis

The incubation period after an infectious mosquito bite is 3 to 6 days.

Liver and kidneys show maximal lesions but hemorrhage may occur in all organs. Hepatic changes include widespread necrosis, and degeneration of liver cells. Renal changes include acute tubular necrosis and subcapsular hemorrhages.

Bleeding diathesis is due to depletion of hepatic clotting factors, intravascular coagulation, and platelet

abnormalities. Direct damage to the myocardium, kidneys and other organs and the effects of vasoactive cytokines, lead to fatal complications such as multi-organ failure and shock.

CLINICAL FEATURES

In the majority of cases the disease is a self limited with fever and myalgia. 25 to 50% of cases may develop the full syndrome with complications such as hemorrhages, jaundice, renal involvement and shock.

The first stage (i.e. period of infection) is due to the direct effect of the virus. It starts abruptly with fever, headache and myalgia. In severe illness there is, nausea vomiting, abdominal pain and distressing pain in the back, and limbs. There is relative bradycardia. This stage lasts about 3 days and by 4th day the temperature comes down and **the second stage** (period of remission) starts. Many cases recover without going to the third stage. Some progress to **the third stage** (period of intoxication). It starts after a day or a few days, with resumption of high fever, body pains, nausea, vomiting, abdominal pain and changes in the level of consciousness. Bradycardia, jaundice, wide spread hemorrhages and renal failure may supervene. Death is due to hepatic or renal failure and shock.

Diagnosis

In endemic areas, fever, leukopenia and proteinuria with or without jaundice should suggest the possibility of yellow fever. Specific diagnosis is established by the isolation of the virus from the blood in the first few days of fever or demonstration of rising titer of antibodies in serum.

Treatment

There is no specific antiviral treatment. Symptomatic and supportive measures should be instituted. Hepatic and renal failure have to be anticipated and managed accordingly.

Prevention

Vaccination using live attenuated vaccine (17D strain) is very effective. Vaccination gives immunity starting from ten days and full protection for 10 years. Though side effects are generally negligible, children below 9 months may develop encephalitis. Pregnancy is not a contraindication for vaccination.

India and many other countries insist on yellow fever vaccination for persons entering the country or remaining during transit, if they come from endemic areas. Persons travelling to endemic areas have to take vaccination. Yellow fever vaccination is available at recognized centers in India.

Kyasanur Forest Disease (KFD)

Kyasanur forest disease (KFD) is an acute febrile illness caused by a *group B arbovirus*, clinically characterized by sudden onset of fever with rigor, severe body pains, headache, meningism, delirium, mental confusion and dehydration. The original description was from Shimoga district of Karnataka State in South India in 1956.

The disease was prevalent among people living in the villages around the forest area. The infection developed in persons who had gone into the forest (usually to fetch wood) and who had come into contact with dead monkeys. The ticks *Hemaphysalis spinigera* and *Ixodes* act as vectors to transmit the disease from animals to man. Monkeys (black faced langur and macaques), shrews and rats are known to harbor the virus. Man gets infection by the bite of the nymph of *H. spinigera*. Infected ticks carry the virus for long periods. Personnel working in laboratories handling the virus or investigators working in the affected areas are susceptible to infection. In addition to vector transmission, infection can also be spread by inhalation of infected material.

Clinical Features

After the incubation period lasting for 2 to 7 days, sudden fever sets in with chills and rigor. Fever is associated with headache and severe myalgia in the nape of the neck, back and calf. These may be mistaken for dengue fever. Abdominal pain, diarrhea and vomiting may occur between the third and the seventh day. Uncommonly, bleeding tendencies such as epistaxis, bleeding gums and melena may develop around third day. Lymphadenopathy of the neck and axilla, and conjunctival injection may also be seen. Bradycardia and hypotension may develop. Hepatosplenomegaly may occur in some cases. Alteration in mental state, neck rigidity, giddiness, tremors, listlessness and dyspnea have all been reported.

In uncomplicated cases, the fever lasts for about 10 to 12 days and temperature comes down. A second febrile phase may follow 2 to 12 days after the temperature has touched normal and this may continue so for 9 to 21 days. The mortality rate is around 5%. Death is usually caused by pulmonary edema.

Laboratory Diagnosis

Leukocyte count is low (about 3000/cmm). The virus can be isolated from blood during the course of the fever. Paired sera show rise in antibody titers. During the second febrile phase CSF may show features of aseptic meningitis.

Treatment

In the absence of specific treatment only supportive therapy is to be given.

Prevention

Anti-tick measures have to be instituted during jungle clearing operations. Persons at risk should use protective clothing and insect repellants. Though a vaccine was developed against KFD, it was not found to be very effective.

Chikungunya

Chikungunya (CHIK) fever is an acute infective disease, characterized by symmetric polyarthropathy, fever, rash, and rarely, generalized hemorrhages and CNS symptoms. The disease derives its name from the sudden onset of severe joint pain, which cripples the victim. The disease was first described in 1955 following an outbreak in Africa in 1952.

Etiology

CHIK virus is an *alphavirus* in the Semliki Forest complex (Togaviridae) and most closely related to *o'nyong nyong* (ONN) virus.

Distribution and Incidence

CHIK is widely distributed in Africa, the middle east, and Asia. The disease has now become endemic in several parts of India. Epidemics have been reported from southern and eastern parts of India including Tamil Nadu and Kerala. In 1964 an epidemic occurred in Tamil Nadu and surveys showed 38% of the population had antiviral antibodies. It is possible that sporadic or small outbreaks may occur from time to time. A localized outbreak is reported from Tamil Nadu during June-July 2006. Thiruvengadam et al studied epidemic of chikungunya which occurred in the Madras Metropolitan area in 1964. The virus was isolated and rise in antibody titer was confirmed at the ICMR Virus Research Laboratory Pune in a third of the patients studied.

In recent years as extensive epidemic affected several African and Asian countries, affecting millions of people. It is possible that the original virus has undergone genetic mutation.

Charrel RN, et al. N Eng J Med 2007;356:767-71.

Transmission and Epidemiology

In India *Aedes aegypti* mosquito is the main vector. *Aedes albopictus* is also implicated. In Africa there is a sylvian cycle involving forest mosquitoes, humans and possibly other mammals. In Asia, sylvatic viral reservoirs have not been defined.

CLINICAL FEATURES

The incubation period varies from 2-10 days, usually 3-7 days. The onset is sudden with abrupt fever (above

40°C), chills and rigor, headache, body pains and joint pains. There may be mild conjunctivitis, pharyngitis and erythematous rash over the body and face. The joints may be so inflamed that normal activities, standing and walking become painful. Arthropathy is symmetric, affecting the extremities and less often the shoulders and hips. Definite joint effusion is seen in 10% of cases. Small joints of the hands and feet and major joints of the lower limbs are affected most. Pain may be excruciating, crippling the patient quite out of proportion to the general disability. Fever and joint pains persist for up to six days after which they subside. Residual arthropathy lasting for months may occur in up to 30% of adults; especially in elderly patients. Morning stiffness and pain may persist for even a few months. Pre-existing joint problems and neurological disorders considerably worsen the disability and delay recovery. Joint pains are milder and may be even entirely absent in children. A faint maculopapular rash may appear concurrently with defervescence. Complications such as hyperpyrexia, hemorrhagic manifestations, encephalitis, polyneuropathy of the Guillain-Barré type and ECG changes suggestive of myocarditis were recorded in the Madras outbreak. Hyperpyrexia caused death in one patient. Among asymptomatic subjects 38.4% showed hemagglutination (HI) antibodies to chikungunya virus, confirming the presence of the virus in the community.

Ref: Thiruvengadam et al, Clinical and Pathological Studies on Chikungunya fever in Madras city Ind J Med Res 1965; 53 729-43 quoted by JAPI 2006 54, 898.

Hemorrhagic manifestations occur occasionally. CNS manifestations like meningism, convulsions and acute polyneuropathy has been reported in a minority of patients, especially children and infants.

Course and Prognosis

The disease may run a benign course with slow recovery even if untreated. Arthropathy may persist for varying periods and can be disabling. The acute illness in children and infants and elderly persons can be fatal. The primary role of uncomplicated chikungunya as a cause of death is not established. It produces considerable morbidity and impairment of the quality of life for prolonged periods.

Diagnosis

Routine laboratory investigations are not specific. The ESR may be elevated to 20-50 mm/hr and CRP may also be elevated. Isolating the virus or identifying genomic products by PCR in acute phase blood specimens can confirm the diagnosis. Serologically specific IgM or other antibodies can be demonstrated by IgM capture ELISA test. This test will distinguish the condition from dengue which is also transmitted by the same vector. During the prevailing epidemic in south Kerala a few cases of co-infection by chikungunya and dengue have been observed.

Treatment

Rest and symptomatic treatment with non-steroidal anti-inflammatory drugs give relief. Prolonged arthropathy demands symptomatic treatment. Chloroquine given in a dose of 250 mg od or bd has been reported to be useful. In any case results are not impressive.

Prevention and Control

An experimental live attenuated vaccine has been shown to produce high levels of neutralizing antibody in human volunteers but efficacy has not been tested. Anti-mosquito measures and personal protection with mosquito repellents will reduce the spread.

Japanese Encephalitis (JE)

Japanese encephalitis (JE), a severe mosquito-borne infection of the CNS, is a leading cause of childhood encephalitis in Asia.

GENERAL CONSIDERATIONS

Etiology and History

The causative *flavivirus* is related antigenically to *West Nile virus*. The virus was first isolated from human brain of an epidemic case in Japan in 1924 and its transmission by mosquito was proved in 1936. It is an RNA virus. This disease has been reported from several countries in both tropical and temperate zones.

Distribution and Incidence

The disease is widespread in India and south-east Asian countries. Surveys done by National Institute of Virology, Pune, suggest that the flaviviruses are widely distributed in India. Neutralizing antibodies to JE virus were demonstrated in all regions, which had epidemics. In north and north-east India, the disease occurs more during the summer monsoon, whereas the maximum incidence in the south is from September to January. Epidemics occur in several parts of India from time to time. About 30,000 cases occur annually. The outbreaks coincide with the density of mosquito population.

Transmission and Epidemiology

The virus exists in reservoir hosts and man is affected from them. Pigs, birds such as pond herons, cattle-egrets, bats, buffaloes, and cattle harbour the virus. In India, pigs constitute the major reservoir in which the virus multiplies. Migration of birds accounts for the regional spread of infection. Though the virus is seen in several animals, it is pathogenic only to man and a few other mammals like horses. Poverty, unsatisfactory dwelling conditions and co-existence with cattle, birds and pigs facilitate transmission.

The vector Culicine mosquitoes act as the main vectors. Important among them are *Culex tritaeniorhynchus*, *C. pseudovishnui* and *C. vishnui*. *Anopheles barbirostris* can also transmit this virus.

The natural transmission cycle of the virus is birds → mosquito → bird and pig → mosquito → pig. Human infection occurs only when the mosquito population increases and man – mosquito contact is established. Risk for infection is highest in rural locations where rice fields, pigs and humans coexist.

In the vast majority, the infection remains subclinical. The ratio of overt to inapparent infection varies from 1:300 to 1:1000. Children below 15 years suffer more. The peak incidence is between 2 to 10 years and males suffer more.

6

Pathogenesis and Pathology

After an infective bite by the mosquito, the virus propagates locally and in the regional lymph nodes. Viremia leads to affection of several organs mainly the brain unless the infection is modulated by prompt immune response. Neuroinvasion probably occurs as the virus grows through vascular endothelial cells to the parenchymal side. The virus enters the neurons and leads to widespread degenerative and necrotic changes. Most marked lesions occur in the cerebral cortex, thalamic nuclei, corpus striatum, and brainstem with relative sparing of the white matter. Cerebellar cortex and spinal motor neurons may also be affected, but the affection is less marked. There is occlusion of the smaller arterioles leading to extensive focal ischemia and necrosis. Perivascular hemorrhages and mononuclear infiltration are seen.

CLINICAL FEATURES

The incubation period ranges from 5-15 days. Three stages are recognizable- prodrome, acute encephalitis and convalescence.

Prodromal stage: The onset may be gradual (4-5 days) or acute (12-24 hrs) or abrupt (1-6 hrs). The disease starts as fever with chills, headache, meningism, convulsions, psychotic behaviour and coma. Majority of cases recover in 4-5 days and clinical diagnosis can be made initially, only during epidemics.

Acute encephalitic stage: The fever persists at 40-41° C, the pulse is rapid and neurological manifestations predominate. Symptoms such as convulsions (70%), altered sensorium (90%), focal neurological deficits, signs of meningeal irritation (30%) and coma supervene. Supranuclear ocular palsies are common. Cranial nerve palsies and papilledema are uncommon. These features help to identify JE from tuberculous meningitis. Rapid onset of paralysis such as hemiplegia or monoplegia is

characteristic. Plantar responses are bilaterally extensor. Other manifestations of brain involvement include cerebellar signs, extrapyramidal signs and dystonic postures. The syndrome of inappropriate secretion of antidiuretic hormone (SIADH) occurs in about 30% of cases reported from Kerala.

Convalescence: Neurological function is regained gradually over several weeks, most of them by 6-12 weeks. For the rest further recovery occurs after discharge over intervals of months to years.

Laboratory Findings and Diagnosis

Leukocytosis may be present and liver enzymes may be mildly elevated. CSF shows lymphocytic pleocytosis. The cell count varies from 10-1000 cells/cmm, with an average of 100-200 cells. CSF protein may be raised to 50-250 mg/dL; sugar is usually normal. EEG abnormalities are present in the acute phase. These include a pattern of diffuse delta wave activity and rarely, spike and wave discharges. EEG findings are not helpful in predicting the outcome. ECG may show nonspecific ST-T changes indicating myocarditis.

MRI reveals diffuse white matter edema and abnormal signals mainly in the thalamus, often with evidence of hemorrhage in the basal ganglia, cerebellum, midbrain, pons and spinal cord. The clinical diagnosis is easy during epidemics. Since this disease often occurs sporadically, JE should always be considered in cases of encephalitis.

Laboratory diagnosis in most cases depends principally on the serologic testing of the serum and also CSF by antibody capture enzyme linked immunosorbent assay (ELISA).

IgM and IgG antibodies can also be detected by indirect immunofluorescence assay. The assay is more than 95% sensitive when serum specimens are tested 7 to 10 days after the onset.

Hemagglutination inhibition (HI) or complement fixing antibodies can be demonstrated in paired sera and these give evidence of infection in retrospect. Neutralizing antibody titer of 80 in the serum is suggestive. Fourfold rise in titer is confirmatory. CSF neutralizing antibody titer of 10 is confirmatory.

The virus can be isolated from blood only during the first few days of illness, usually preceding the onset of neurologic symptoms. Isolation of the virus from the CSF indicates the absence of protective antibodies and therefore, poor prognosis.

Differential Diagnosis

Features of JE have to be distinguished from various types of meningitis and encephalitis, cerebral malaria, toxic encephalopathies, cerebral tumours and Reye's syndrome.

Prognosis

Complete recovery occurs in one-third of cases, neurological sequelae occur in another one-third and

mortality in the rest. In India mortality rate is 25-45%. Death is usually due to neuronal damage, cerebral edema, pulmonary edema or intercurrent complications like infections from stasis ulcers, urinary tract infection, pneumonia, and bacteremia. Prognosis has to be guarded since it is not always possible to predict the outcome from the clinical features. Neurologic sequelae such as intellectual impairment, motor deficits, extra-pyramidal features and cerebellar disturbances are common. Polio like flaccid paralysis may occur rarely. Parkinsonism is uncommon and this stands in contrast to encephalitis lethargica. The first attack of JE produces immunity, but second attacks do occur since immunity is not lifelong. JE occurring in the first or second trimester of pregnancy may lead to fetal infection and fetal death. Cases acquired in the third trimester have not been reported to interrupt pregnancy.

TREATMENT AND PREVENTION

Treatment

There is no specific treatment. Supportive treatment includes the correction of fluid and electrolyte abnormalities, measures to control cerebral edema, anticonvulsants and maintenance of nutrition. Use of human immunoglobulin in a dose of 150-200 mg/kg bw early in the disease has been claimed to reduce the severity and mortality of the disease. There are preliminary data on the possible effectiveness of alpha-interferon for treatment of JE. Further studies are required to confirm the effect.

PREVENTION

Killed vaccine using Nakayama Yoken strain of the virus is available for prophylaxis. Indian vaccine is available,

originally prepared from Nakayama JE virus at Central Research Institute, Kasauli, HP. It is a formalin-inactivated vaccine. It is supplied as freeze dried vaccine, which has to be stored below 10°C. The reconstituted vaccine should be used within eight hours if kept cold. It should not be frozen. The recommended schedule for adults in JE endemic areas is two doses of 1 mL each given SC at an interval of 1-2 weeks. Protection starts one month after second dose. A booster dose should be given after one month but within one year. One more booster should be given after three years for full protection. In non-endemic areas repeated booster doses should be given every three years.

For children below three years the dose of vaccine is 0.5 mL, other conditions remaining the same. The vaccine is immunogenic, and safe with only rare side effects.

A live attenuated cell culture derived vaccine (SA14 14-2 strain) has been used safely and with high effectiveness in China.

Note: Zydus Biogen manufactures this vaccine in India.

Anti-mosquito measures help to limit the spread. Travellers to endemic areas should protect themselves against mosquito bite.

Points to remember

- 1. Japanese encephalitis is endemic in several parts of India occurring sporadically and as small outbreaks.
- 2. Co-existence of birds, cattle and humans and proliferation of culex mosquitoes provide the ideal environment.
- 3. Once the disease occurs, treatment is only symptomatic.
- 4. Effective vaccination is available for producing solid immunity.

Epstein Barr Virus

INFECTIOUS MONONUCLEOSIS

Introduction

This is worldwide in distribution, occurring in young individuals more frequently and caused by *Epstein-Barr virus (EBV)*. EB virus has been associated with several diseases both benign and malignant. These include infectious mononucleosis, Burkitt's lymphoma, hairy cell leukoplakia of the tongue, seen in relation to AIDS, nasopharyngeal carcinoma prevalent in China and post-organ transplantation lymphomas.

EBV is a member of the herpes virus family. It infects B-lymphocytes. MHC class II molecules act as cofactors for infection. The virus infects epithelial cells primarily and replicates in them, leading to lysis of the cells. In EB virus induced pharyngitis, the saliva contains infective virus. Other sites of invasion are the cervical epithelium and B-lymphocytes. Immunosuppressant therapy predisposes to, and augments the development of EB virus induced lymphoproliferative syndromes. One of the modes of spread of infection is through saliva and kissing is attributed to play a role.

Pathogenesis

Only B lymphocytes have receptors for EB virus, and therefore, EB virus attacks B lymphocytes initially. These cells begin to proliferate and are altered antigenically. Though T lymphocytes are not affected by EB virus they also proliferate enormously. Around 90% of the atypical lymphocytes which are characteristic of the disease have T lymphocyte markers, whereas only 10% have B lymphocyte markers. The T cells destroy EB virus infected B cells resulting in the liberation of antigenic materials which stimulate the formation of autoantibodies. The antigenic stimulus to heterophilic antibody is not known. Both cellular and humoral responses occur, the former is more effective in conferring immunity. The virus develops strategies to elude the immune system and the infection tends to persist.

Clinical picture resembling infectious mononucleosis can be evoked by *Toxoplasma gondii* and *cytomegalovirus*, but in these the antibody responses are not seen.

CLINICAL FEATURES

The incubation period may range from 1 to 10 weeks, usually 2 weeks. The clinical spectrum may vary from that of a mild benign illness to that of a more severe and prolonged one. In children the infection is less severe whereas in adolescents and adults it produces the syndrome of infectious mononucleosis. The onset is

Fig. 61.1: Blood film atypical lymphocytes—line drawing. Arrows-note the amoeboid shapes. Arrow heads—neutrophils

usually insidious with general malaise, headache, diffuse myalgia, variable grades of fever, and other constitutional symptoms. A petechial rash occurring at the junction of the soft and hard palate associated with sore throat may herald the onset. The sore throat may persist for days and this may be mistaken for follicular tonsillitis. The posterior cervical lymph nodes enlarge initially, later generalized lymphadenopathy may occur. Spleen is moderately enlarged to 2 to 3 cm below the costal margin, it is soft and non-tender. If gross splenomegaly occurs, the organ tends to rupture even with slight trauma. Rarely jaundice and neurological manifestations may develop.

Blood: Initially there is leukopenia due to decrease in neutrophils, but this is followed by leukocytosis in which the leukocyte count may go upto 15-20,000/cmm. The characteristic finding is the presence of atypical lymphocytes which may form 60-80% of the total. The nuclei of the atypical lymphocytes do not have a regular shape but may be kidney shaped, oval, lobulated, or polymorphic. Nucleoli are not seen. The cytoplasm is non-granular, foamy, vacuolated, and appears amoeboid. The rest of the cells are mononuclear cells. In uncomplicated cases platelet count is normal (Figs 61.1 and 61.2).

Complications may occur. These include hemolytic anemia, thrombocytopenia, aplastic anemia, myocarditis, hepatitis, genital ulcers, splenic rupture and Guillain-Barré syndrome. Some cases go into chronicity.

Diagnosis

Clinically the disease should be suspected when small outbreaks occur in closed communities like hostels and dormitories, or when there is close personal contact with cases. The presence of oral lesions, posterior cervical lymphadenopathy, splenomegaly, and erythematous rashes

Fig. 61.2: Infectious mononucleosis—blood film arrow points to atypical lymphocyte

are suggestive. Diagnosis should be strongly suspected if the proportion of atypical lymphocytes exceeds 50%.

Presence of heterophile antibodies demonstrable by the *Paul-Bunnell test* (*sheep-cell agglutination*) strongly suggests the diagnosis of infectious mononucleosis. The titre of antibodies increases with the passage of time. They are detectable for 4 to 6 weeks. Since similar antibodies develop in serum sickness as well, differential absorption techniques are employed to differentiate infectious mononucleosis antibodies from those due to serum sickness.

Recently a rapid slide test called *monotest* has become available for quick diagnosis. Specific antibody to EB virus can be demonstrated by immunofluorescence, complement fixation, and gel diffusion wherever facilities exist.

Chronic active EBV infection is diagnosed by the following features:

1. Severe illness more than six months duration.
2. Histological evidence of organ involvement such as pneumonitis, hepatitis, bone marrow hypoplasia and uveitis and
3. Demonstration of EBV antigens or EBV DNA in tissues.

The differential diagnosis includes rubella, measles, viral hepatitis, secondary syphilis, follicular tonsillitis, diphtheria, and herpetic pharyngitis. The prolonged fever and constitutional symptoms may suggest enteric fever, influenza, or even acute rheumatic fever. The cases which present with neurological manifestations may have to be distinguished from encephalitis or lymphocytic choriomeningitis. Other hematological disorders like acute leukemia and lymphoma have to be distinguished by suitable tests.

Treatment

There is no specific therapy and symptomatic measures are indicated. Acyclovir arrests viral growth, but does not effectively allay the clinical course. This drug is quite

effective in oral hairy leukoplakia. It is seen that ampicillin aggravates the lymphadenopathy, skin rash, and laryngeal edema in many cases and hence this drug should not be employed. Other antibiotics are indicated if there is evidence of secondary infection.

In severe cases acyclovir and corticosteroids may help, especially when there is respiratory distress. In the vast majority recovery is usually complete in 3-4 weeks without any sequelae. Recent epidemiological evidence suggest that in some cases, due to continued antigenic stimulation, a lymphomatous process may be triggered off. Attempts to produce a vaccine are going on.

Cytomegalovirus Infection (CMV)

This virus which belongs to the family herpesviridae commonly affects humans and 40-90% of adults may show antibodies to the virus. The virus is shed in saliva and urine and from the genital tract. Infection is acquired by contact with saliva or urine or by sexual contact. Uncomplicated CMV infection in immunocompetent subjects may be asymptomatic in the vast majority. Clinical illness resembles infectious mononucleosis caused by Epstein Barr virus (EBV), with rash, Hepatitis, retinitis and neuropathy resembling Guillain-Barré syndrome may occur rarely.

In immunocompromised states the virus produces more severe illness leading to retinitis, pneumonitis, enteritis and generalized infection. It may occur as a co-infection in AIDS when the CD4 counts falls below 50/cmm. Patients receiving immunosuppressive therapy after organ transplantations may get CMV super-infection. Pregnant women who develop CMV infection may transmit the same to the fetus in up to 40%. Congenital infection may lead to hepatosplenomegaly, purpura, encephalitis, deafness and mental retardation in a small proportion.

Treatment

The drug of choice is **ganciclovir** 5 mg/kg bw given IV infusion given slowly over 1 hour b.d for 2 to 3 weeks. Maintenance dose is 5 mg/kg/day for long periods. An alternate drug is **foscarnet** given I V in a dose of 90 mg/kg b. d for 14 to 21 days. Intravenous administration of hyperimmune anti-CMV globulin given during pregnancy protects the fetus. An oral preparation of ganciclovir is available for prophylaxis in immunocompromised person.

Parvovirus Infections

Parvoviridae is a large family containing several members pathogenic to vertebrates. Of particular importance is parvovirus B19 belonging to the genus erythrovirus, and it propagates best in erythroid progenitor cells. Spread is

by respiratory droplets and through transfusion of blood and blood products. The virus does not have a lipid envelope and therefore it is resistant to heat-inactivation and solvent detergents. Infection is very common and more than 50% of people acquire antibodies to the virus by 15 years of age. The natural host for parvovirus B₁₉ (PV B₁₉) is the human erythroid precursor cells which contain globoside, which is a neutral glycolipid which acts as a cellular receptor (also known as group P antigen) on the RBC. Antibodies develop against the virus. These help to limit and eliminate the infection. Failure to produce antibodies results in persistence of the infection. Most of PB B₁₉ infections go without consequence. Active infection can lead to significant pathology especially in those with impaired red cell production, accelerated destruction or immunosuppression. PV B₁₉ directly infects erythroid progenitor cells leading to their lysis. The impaired erythropoiesis lasts for 7-10 days, with a drop of hemoglobin of up to 2g/dL in otherwise normal people. Markers of infection include B₁₉ IgM and/or B₁₉ DNA.

Clinical Features

Several syndromes are caused by parvovirus B₁₉.

1. *Fifth disease in children*: This manifests as fever with rash on the cheek-called erythema infectiosum. This rash is due to the deposition of immune complexes in the skin. The rash may tend to recur.
2. *Arthralgia and even arthritis* in older age groups
3. *Pure red cell aplasia*: This may lead to insidious onset of anemia in otherwise normal people. Generally the infection is short lived and spontaneous recovery is the rule. In hemolytic anemias where erythrocyte life span is reduced such as sickle cell disease, hereditary spherocytosis, thalassemias, congenital aplastic anemias and even iron-deficiency anemia, the virus causes aplastic crises.
4. *Persistence of parvovirus infection*: This leads to severe pure red cell aplasia of prolonged duration.
5. In pregnant women the virus may infect the fetus and produce fetal loss, or hydrops fetalis. 20% of non-immune-mediated hydrops fetalis is due to parvovirus infection.

Diagnosis can be established by demonstrating the antibodies.

Treatment: is symptomatic.

Hantavirus Infections

Hanta virus is a natural inhabitant of rodents and the virus is shed in their urine, feces and saliva. This virus affects the vascular endothelium and causes two major syndromes:

1. Hemorrhagic fever with renal syndrome (HFRS) and
2. Hantavirus cardiopulmonary syndrome (HCPS)

Antibodies to these virus has been reported in 15% of febrile patients in Vellore. S. India (Chandy S et al. Indian J Med Res 2005;122:211-5). Infection is by aerosol inhalation of infective material. Incubation period is about 3 weeks.

The virus affecting the endothelium leads to immune response against viral antigens expressed on the endothelial cells of the heart, lungs, kidney and lymphoid organs. The immune reactions are mediated by T-lymphocytes and macrophages. TNF- α and IL-1 beta increase capillary permeability. Nitric oxide released by TNF leads to vasodilation and shock.

HFRS: Nonspecific constitutional symptoms occur followed by hemorrhagic manifestations along with renal lesions.

Shock, oliguria and DIC follow. Survivors enter a diuretic phase by day 10-14. Thrombocytopenia, leukocytosis with shift to the left, increase in the number of circulating immunoblasts (up to 10% of circulating lymphocytes) and increase in serum levels of LDH should suggest the diagnosis. Specific tests include the demonstration of IgM and IgG antibodies by ELISA.

HCPS: Constitutional symptoms lasting for 3-7 days are followed by hypotension and shock. Pulmonary edema, cardiac arrhythmias and cardiac arrest may occur. Renal lesions may develop leading to oliguria lasting for 3-8 days, and later followed by polyuria.

Treatment is supportive with I V fluids, ionotropes, mechanical ventilation and blood products. Ribavirin has been used in usual doses- with variable results.

Marburg Virus and Ebola Virus

Marburg virus and Ebola virus are filoviruses which cause a severe, and often fatal hemorrhagic disease. In 2004-2005 an outbreak occurred in Angola with a case fatality of about 90%. Authentic reports on their presence in India are not available. Studies are going on with live attenuated recombinant vesicular stomatitis virus (rvsv) expressing the glycoprotein of Marburg virus and vaccination with this vector completely protected non human primates against experimental infection. The use of such vaccines for post exposure and pre-exposure prophylaxis in experimental animals shows promising results.

Chandipura Virus Encephalitis

This is a rapidly developing encephalitis which has affected parts of India from time to time. The virus belongs to the genus vesiculovirus and family Rhabdoviridae. An outbreak was documented in Jamshedpur in 1954. The virus was originally discovered in 1965 at the National Institute of Virology, Pune. A recent outbreak was described in 2003 in Andhra Pradesh and adjoining

areas of Maharashtra. In 1980 the virus was isolated from a case in Madhya Pradesh. It has also been reported from Senegal and Nigeria. Vectors are most probably female sandflies- *phlebotomus* spp.

The onset is with sudden fever, rigor, drowsiness leading to unconsciousness and death in 6-48 hours. The age group ranged from 2.5 to 15 years. The case fatality was 52.3%.

62

Systemic Fungal Infections

6

K.V. Krishna Das

Chapter Summary

General Considerations	351
Candidiasis	352
Aspergillosis	352
Histoplasmosis	353
Cryptococcosis	354
Rhinosporidiosis	355
<i>Pneumocystis Jirovicii</i> Infection	355
Other Fungal Infections	356

General Considerations

Fungi are present in abundance in the soil as saprophytes and they generally invade immunologically compromised hosts. In the human body they are present as commensals abundantly in the mucosal regions, skin and alimentary tract. The normal flora keep the fungi under check. With the widespread use of antibacterial drugs and immunosuppressive therapy fungal infections have assumed greater importance. Advances in surgery, organ transplantation, widespread use of prosthetic materials inside tissues, extensive use of broad-spectrum antibacterial agents and long-term use of immunosuppressant drugs have paved the way for the emergence of life-threatening fungal infections. Prophylaxis against such infections and vigorous curative therapy have to be undertaken to achieve the desired benefits in such patients.

Fungi may be unicellular such as *Cryptococcus* or multicellular such as *dermatophytes* and they show varying degrees of differentiation. Hyphae are elongated tubular structures formed by the cells. Hyphae may be

septate or nonseptate. A tangled mass of hyphae is called mycelium.

Pathogenic fungi may be classified into four groups morphologically.

1. **Yeasts:** These are unicellular fungi, spherical or ellipsoidal in shape, which reproduce by simple budding, e.g., *Cryptococcus neoformans*.
2. **Yeast-like fungi:** These show spherical and hyphal forms, e.g., *Candida albicans*.
3. **Moulds:** These are filamentous fungi which are capable of spore formation, e.g., *dermatophytes*.
4. **Dimorphic fungi:** These may grow as yeasts in tissues and moulds in the soil. Most of the systemic mycoses are due to such organisms.

Another basis for classification takes into account sexual spore formation. According to this classification, fungi may be divided into phycomycetes, ascomycetes, basidiomycetes and fungi imperfecti. Most of the human fungal pathogens belong to the class of fungi imperfecti.

Diagnosis of fungal diseases is established by demonstration of the organism in tissue specimens, body fluids or discharges. Fungi can be easily cultured in prepared media such as Sabouraud's glucose agar at pH 5.4.

Fungal lesions occurring in man can be broadly classified into superficial and deep mycoses. Superficial mycoses are more common and include the various types affecting the skin, nails, hair and mucous membranes. They are more common in those parts which are prone to be moist, such as intertriginous areas of skin, e.g., groin, gluteal folds, and webs of fingers. They occur in individuals who are otherwise healthy.

Primary systemic fungal infections are caused by organisms that are mostly soil saprophytes and the infection is accidental. Immunocompromised individuals run the risk of opportunistic infections by fungi that are usually avirulent such as mucor, cryptococcus, candida and aspergillus, but which become invasive when body resistance goes down.

A range of antifungal drugs are available at present for topical and systemic use. Early detection of fungal infection and appropriate therapy are essential for successful result.

Candidiasis

Candida albicans is a common inhabitant of the oropharyngeal, genital and intestinal cavities of man. Candidiasis is infection by *Candida albicans*. In most of the cases it remains as a local infection affecting the skin or mucous membranes of the mouth or genitalia. In the mouth it presents as oral thrush which is seen at the extremes of ages, those on antibiotic therapy or in immunosuppressed individuals. In the genitalia it usually presents as vulvovaginitis in diabetic women who are not well-controlled. Cutaneous candidiasis usually affects the intertriginous areas.

Systemic candidiasis occurs in immunocompromised individuals and in drug addicts who share needles. The fungus becomes invasive and spreads through the blood stream to produce several lesions.

1. Localized lesions: Urinary tract, liver, heart valves, meninges and peritoneal cavity.
2. Widely disseminated: Associated with septicemia (candidemia).

In disseminated candidiasis also the main targets of attack are the kidneys, brain, liver, gastrointestinal tract, eye (endophthalmitis) and heart valves.

Extensive, recurrent and persistent oropharyngeal and esophageal candidiasis is a common AIDS associated infection.

Diagnosis

The organism can be demonstrated microscopically by examining samples from local lesion. In tissues, PAS staining or methenamine silver staining reveals the organism.

The fungus can be grown in Sabouraud's medium. Antibodies to *Candida* can be detected by ELISA or immunodiffusion. The candidal antigen can be demonstrated by ELISA or radioimmunoassay.

Treatment

Amphotericin B, fluconazole, ketoconazole and itraconazole are all effective in appropriate dosage to control the systemic infection. Local surgical therapy should be aimed at removal of the source of infection.

Dose: Amphotericin B up to 50 mg/day IV for 1-2 weeks and more.

Fluconazole 400 mg/day.

Ketoconazole 400 mg/day for several weeks.

Itraconazole 200-400 mg/day (Table 62.1).

Itraconazole and fluconazole are less adreno-suppressive compared to ketoconazole. Superficial skin and mucous membrane lesions respond well to nystatin ointment or nystatin mouth washes. Fluconazole given orally is very effective to cure vaginal candidiasis.

Aspergillosis

The species of aspergillus pathogenic to man are *A. fumigatus*, *A. niger*, *A. flavus*, *A. terreus* and *A. nidulans*. Of these *A. fumigatus* is most common. Infection occurs when general resistance is lowered or local disease favours superinfection. Aspergillus is very widespread in nature and their spores are found in dust. Both superficial and systemic lesions may develop. The commonest superficial lesion is otomycosis. Systemic infection may be pulmonary or disseminated. Major portal of entry is the respiratory tract.

Pulmonary form: Allergic alveolitis may develop due to inhalation of fungal spores in sensitized individuals. *Aspergillus* may grow in the bronchi to produce bronchopulmonary disease. The hyphae may obstruct the lumen. Healed tuberculous cavities or other types of cavities may be the seat of colonization by the fungus. The mycelia grow to form a tangled fungal ball which is recognizable in X-rays (aspergilloma) (Fig. 62.1). It may remain asymptomatic or may cause massive hemoptysis. Invasive aspergillosis occurring in immunosuppressed individuals leads to widespread pulmonary necrosis with marked systemic symptoms.

TABLE 62.1

Comparative data of the three azole antifungal drugs

	Water solubility	Bioavailability	Urinary excretion	Half-life (hours)	Level in CSF/ Serum %
Fluconazole	Good	85%	64%	22	60
Ketoconazole	Poor	75%	2%	8.1	10
Itraconazole	Poor	99.8%	1%	17	10

Fig. 62.1: Skiagram aspergilloma in cavity, left lung and upper zone

Other sites of lesion are the central nervous system and naso-orbital cavities. Diagnosis can be made by histological demonstration of the fungus and isolation of the organism from the exudates. Since *Aspergillus* is a common contaminant in respiratory secretions, mere isolation does not prove its pathogenic role. Precipitating antibodies can be demonstrated by gel diffusion test and this test is of great value in diagnosis.

Treatment

Amphotericin B in a dose of 1 mg/kg/day is effective in systemic aspergilloma. Amphotericin B and 5-fluocytosine are effective in CNS disease. The underlying predisposing factor should be attended to. Cavities containing aspergilloma producing intractable hemoptysis have to be removed surgically. Other drugs like clotrimazole which are also effective *in vitro* are being evaluated. Other drugs effective against aspergillus include oral fluconazole itraconazole, voriconazole and posaconazole. Posaconazole can be given prophylactically against aspergillus and other fungal infections in neutrophilic patients. The dose is 200 mg tds oral. Caspofungin a new anti-fungal drug effective against aspergillus and other yeast species.

Histoplasmosis

Syn: Darling's disease, cave disease

Etiology

This infection is worldwide in distribution but maximum number of cases have been reported from the West, especially the USA. Limited studies show that the infection is present in India. *Histoplasma capsulatum* is

Fig. 62.2: X-ray chest histoplasmosis—
Lesion resembling tuberculosis

seen in soil enriched by the droppings of birds especially fowls. When the spores are inhaled yeast-like forms develop in tissues. It grows as a mould in its natural habitat and *in vitro*.

Pathology

The lesions are granulomas produced in several organs. Reticuloendothelial organs, lungs, adrenals, brain and other tissues may be affected. Lesions may resemble tuberculosis. Healing occurs with calcification. Cerebral lesions can be mistaken for those of cerebral thrombosis or hemorrhage.

Clinical Features

The majority of cases are asymptomatic. Pulmonary lesions may resemble different types of tuberculosis (Fig. 62.2). Common manifestations include fever, cough, hilar adenopathy, pneumonitis, apical infiltrates, fibrocavitary lesions and subpleural solitary pulmonary nodules. Scattered miliary calcification may develop in disseminated histoplasmosis (Fig. 62.3). Other manifestations include mediastinal syndrome, uveitis and adrenal insufficiency.

Disseminated Histoplasmosis

Fatal disseminated histoplasmosis may develop in persons who harbour the infection, and who receive corticosteroid therapy. Lesions occur in the liver, spleen, bone marrow, lymph nodes and adrenals. Clinical features include fever,

Fig. 62.3: X-ray chest histoplasmosis—Miliary calcification

hepatosplenomegaly, generalized lymphadenopathy and mucocutaneous ulceration.

Diagnosis

X-ray chest shows the pulmonary lesions. Delayed hypersensitivity test using histoplasmin is helpful in diagnosing past infection. The test shows cross-sensitivity with other fungi. It is more useful for epidemiological studies to determine the prevalence of histoplasmosis in the community. Its use in the diagnosis of individual cases is limited. Complement fixing antibodies are detectable in the serum and these, being more specific, are useful in diagnosis. Diagnosis can be confirmed by demonstrating the fungus in tissue biopsies or other suitable material.

Prognosis

Histoplasmosis is generally benign. In immunosuppressed individuals complications are more.

Treatment

Specific treatment is not indicated in asymptomatic cases. In disseminated disease and in chronic pulmonary lesions, intravenous amphotericin B given for 10-12 weeks is curative.

The dose is 0.5 to 0.6 mg/kg bw daily or 1.0-1.2 mg/kg bw on alternate days. Immunocompromised subjects should receive amphotericin as the drug of choice.

Ketoconazole 400 mg daily for 6 months is a less toxic alternative. This drug may produce transient adrenocortical insufficiency.

Persistent cavities and mediastinal fibrosis may demand surgical removal.

Cryptococcosis

Syn: Torulosis, European Blastomycosis, Busse-Bushke's disease

Infection by *Cryptococcus neoformans* leads to a clinical picture of subacute or chronic meningoencephalitis commonly. Sometimes the infection becomes generalized and lungs, skin, bones and viscera may be involved. The fungus is present in nature especially in soil contaminated by the droppings of birds like fowls and pigeons.

Etiology

Cryptococcus neoformans is a yeast like fungus, distributed all over the world. In tissues it remains encapsulated in a polysaccharide capsule. Infection in the majority of cases is subclinical, but generalized disease occurs in immunologically deficient subjects. It is a common opportunistic infection in AIDS.

Pathogenesis and Pathology

It is probable that the fungus reaches the lungs by inhalation. The pulmonary lesions tend to heal spontaneously without becoming symptomatic. Histologically, the lesions range from mild inflammatory reaction to definite granulomas. Intracranial infection leads to basal meningitis. The organism reaches the meninges by the bloodstream.

Clinical Features

The pulmonary involvement may be subclinical. It may be detected during routine investigation or accidentally, as inflammatory or tumour-like lesions. Often these lesions are mistaken for tuberculosis. Meningoencephalitis closely resembles tuberculous meningitis. Papilledema and cranial nerve palsies occur in some cases. The course is prolonged with remissions and exacerbations.

Papular or suppurative lesions occur in the skin in 10% cases. These ulcerate and discharge hairy material containing the fungus. Other viscera such as liver, pericardium and endocardium may be affected.

Diagnosis

Diagnosis is confirmed by finding the encapsulated fungus in the sputum, urine, tissues and cerebrospinal fluid. The fungus can be cultured and identified. *The encapsulated organism can be demonstrated in the CSF by microscopic examination after mixing with a drop of India ink.* Serological tests like complement fixation and latex agglutination are available, but being non-specific, they are not of great help. Cryptococcal antigen can be detected in CSF or blood by enzyme immunoassay.

Treatment

Cryptococcosis of the CNS is treated with fluocytosine, given 150 mg daily orally in four divided doses or intravenous amphotericin B. Amphotericin B is started in a daily intravenous dose of 10 mg in a drip as the initial dose and it is increased to 50 mg/day to reach a total dose of 2 g or more. Mild toxic effects include nausea, vomiting, chills, fever, headache and malaise. The drug is nephrotoxic and increase in blood urea is a contraindication for further therapy. Fluconazole 400 mg/day can be given IV daily for 14 days or more.

Combination of amphotericin B 0.7 mg/kg bw and fluconazole 200-400 mg I V daily along with other drugs results in earlier resolution of both meningitis and pneumonia. In cases where cryptococcosis complicates AIDS treatment has to be continued till the CD4⁺ count rises about 200/cmm with ART.

Rhinosporidiosis

It is a chronic localized proliferative lesion caused by *Rhinosporidium seeberi* which affects the mucous membranes of the nose, larynx, eyes, ears, mouth, genitalia, rectum and skin.

Etiology

The etiological agent which is most probably a fungus was included under the class phycmycetes. The source of infection is stagnant water or aquatic life. The disease is endemic in Sri Lanka and India, but only rarely seen in other parts of world. Mode of infection is not clearly known.

Pathology

Typical lesions are soft, nodular, and polypoid with greyish-white areas over the surface. Chronic inflammatory cell infiltration may be demonstrable. Histology shows a large number of fungal spherules containing endospores, embedded in a stroma of vascular connective tissue.

Clinical Features

The incubation period is not clearly known. The patients often seek medical help only when polypoidal masses have developed. The symptoms depend on the site of affection. Nasal cavity is affected most commonly (Fig. 62.4). Symptoms include local pruritus, presence of mass, nasal block and epistaxis. The polyps are soft, pink, friable, and easily bleeding on touch. Their sizes vary and they show small yellowish dots on the surface. Cutaneous lesions resemble warts and are initially painless but become painful later.

Diagnosis can be made clinically in endemic areas. Nasal discharge may show free spores demonstrable microscopically. Histology is confirmatory.

Treatment consists of surgical removal.

Fig. 62.4: Rhinosporidiosis—
Note the polypoid lesions - arrow

Pneumocystis Jirovicii Infection

This organism, previously known as *Pneumocystis carinii* is considered to be more similar to fungi, though for several decades it was included among the protozoa. The parasite that is specific to man has been re-designated as *Pneumocystis jirovicii*. It is a pathogen of low virulence. It measures 1-8 μ and is round or elongated. It is seen widely in nature in man and several animals. It is not very clear how *P jirovicii* is transmitted. It may spread from the environment or from person to person. In those with suppression of immunological function it becomes invasive and causes pneumonia. This parasite has unique tropism for the lungs where it remains as an alveolar pathogen without invading deeper tissues. Tissue reaction to infection leads to inflammation and diffuse alveolar damage. Immunity is CD4 T cell mediated.

Pneumocystis jirovicii infection complicates hematological malignancies, immunosuppressant therapy and organ transplantation.

Homosexual men and subjects with acquired immunodeficiency syndrome (AIDS) show predilection. In children, pneumocystosis may supervene on congenital immunodeficiency states and protein-calorie malnutrition.

Immunodeficiency also predisposes to infection by *cytomegalovirus*, *candida* and *mycobacteria* which may coexist with pneumocystosis. In many patients with AIDS, the presentation is pneumocystis pneumonia. Infection is heralded by fever, nonproductive cough and progressive dyspnea. The condition generally deteriorates within weeks to months. Physical examination may show nil, or only minimal signs. X-ray shows infiltration, going on to extensive consolidation. Less commonly other organs such as lymph nodes, spleen, liver, bone, bone marrow, meninges, pancreas and endocrine glands may show lesions (See also Chapter 48 AIDS).

Diagnosis

Pneumocystis pneumonia should be suspected when fever and respiratory symptoms occur in immunosuppressed

individuals. Chest skiagram shows diffuse interstitial infiltrates. The organisms can be demonstrated in bronchial aspirates or lung biopsy specimens taken at bronchoscopy or by needle biospy. Though positive results confirm the diagnosis, negative results do not exclude the condition.

Treatment

Cotrimoxazole in doses up to 6 to 7 g/day in divided doses for 2 weeks is beneficial. Pentamidine isothionate given intramuscularly in a dose of 2-4 mg/kg body weight daily for 10-14 days is also effective as a curative drug. If the drug is started early, results are good. Improvement starts in 5-7 days. Other drugs which are also beneficial include dapsone and pyrimethamine.

If the results are not good with the specific drugs alone addition of prednisolone in a dose of 1 mg/kg bw brings about rapid relief. This has to be tapered off with improvement. The underlying condition should also receive attention.

Prophylaxis against pneumocystis pneumonia should be instituted in patients infected with HIV when the CD4 lymphocyte count falls below 200/cmm. Cotrimoxazole is very effective in preventing infection, if given in a dose of one double strength tablet daily for prolonged periods.

TABLE 62.2

Other fungal infections		
Disease	Organism	Geographical distribution
Coccidioidomycosis	Coccidioidis immitis	Worldwide
Paracoccidioidomycosis	Paracoccidioides brasiliensis	South America
Blastomycosis	Blastomyces dermatidis	Worldwide
Sporotrichosis	Sporothrix schenkii	Worldwide
Chromoblastomycosis and mycetoma	Genera Fonsecaea and Cladosporium	Tropics
Zygomycosis	Absidia, Mucor, Rhizopus	Worldwide

Other Fungal Infections

With the advent of numerous antimicrobial drugs and immunosuppressant drugs, the number of immunocompromised subjects has increased. The epidemic of HIV has rendered many patients immunosuppressed. Due to all these factors the number and variety of fungal infection have also increased. Some of the less common fungal infections are given in Table 62.2.

63

Actinomyces and Nocardia

K.V. Krishna Das

Chapter Summary

Actinomycosis 356
Mycetoma 357

These are gram-positive bacteria with branching filaments sometimes forming a mycelium. These are included under the order Actinomycetales. Mostly they are soil saprophytes. Two genera—Actinomyces and Nocardia are pathogenic to man.

Actinomycosis

Syn: Ray-fungus disease

Actinomycosis is a chronic, slow-growing, progressive, granulomatous lesion caused by *Actinomyces israeli*. Actinomycetes are bacteria. They form mycelia like fungi. They are susceptible to antibiotics and in this regard behave more akin to bacteria. They are gram-positive. The two genera of medical importance are *Actinomyces* and *Nocardia*. *Actinomyces* are anaerobic or microaerophilic whereas *Nocardia* are aerobic. *Actinomyces israeli* is

present in the mouth as a commensal and tissue invasion occurs due to minor trauma.

Pathology

The lesions are granulomas with added suppuration. The pus shows microcolonies of the organisms as yellowish granules (sulphur granules). These granules become more distinct when the pus is shaken vigorously with water.

CLINICAL FEATURES

The disease presents as the cervicofacial form, thoracic form, abdominal form and bony lesions. Symptoms depend on the anatomic location.

1. **Cervicofacial form:** 40-60% of the total. This form starts as painless, slow growing lump near the jaw or a painful lesion resembling an abscess. The lesion progresses to involve deeper tissues and bone and sinuses develop. Trismus may occur. Lymph nodes are generally spared. Systemic symptoms are few or absent. The lesion progresses slowly to destroy all tissues and discharge the characteristic pus. Presence of extensive destructive lesions in the presence of minimal general symptoms should suggest the possibility of actinomycosis.
2. **Thoracic form:** This form results from aspiration of the organism from the mouth. Manifestations include pulmonary infiltration and cavitation, pleurisy, empyema and pericarditis. Pulmonary lesions may be unilateral or bilateral and may closely resemble tuberculosis. The lesion may spread to the pleura and chest wall leading to periostitis of the ribs and formation of discharging sinuses.
3. **Abdominal form:** This form results from ingestion of the organisms. Lesions occur in the cecum and appendix. The disease may present as acute appendicitis or a slow growing lump in the right iliac fossa. This may resemble ileocaecal tuberculosis, Crohn's disease or malignancy. The lesion may become adherent to the anterior abdominal wall and form sinuses. Rarely the liver and genitals may be involved.
4. **Bone:** The bony lesions include osteomyelitis of the mandible, ribs and lumbar vertebrae.

Diagnosis

Strong clinical suspicion is necessary to make the diagnosis. Microscopy of the discharges reveals the mycelia. Histopathological examination confirms the diagnosis. The organism can be grown in culture anaerobically.

Prognosis

Early diagnosis and proper treatment result in resolution of the lesions.

Treatment

Penicillin is the drug of choice giving cure rates over 80% in 6-8 weeks. Tetracycline and stilbamidine have to be given when penicillin is contraindicated. Erythromycin, fusidic acid, lincomycin and rifampicin are all effective. Surgery may be necessary in advanced cases if drug treatment fails.

MYCETOMA

Syn: Madura foot, Maduramycosis

Definition

This is a chronic granulomatous inflammation caused by several species of nocardia, actinomycetes and fungi. *Nocardia* are normally present in soil and infection may be exogenous.

The classic lesions are Madura foot and other mycetomas. The organisms causing Madura foot are *Nocardia madurae*, *N. asteroides* and *N. brasiliensis*. In addition to nocardia actinomycetes and fungi can also lead to mycetoma.

The lesion starts in the subcutaneous tissues and later on involves deeper structures, including the bones, to form sinuses leading to the eventual destruction of the part. *This condition was described in Madurai in 1842 by Gill.* This disease is confined to the tropics and is particularly endemic in India, Africa and South America. Most of the cases in India have been reported from Tamil Nadu, Andhra Pradesh and Maharashtra.

Pathogenesis and Pathology

The organisms enter through abrasions on the skin. The lesions are manifest after a long incubation period. A granuloma develops. The organisms are seen to lie in abscesses, surrounded by a zone of chronic inflammatory cells. The organism can be easily identified on microscopic examination. The inflammation spreads along fascial planes by contiguity. Nerves and tendons are highly resistant to invasion. Regional lymph nodes are not generally affected.

Clinical Features

A small painless firm subcutaneous tumour develops in both the nocardial and actinomycotic types. The lesions slowly progress to destroy the part. Sinuses develop which discharge pus containing the organisms. The progress of an actinomycotic granuloma is more rapid than that of a nocardial lesion.

The most common site is the dorsum of the foot, but other regions like the hands, buttocks, back, scalp and orbits may be affected. Systemic symptoms do not occur.

Radiological Features

Bone destruction and endosteal or periosteal new bone formation may be demonstrable in localized areas or more diffusely.

Progressive painless destructive lesions of the extremities occurring in endemic areas should raise the possibility of mycetoma. The differential diagnosis includes chronic osteomyelitis, tuberculosis, syphilis, elephantiasis and neoplasms. Histology of the lesion and isolation of the organism from the lesion help to establish the diagnosis. Antibodies to the organism can be demonstrated by agar-gel precipitation tests.

Treatment

Drug treatment is effective for actinomycotic lesions, but not so readily for nocardial lesions. Actinomycetomas respond well to prolonged treatment (6-12 months) with dapsone (200 mg/day), sulfisoxazole, streptomycin, sulphamethoxypyridazine, cotrimoxazole, nalidixic acid or rifampicin. Therapy of choice for nocardia is sulphonamide with or without trimethoprim.

Surgery

In addition to drug therapy, surgery may be needed to excise early lesions or to amputate grossly damaged limbs. The lesion may recur after surgery. Mycetomas can be prevented by hygienic habits and regular use of footwear.

Protozoal Diseases

General Considerations

Protozoa are unicellular organisms containing cytoplasm, nuclei and other organelles. Based on the mode of locomotion, protozoa have been classified into flagellates, ciliates, amebae and sporozoa. Even though differences occur between the different classes, basic similarities exist. The cytoplasm is divided into an outer ectoplasm and inner endoplasm. Both layers contain several organelles, the ectoplasm performs the functions of protection, locomotion, respiration, nutrition and excretion.

The nucleus is made up of fine delicate filaments studded with masses of chromatin granules and is enclosed by the nuclear membrane. The karyosome lies in the center of the nucleus. It may be minute or large and conspicuous. Under adverse conditions, free-living protozoa change from the vegetative to the cystic form by encasing themselves in a tough membranous wall.

Protozoa are found extensively in the environment. Many, such as *Entameba coli* and *Trichomonas hominis* are free living commensals, while others become invasive and pathogenic when circumstances are favourable, e.g.,

Entameba histolytica, and *Giardia lamblia*. Some are obligate parasites of man or other vertebrate hosts, e.g., malarial parasites, trypanosomes and leishmania. These have a developmental cycle in arthropod vectors. Distribution of the vector determines the endemicity to particular geographical regions. Rise in vector population leads to outbreaks of epidemics from time to time. Since tropical climate offers the ideal situation for the breeding and proliferation of the vector arthropods, such vector-borne diseases are most prevalent in the tropical belt. High density of population, low socioeconomic conditions and poor hygienic environment favour the persistence and spread of many of the diseases – both faeco-orally transmitted and vector-transmitted.

Malaria

Definition

This is a febrile illness caused by the hemoprotozoa of the genus *Plasmodium*. It is characterized by periodic fever, splenomegaly, hemolytic anemia, and a recurrent and chronic course. The plasmodia affecting man are *P. vivax*, *P. falciparum*, *P. ovale*, and *P. malariae* and they produce benign tertian, malignant tertian, ovale tertian and quartan malaria respectively. The falciparum variety, is the most serious form, with high morbidity and considerable mortality, especially so in children and in travellers who visit endemic area. Malaria also may run a chronic course with variable morbidity and uncommonly, mortality. The disease is transmitted from man to man by the infective bites of female anopheles mosquitoes. Several vertebrate animals, birds and other members of the animal kingdom have malaria caused by parasites exclusive to them.

EPIDEMIOLOGY

Malaria is endemic in all tropical countries like India, Bangladesh, Sri Lanka, Myanmar, Middle East, Far East, several parts of Africa and tropical America. Present facilities for quick travel and migration of population have helped to introduce this disease in all countries. The disease is rare in stations above an altitude of 1500 m or where the ambient temperature is low. Presence of susceptible population, vector mosquitoes, and availability of reservoir hosts determine the endemicity.

Vivax malaria is more widespread generally, but in some parts falciparum is more common. Malaria, occurs in 90 countries of the world. 500 million cases occur annually with 2.7 million deaths. At present along with *M. tuberculosis* and measles, malaria has the distinction of being one among the three pathogens causing the maximum human morbidity and mortality especially in the developing countries. For India it is a major medical problem (Fig. 64.1).

Fig. 64.1: Epidemiology of malaria

After successful attempts at reducing the incidence and prevalence of malaria in India, due to several factors the disease re-emerged and by 1976 the annual incidence went up to 6-7 million. With preventive strategies to control the epidemic, incidence of the disease is stable around 2 million annually at present.

World Bank assisted enhanced Malaria Control Project is in operation in high risk districts. Resurgence and persistence of malaria are due to insecticide resistance of the vector, drug resistance of the parasite, slack organizational structure and financial constraints. There is relative and absolute increase in *Plasmodium falciparum* cases which are multi-drug resistant. This poses difficulty in treatment and control and also causes heavy economic burden to India and all developing countries. The term **airport malaria** denotes the spread of malaria to people living near airports. Spread of malaria to persons traveling in aircraft caused by mosquitoes lurking in the aeroplane is called **commuter malaria**.

The vectors are female anophelene mosquitoes. The main anophelene mosquito vectors in India are *Anopheles culicifacies*, *A. stephensi*, *A. fluviatilis*, *A. minimus*, *A. dirus* and *A. sundaicus*. Ronald Ross, an English doctor belonging to the Indian Medical Service demonstrated the transmission of malarial parasite by anophelene mosquitoes, while working in Hyderabad, Andhra State. He was awarded the Nobel Prize for his discovery.

Depending on their individual preferences, these thrive in stagnant and/or running fresh water or brackish water.

Terms used in Malariology

The prevalence of malaria in a community is estimated by the **spleen rate**, **parasite rate**, **infant parasite rate** and other indices (Table 64.1). *Spleen rate* represents the percentage of children aged 2-9 years showing palpable spleens. *Parasite rate* represents the percentage of positive cases of malaria detected by the examination of thick or

TABLE 64.1

Classification of endemicity		
Endemicity	Spleen rate	Parasite rate
Hypoendemic	0-10%	0-10% in children aged 2-9 years
Mesoendemic	11-50%	11-50% in children aged 2-9 years
Hyperendemic	over 50%	over 50% in children aged 2-9 years
Holoendemic	over 75%	over 75% in infants

thin blood films in a community. *Infant parasite rate* is the percentage of positives among children aged 0-11 months. This is closely related to the incidence of malaria and active transmission.

In hyper- and holoendemic areas, the local inhabitants develop immunity due to repeated encounter with the parasite. Such persons do not develop clinical disease even though parasites are demonstrable in blood. This phenomenon is called **premunity**. Children and newcomers suffer heavily. In hypo- and mesoendemic areas, the local inhabitants do not acquire strong immunity and, therefore, both local inhabitants and newcomers suffer. Single attacks of malaria do not give immunity since the parasite especially *P. falciparum*, undergoes rapid antigenic variations. Repeated attacks produce variable degrees of immunity which includes both the humoral and cellular types. Hyperimmune individuals, in hyper- and holo endemic areas remain asymptomatic even while harbouring the parasites. This immunity may wear off over a period of time, if they leave the endemic areas.

LIFE CYCLE OF THE PARASITE

There are two stages-sexual cycle (**sporogony**) in the mosquito which is the definitive host and the asexual cycle (**schizogony**) in man who is the intermediate host. In the human, schizogony leads to the development of the vegetative forms such as merozoites, trophozoites and schizonts which all can divide and multiply further and invade more erythrocytes. A proportion of the parasites develop into sexual forms which are the male and female gametocytes. These are incapable of further division and development in the humans, they develop further only if taken up by the mosquito. Gametocytes remain viable in circulation for 2-3 weeks. They die if not ingested by the mosquito. Female gametocytes outnumber the male gametocytes.

Mosquito Cycle (Sporogony)

Sporogony (Sexual Cycle)

When the female anophelene mosquitoes take blood from infected persons, gametocytes are also ingested. Only

gametocytes develop further. In the mosquito's stomach the gametocytes are released from the erythrocytes and they transform into gametes which develop further. The asexual forms of the parasite die. The male gametocyte exflagellates into 6-8 flagella and each flagellum fertilizes a female gamete. A zygote is formed which develops into ookinete and oocyst in the stomach wall. About 10,000 sporozoites develop within each oocyst. A mosquito may harbour a few to more than a hundred oocysts at a time. The time taken for the sporozoites to develop depends on the environmental temperature and humidity, higher temperatures favouring quicker maturation. The oocysts rupture releasing the sporozoites into several tissues. Many reach the salivary glands and remain in the saliva ready to be injected into the next victim during the blood meal. Once infected, the mosquito remains infective for its life span of about a month. Since *P. vivax* can develop even at lower temperatures compared to the other species of parasites, the former has a more widespread distribution over the globe.

Human Cycle—Schizogony

Schizogony (asexual cycle): This occurs in man and it consists of the exo-erythrocytic and erythrocytic cycles.

Primary Exoerythrocytic Cycle (Pre-erythrocytic Cycle)

This is the phase in which the parasite adapts to the new host; and this takes place in the liver. After inoculation by the mosquito, the sporozoites circulate in blood and within hours they enter the hepatocytes to develop and multiply within them. Each sporozoite can produce several thousands of merozoites within a few days. Merozoites come out of the liver cells after about a week and invade erythrocytes to initiate the erythrocytic cycle.

Entry of sporozoites into liver cells and attachment of merozoites to surface of erythrocytes are all processes mediated by specific receptors. The interval required for the sporozoites to develop in the liver cells and merozoites to appear in erythrocytes is called the *pre-patent period*. Sporozoites do not cause any permanent damage to the liver cells.

All the sporozoites do not complete their development and emerge out of the liver cells at the same time. In the case of *P. vivax* *P. malariae* and *P. ovale* many of the sporozoites can remain dormant in the liver cells for periods extending up to several months or years and get released into the circulation to start their erythrocytic phase. These dormant sporozoites are called *hypnozoites*. They lead to late relapses in case of *P. vivax* and *ovale*. It is now the consensus that *P. falciparum* and *P. malariae* do not have the hypnozoite stage. In them the relapses are caused by merozoites lurking in erythrocytic cycle, depending on the immune status of the individual.

Erythrocytic Cycle

The merozoite develops in the erythrocyte utilizing its hemoglobin for metabolism. The parasite makes a vacuole within the red cell for it to grow. It absorbs nutrients voraciously. It grows into a ring form and later becomes the *trophozoite* which shows ameboid movement.

Within 48-72 hours the trophozoite reaches full growth and divides by binary fission to form a *schizont*, which contains several *merozoites*. The parasite utilizes glucose and oxygen for its metabolism while developing in the erythrocyte. Hemoglobin is converted into its metabolic end product hemozoin, which is ingested by macrophages. This appears as malarial pigment in the parasites, when stained appropriately. Accumulation of malarial pigment occurs in the reticuloendothelial organs such as the spleen, liver and bone marrow. The spleen and liver enlarge progressively.

Several abnormalities of erythrocytes inhibit the development of the parasite in them and render natural immunity. *P. falciparum* fails to thrive in erythrocytes having glucose-6-phosphate dehydrogenase (G-6-PD) deficiency and sickle cell hemoglobin. Heterozygous sickle cell trait, alpha and beta thalassemias, female heterozygous G-6-PD deficiency and hereditary ovalocytosis give partial protection against *P. falciparum* infection. Duffy negative blood group individuals show resistance to the development of *P. vivax* in the erythrocytes. This advantage offered by inherited abnormalities in hemoglobin is attributed to be a reason for the widespread prevalence of hemoglobinopathies in many tropical countries.

After full development, the erythrocyte is ruptured and the contents-merozoites, metabolites and toxic products are liberated into circulation and this gives rise to the febrile paroxysm. The periodicity of the febrile paroxysms generally correlates with the liberation of the merozoites at the end of the erythrocyte cycle. It may be tertian (occurring once in 3 days), quartan (occurring once in 4 days), or sub tertian or quotidian (occurring daily).

The average number of merozoites and time taken for schizogony vary with each species (Table 64.2).

P. falciparum can multiply much faster than the other species and also reach dangerous parasitemic levels, on account of the larger number of merozoites and shorter period for maturation.

TABLE 64.2		
Number of merozoites and time for their development		
	No. of merozoites	Time for schizogony
<i>P. vivax</i>	8-16	48 hours
<i>P. falciparum</i>	12-24	48 hours or less
<i>P. ovale</i>	8-12	48 hours
<i>P. malariae</i>	6-12	72 hours

The erythrocyte ruptures liberating the merozoites into the plasma. Many of them are destroyed, but others attach to fresh erythrocytes and successively repeat the cycle of multiplication. The number of parasites progressively increases. When the parasite level reaches a threshold, clinical symptoms set in. In a primary infection, after a few erythrocytic cycles lasting for 2-3 weeks, some of the merozoites develop into the male and female gametocytes, which are the sexual forms destined to continue sporogony in the mosquito. They continue further development only if ingested by the vectors. If not, they die within 2-3 weeks (upto 8 weeks for *P. falciparum*) and are disposed off by macrophages. The erythrocytic merozoites infect only further erythrocytes and do not re-enter liver cells.

PATHOPHYSIOLOGY

The pathogenesis of malaria is complex, multifactorial and only partly understood. Most of the studies have been done on malaria in general and on the development of complications associated with *P. falciparum*(Pf). The factors contributing to pathogenesis include direct invasion of erythrocytes leading to hemolysis, affection of vascular endothelium, immunological phenomena and toxemia affecting one or more organ systems.

During schizogony *P. falciparum* (Pf) leads to adhesion of parasitized erythrocytes to endothelium, and to themselves (cyto-adherence) and endovascular sequestration leading to rosette formation, vascular occlusion, release of cytokines and vasomediators and, organ dysfunction. This is the basic pathology in complicated forms of Pf malaria. The clinical features may not directly correlate with the immunopathological alterations, since host immunity and antigenic make up of the parasite also play their roles. Pf erythrocyte membrane protein (PfEMP-1) antigen forming knobs on the surface of red cells are responsible for cyto-adherence. They bind to the vascular endothelium. Platelets and leukocytes adhere and this slows the circulation and initiate the coagulation cascade. In cerebral malaria this is the major event that occurs. In pregnant women, placental syncytiotrophoblast is a particularly vulnerable site for these changes.

Parasites can be demonstrated in variable numbers in the erythrocytes and tissues such as bone marrow, liver and spleen depending on the severity of infection. Fever develops when the parasite number reaches the threshold minimum and this is achieved by successive schizogony after the pre-erythrocytic phase. In *P. vivax*, all stages of the developing parasites are seen in peripheral blood. On the other hand only the ring forms and gametocytes of Pf are seen in peripheral blood except in severe infection. The growing stages of Pf adhere to the small blood vessels of vital organs and, therefore, in uncomplicated malaria the peripheral blood does not contain all the stages. The alteration in physical state of the erythrocyte leads to

stickiness of the red cells and their sludging in the microcirculation. Such erythrocytes, along with a large number of phagocyte cells, occlude the small blood vessels. Falciparum malaria causes significant mortality; the others do so only less commonly.

The virulence of *Pf* depends mainly on its capacity to induce erythrocytes to adhere to vascular endothelium and disrupt the blood flow. The changes in the parasitized erythrocytes include the following:

1. Visible change in shape
2. Reduced deformability leading to inability to negotiate the microcirculation
3. Formation of electron-dense protrusions (knobs)-consisting of Plasmodium falciparum erythrocyte membrane protein PfEMP-1
4. Expression of new sugar moieties on the surface
5. Presence of new metabolic channels.
6. Appearance of new parasite- specific antigens on the red cell membrane.
7. Reorganization of the normal components of RBC, expressed as surface antigens.

Cerebral Malaria

Of all pernicious forms, involvement of the central nervous system (CNS) is the most important life-threatening event that should be recognized early. Vivax malaria causes central and peripheral neuronal alterations only very rarely, whereas for *Pf* neuronal involvement is much more common so as to make the term “cerebral malaria” is almost synonymous with *Plasmodium falciparum* lesion. The two major pathological processes in cerebral malaria are:

1. Sequestration of parasitized erythrocytes and
2. Metabolic changes including hypoglycemia and acidosis.

In adults the former mechanism predominates, whereas in children the picture is a combination. There is increased expression of vascular and intercellular adhesion molecules and rise in tumour necrosis factor (TNF), interleukin-1, soluble thrombomodulin (sTM) and lymphotoxin. The clinical spectrum is related to the extent, site and duration of involvement.

Changes in Liver

Malarial hepatitis leads to predominantly conjugated hyperbilirubinemia, raised hepatic enzymes-(transaminases and lactic dehydrogenase) along with histopathological evidence of centrilobular hepatocellular necrosis, Kupffer's cell hyperplasia, malarial pigment deposition and hepatocyte congestion. Hemolysis which occurs as a consequence of rupture of red cells increases the hyperbilirubinemia. Fulminant hepatic necrosis, and hemolytic anemia can be fatal, unless recognized and managed early.

Blood

Anemia is a common complication of moderate and severe forms of malaria, both acute and chronic. Anemia is caused by;

1. direct destruction of erythrocytes by the parasites
2. immune-mediated hemolysis
3. partial suppression of bone marrow function caused by toxins and cytokines and
4. in some cases adverse effects of drugs. Anemia is worsened by co-existing nutritional deficiencies, parasitic diseases and sources of blood loss.

Co-infection with human immunodeficiency virus (HIV) and malaria increases the severity of both diseases.

Other organs: (Kidneys, lungs, peripheral nerves)

Abnormalities in parasitized erythrocytes result in changes in the microcirculation. In addition abnormal immune processes develop leading to changes in renal glomeruli and tubules, pulmonary alveoli and interstitium, intestines and other tissues. Both IgM and IgG antibodies are formed and these may persist for long periods. They do not confer absolute protection. Acute nephritic syndrome, nephrotic syndrome, hemolytic anemia, particularly **black water fever** and polyneuropathy are all mainly immune mediated. Nephrotic syndrome is more common in *P. malariae* infection. Depression of monocyte- macrophage phagocytic function predisposes to secondary bacterial infections.

Autopsy Changes

Enlargement of spleen and liver, bile staining of tissues and fibrosis due to deposition of malarial pigment and parenchymal and vascular changes in the brain and other organs constitute the main findings.

CLINICAL FEATURES

General Considerations

The immune status of the individual determines the clinical picture. The immunity is both humoral and cell-mediated. The classic picture develops in non-immunes. Manifestations are milder in semi-immunes. Maternal antibodies are passively transferred to the fetus and these persist for the first few months of life after which the infant becomes susceptible. Antibodies passed in mother's milk may have a mild protective role. In general, the normal placenta acts as an effective barrier against congenital transmission, though such transmission may occur in non-immunes.

Co-infection of HIV with *Pf.* malaria leads to greater viral load, possibly higher infectivity, and more rapid disease progress.

Vivax Malaria (Benign Tertian Malaria)

The incubation period in this infection ranges from 10 to 15 days which may be prolonged in subjects taking

antimalarial prophylaxis irregularly. The disease manifests with fever, headache, vague discomfort, aches and pains, nausea and vomiting, all of which may resemble other febrile illnesses. The pattern of fever does not show periodicity in the early phase of the illness.

After a week or two of the primary attack, periodicity gets established. The paroxysms occur in three stages-*cold stage, hot stage and sweating stage*. These stages are very characteristic of malaria.

The cold stage starts with the feeling of chills and rigor. The temperature shoots up to 40 °C or more, and the pulse is rapid. The skin is pale and cold.

The hot stage sets in 30-60 min. later with flushing of the skin, bounding pulse, severe headache and restlessness. Hyperpyrexia may occur in non-immunes. Herpes labialis is common. Sweating starts after 2 to 6 hours and this becomes profuse. Temperature rapidly comes down to normal, the pulse becomes slow and the patient goes to sleep, fully exhausted and dehydrated, to wake up fresh. These paroxysms repeat at an interval of 48 hours. This is the tertian periodicity-i.e. fever once in 3 days. The temperature is normal and the patient feels well in between the attacks. These paroxysms recur for about three months after which they subside even without treatment. Late relapses may occur even 2-3 years after leaving the endemic area. Liver and spleen become palpably enlarged after two weeks of illness. Vivax malaria is not usually fatal. The relapse may resemble the primary attack except for the fact that the typical periodicity is evident from the beginning.

Ovale tertian malaria is similar to vivax malaria, but the paroxysms may be milder.

FALCIPARUM MALARIA: (Malignant tertian malaria)

The incubation period ranges between 10-14 days. Prodromal symptoms like bodyache, headache, and vomiting may be more severe than those of vivax malaria. The disease starts either acutely or insidiously in the classical form with the three stages, or atypically. Unlike as in vivax malaria, the patient may not feel well in between the febrile paroxysms. The periodicity may be either quotidian (daily) or subtertian (less than 48 h). In some cases, the fever may be remittent or continuous when two groups of parasites develop simultaneously and sporulate on alternate days. The initial symptoms may be deceptively mild and fatal complications may set in unexpectedly at any time. When mixed infections with different species occur, symptoms due to *P. falciparum* predominate.

Rapid hemolysis may give rise to normocytic anemia. In severe cases hemoglobinuria may develop. In the majority of cases only ring forms and gametocytes are present in peripheral blood. Leukopenia, especially

neutropenia, is common. Pregnancy may result in abortion or premature labour.

Complications

Falciparum malaria is dreaded on account of the development of pernicious complications. Pernicious complications should be anticipated (1) when more than 5% of erythrocyte are parasitized (2) more than one parasite is seen in the same RBC and (3) the growing forms of the parasite are seen within erythrocytes in peripheral blood.

The pernicious complications of malaria include *cerebral malaria, malarial hyperpyrexia, gastrointestinal and hepatic forms, renal failure, algid malaria and black water fever*.

The WHO (1990) has stated that the occurrence of any one of the following clinical presentations would qualify for the term '**severe falciparum malaria**'.

1. Cerebral malaria
2. Severe anemia PCV < 15% or Hb < 5g/dL in the presence of parasitemia > 10000/uL
3. Renal failure-urine output < 480 mL/24 hours in adults or 12 mL/kg/24 hours in children and serum creatinine > 3 mg/dL
4. Pulmonary edema or respiratory distress syndrome
5. Hypoglycemia- whole blood glucose < 40 mg/dL
6. Shock –systolic BP < 50 mm Hg in children or < 70 mm Hg in adults
7. Spontaneous hemorrhage
8. Repeated generalized seizures
9. Acidosis-This is a marker of severe malaria
10. Hemoglobinuria

CEREBRAL MALARIA

Involvement of the central nervous system is the most severe presentation of falciparum malaria. This is invariably fatal if untreated. If recognized and treated early the mortality may still be upto 10%. Delay in treatment worsens the prognosis for mortality and morbidity. Clinical presentation depends on the site of maximal affection.

Predominant Features in Cerebral Malaria	
Site of Maximum Lesions	Clinical Presentation
1. Frontal Lobe	Organic brain syndrome
2. Cerebellum	Cerebellar disturbances
3. Pyramidal and /or extrapyramidal system	UMN lesions, or extra-pyramidal lesions
4. Cerebral blood vessels	Strokes
5. Brainstem	Brainstem syndromes
6. Spinal cord	Paraplegia, monoplegias
7. Spinal roots, peripheral nerves	Guillain-Barré syndrome, peripheral neuropathy
8. Meninges, subarachnoid bleed	Meningial syndrome

Onset may be sudden or subacute with changes in higher function, signs of meningitis or seizures. Affected patients may, all on a sudden, throw seizures followed by persistent coma. Subarachnoid bleed, retinal and intracerebral bleed, vasculopathy, or disseminated intravascular coagulation (DIC) are other forms of presentation. Presence of neck stiffness raised intracranial tension and cerebrospinal fluid alterations such as increase in protein, and lymphocytosis are common. Presence of features such as urticaria and disseminated intravascular coagulation (DIC) may suggest a clinical diagnosis of bacterial or other forms of meningo-encephalitis.

Neurological sequelae may develop in up to 10% of cases. These include hemiplegia, cranial nerve palsies, paraplegia, aphasia, extrapyramidal features, cerebellar dysfunction, peripheral neuritis, amyotrophic lateral sclerosis- like picture and psychoses.

Even though those complications accompany or follow the clinical picture of cerebral malaria in most cases, occasionally post malarial neurological complications may develop after full clinical recovery and parasite clearance. These include convulsions, cerebellar ataxia, tumour-like syndromes and psychoses. Retinal lesions include hemorrhage, pallor of optic disc, retinal vessel changes, papilledema, and cotton-wool patches. Retinal lesions may be associated with higher mortality. With clinical recovery, the retinal lesions also resolve and prognosis for vision is good. At times retinal lesions occur without clinical cerebral malaria.

Malarial hyperpyrexia: Hyperpyrexia (temperature 41°- 43°C) may develop and this may be mistaken for heat stroke.

Gastrointestinal Form

This manifests with severe nausea, vomiting, epigastric tenderness, hematemesis and diarrhea. In some cases, the stools are watery as in cholera, in others it is bloodstained as in dysentery. Some patients develop severe jaundice, hepatomegaly and a picture clinically resembling fulminant hepatic failure. This used to be known as *bilious remittent fever*. Death may occur due to dehydration, shock, acute renal failure or hepatic failure.

Renal Form

Clinically this may resemble acute glomerulonephritis or tubular necrosis, with all their associated consequences. Black water fever results from acute tubular necrosis.

Pulmonary Complications

These may develop uncommonly. When present they worsen the prognosis. These include non-cardiogenic pulmonary edema, aspiration pneumonia and respiratory

distress. These necessitate treatment on their own merits. Idiopathic pulmonary edema may occur without warning, sometimes during apparent recovery. If this is missed mortality may reach 50%.

Hypoglycemia

This occurs not infrequently and is missed unless particularly looked for. It may be spontaneous, occurring as part of the infection or hepatic involvement. Drugs like quinine also lead to hypoglycemia as an adverse effect. Non-recognition of hypoglycemia may increase mortality.

BLACK WATER FEVER (BWF)

This condition is only rarely reported at present. This is immune mediated intravascular hemolysis occurring in persons suffering from chronic *Pf* malaria. Intermittent and inadequate drug therapy with quinine or other suppressant drugs may trigger the hemolysis. Onset of hemolysis is sudden associated with, fever, rigor, rapidly developing anemia, jaundice and hemoglobinuria. In severe cases shock and acidosis supervene.

Urine contains hemoglobin and this accounts for the dark colour of urine which is indicated by the term *black water fever*. If untreated, many of them may die of renal and hepatic failure, severe anemia and secondary infection.

Malaria in Children

Manifestations of *Pf* malaria may differ in children (Table 64.3).

In non-immunes *P. falciparum* malaria carries a higher mortality than in partially immunes. Children are the more frequent victims. In them the poor prognostic factors are:

- 1. age below 3 years
- 2. deep coma
- 3. witnessed convulsions
- 4. absence of cortical reflexes
- 5. organ dysfunction—renal failure or pulmonary edema
- 6. retinal hemorrhage, and

TABLE 64.3

<i>Pf</i> malaria in children and adults		
Clinical feature	Children	Adults
Cough	Uncommon	Common
Convulsions	Common	Rare
Neurological sequelae	Common	Rare
Jaundice	Rare	Common
Pretreatment hypoglycemia	Common	Uncommon
Pulmonary edema	Rare	More frequent
Renal failure	Rare	More frequent

7. laboratory features such as signs of hyper infection, blood glucose below 40 mg/dL and blood urea nitrogen above 60 mg/dL.

Malaria in Pregnancy

Maternal death, abortion, still-birth and premature delivery are all common, so also low-birth weight babies. Both hypoglycemia and pulmonary edema are more frequent. Placenta is the site of preferential sequestration and development of malarial parasites. Congenital malaria in the newborn is a rare sequel. Early intensive treatment is mandatory for maternal and fetal recovery.

Atypical Features

In endemic areas, rarely atypical presentation may be encountered. These include

- 1. Mild non-characteristic fevers,
- 2. Chronic refractory anemia,
- 3. Presistant jaundice,
- 4. Neuro-psychiatric syndromes and
- 5. *Tropical splenomegaly syndrome*.

In meso-or hyper endemic areas, spleen may assume large sizes and such patients may manifest with pancytopenia or depression of one of the formed elements of blood. Thrombocytopenia may lead to hemorrhages, subcutaneous or visceral.

Course

Majority of cases vivax malaria recover without sequelae after suffering from the disease for varying periods which may extend for years, even if untreated. Due to the persistence of the exoerythrocytic cycle, *P. vivax* and *P.*

Fig. 64.2: PB slide Plasmodium falciparum malaria. Arrow points to parasite in RBC

ovale may give rise to relapses for prolonged periods. The longest relapses occur for *P. malariae*, caused by parasites lurking in the erythrocytes. In endemic areas re-infection has to be distinguished from relapses. Plasmodium falciparum is associated with higher mortality, variable clinical picture, unexpected deterioration and serious pernicious complications. Those who recover do so within a year if re-infection is avoided. In all cases the patients remain infective to others as long as they harbour the parasites.

DIAGNOSIS

Malaria should be considered in the differential diagnosis of fever in all tropical countries. Fever may be associated with severe headache, splenomegaly and or anemia. Examination of stained blood film is mandatory for diagnosis. Demonstration of the parasites in the peripheral blood confirms the diagnosis of infection. Examination of a properly stained blood film reveals parasites in most of the cases. Leishman’s, Wright’s, or Giemsa’s staining is usually done (Fig. 64.2 and Table 64.4). Thick smear

Morphological features of the different species of plasmodium				
	<i>P. vivax</i>	<i>P. falciparum</i>	<i>P. malariae</i>	<i>P. ovale</i>
Size of parasitized erythrocyte	Larger	Not larger	Normal size	Variable, the erythrocyte is often oval
Common stages present in peripheral blood	All stages gametocytes	Only rings and	All stages	All stages
Pigmentary change in erythrocyte	Schuffner’s dots seen in the erythrocyte outside the parasite	Maurer’s clefts	Nil	Schuffner’s dots
Number of merozoites in the schizont	8-16	12-24	6-12	8-12
Morphology of the rings	Thick and large	Fine rings-marginal forms (applique)*	Large coarse ring	Large ring
Multiple infection in erythrocyte	Nil	Present	Nil	Nil
Number of chromatin in the rings	One	One or two	One	One
Gametocyte	Oval or circular	Crescentic	Oval or circular	Oval or circular
* Applique forms of <i>P. falciparum</i> are the ring stages of the parasite attached along the margin of the erythrocyte.				

Fig. 64.3: (1) *P. vivax* and (2) *P. falciparum*. a. Ring form, b. Trophozoite, c. Schizont with merozoites, (rosette), d and e. Male female gametocytes (Diagrammatic)

examination may be required if parasites are scanty. Identification of morphological details is done in the thin blood smear. Prior administration of anti-malarial drugs reduces the number of circulating parasites within hours if they are sensitive and therefore they may not be readily visible in peripheral blood smears. Hence blood smear should be taken for microscopy before starting drug therapy. In any case therapy should not be delayed for want of definite diagnosis if the clinical suspicion is strong. Presence of only gametocytes indicates chronic infection without active malaria (Fig. 64.3).

Other Diagnostic Methods

Though properly stained smear microscopy remains the gold standard for the diagnosis of malaria, alternate rapid tests are becoming increasingly available. These include Para sight F test (Becton Dickinson, France) based on the detection of the HRP-2 antigen secreted by Pf and a test that detects parasite specific lactic dehydrogenase (PLDH). Use of fluorochrome stains and quantitative buffy coat (QBC) analysis gives higher positive rates. These tests are also reliable if properly done. Their availability is less and costs are higher.

Serological tests for malarial antibodies do not have value in the initial diagnosis and often do not differentiate between past and current infection. They may however, be valuable for community studies.

Differential Diagnosis

This includes all febrile conditions, other causes of jaundice, anemia splenomegaly, neurological syndromes, acute liver syndromes, and nephritis, in endemic areas and travelers who have visited endemic areas.

Drug Resistance

Prior to 1959 all species of parasites were susceptible to chloroquine which was the most widely used drug for all forms of malaria both uncomplicated and complicated forms. Resistance to chloroquine was demonstrated in *P. falciparum* in 1959 in Venezuela followed by observation in India and south east Asian countries. The parasite rapidly acquired resistance and the geographical distribution of resistant *P. falciparum* widened. At present in India in all states, Pf should be considered to be resistant to chloroquine unless proved otherwise. *P. vivax* is susceptible to chloroquine in the vast majority of cases (Table 64.5).

RI resistance is likely to be missed as patients are not usually observed for disappearance of parasitemia with the relief of symptoms. Patients with severe malaria,

TABLE 64.5		
Grading of chloroquine resistance of <i>P. falciparum</i> (WHO 1973)		
Recommended Response symbol		
Sensitive	S	Clearance of asexual parasitemia within 7 days of treatment without any recrudescence
Resistance (mild)	R1	Clearance of asexual parasites within 1 week but reappear within 28 days (7-28)
Resistance (moderate)	R2	Significant regression but no clearance
Resistance (severe)	R3	No marked reduction or increase, with persistent symptoms

pernicious forms and/or increasing parasitemia should be straight away put on alternate effective combinations of anti-malarial drugs without losing time for assessing resistance.

TREATMENT

This can be considered under three heads

1. Control of overt attack-by schizonticidal drugs
2. Treatment of complicated forms of *Pf* by combinations of specific drugs and supportive measures.
3. Eradication of infection from the patient in order to prevent relapse and also to stop transmission to others.

The anti-malarial drugs available freely in India are given below.

Schizonticidal drugs: These act on the erythrocyte forms of the parasite and help to terminate the clinical attack of malaria.

Chloroquine

This is a 4-aminoquinoline drug. It destroys the trophozoite forms of all species of the parasite very effectively. Dose is 600 mg of chloroquine base given as single dose oral, followed by 300 mg six hours later and 150 mg twice a day for two more days, making the total dose at 25 mg/kg over 3-4 days.

The tablet contains 250 mg of chloroquine diphosphate and it provides 150 mg of chloroquine base. Drug sensitive organisms rapidly disappear on administering chloroquine and the blood smear may become negative for the parasite within 24-36 hours. Though the acute attack will subside the parasites will not be eradicated.

Chloroquine phosphate is available freely at a low cost; it is safe and well tolerated. Adverse side effects include gastrointestinal upset, allergic reactions, psychosis, convulsions, photosensitization and ocular-toxicity on long term use. Chloroquine gets deposited in the cornea and retina. These lead to visual impairment. Funduscopy examination is needed at all follow up visits to make early diagnosis. Corneal lesions resolve on withdrawing chloroquine, whereas retinal lesions tend to progress.

Ocular-toxicity is a major contraindication for continuation of chloroquine therapy.

Chloroquine hydrochloride is available as 200 mg doses for IM and IV therapy. This is seldom used at present for therapy of pernicious malaria.

Chloroquine is the drug of choice for *P. vivax*, and drug sensitive *P. falciparum*. Since drug resistance is widespread in *Pf*, in any severe form of malaria chloroquine may not be readily effective and so the present trend is to use more reliable and definitely potent drugs and drug combinations.

There are reports that avoidance of chloroquine in different countries over long periods has led to disappearance of chloroquine resistance.

Amodiaquine which is also a 4- aminoquinoline is schizonticidal and effective in treating overt attack of malaria. Chloroquine resistant *Pf* may at times be sensitive to amodiaquine. This drug is only seldom used in India.

Quinine

This is the most time-tested schizonticidal alkaloid drug obtained from cinchona bark, (cinchona is grown in India). The preparation is quinine sulphate available as 325 mg tablets, given orally. The dose is 650 mg b.d for 10 days or more. Quinine is effective against all species of parasites and this is a good alternative for chloroquine. *Pf* is generally sensitive to quinine but in many areas partial resistance has developed.

Adverse side effects include its bitter taste, cinchonism (tinnitus, deafness, nausea, blurring of vision and restlessness), hypoglycemia, myocarditis and peripheral neuropathy. Quinine- induced hypoglycemia can be fatal if unrecognized.

Combination of quinine with ciprofloxacin 500 mg bd or tetracycline 250 mg qid helps to overcome partial resistance. It is the better to use alternate more effective drugs, such as artemisinin if the patient's condition is serious.

Quinine ethyl carbonate is also available as tablets. It is less bitter. Doses and actions are similar to quinine sulphate.

Quinine hydrochloride is available for IV use in vials containing 600 mg/mL. This is given in doses of 10 mg/kg bw as IV injection diluted in 5% glucose given slowly or as IV infusion over 20 minutes. This dose is repeated 8 hourly till the patient can accept oral medication. In severe falciparum infections a loading dose of 20 mg/kg bw may be given initially.

Adverse side effects include anaphylactic shock, severe hypoglycemia, reactions at site of injection, and others.

Quinidine which is related to quinine has anti-malarial properties. It is seldom used for this indication at present. Several other drugs were in use from time to time as schizonticidal drugs. Due to their weak actions, non-availability and variable efficacy due to development of resistance these are seldom used as primary drugs in an overt attack. These include proguanil, pyrimethamine, sulfadoxin, sulphalene, mefloquine, dapsone and others.

The antibiotics tetracycline, ciprofloxacin, macrolides and co-trimoxazole all have schizonticidal properties, especially effective when combined with drugs like quinine. These combinations can be used for chloroquine resistant *Pf*. from the beginning.

TABLE 64.6

Preparations of Qinghaosu derivatives			
	Dose	Route	Effect
1. Artemisinin	80 mg day 1, 40 mg on days 2-4	IM injection, oral or rectal	Schizonticidal on all species including <i>Pf</i>
2. Artesunate, an ester of artemisinin	120 mg day 1 60 mg/for 4 days	Oral, IM and rectal	Effective particularly used for cerebral malaria
3. Artemether methyl ether derivative of artemisinin	80 mg bd for 3 days	IV IM and oral	Same as above
4. Arteether	150 mg/ day for 3 days	I M	Same as above + gametocidal

Qinghaosu Derivatives

These are derived from the plant *Artemisia annua*, initially studied extensively in the People's Republic of China and their anti-plasmodium effect was demonstrated in 1979. The available preparations are given in Table 64.6.

They are powerful schizonticides which act rapidly. The target of their action is *Pf* ATP. They also possess gametocidal properties.

Contraindications include G-6 PD deficiency, immuno-suppressed states, and first trimester of pregnancy. Adverse side effects include gastrointestinal upsets, neutropenia minor ECG changes, first degree heart block and transient rise in liver enzymes.

In severe or pernicious forms of *Pf* the World Health Organisation (WHO) recommends a combination regimen containing an artemisinin derivative. Chloroquine resistant *Pf* often reveals resistance to other drugs including mefloquine and sulfadoxine-pyrimethamine (multi drug resistance). WHO recommends artemether + lumefantrine or mefloquine+ artesunate as the first line drug combination. Lumefantrine-artemether tablets contain 120 mg and 20 mg respectively. The course consists of a total of 16 tablets over 4-5 days.

Availability of artemisinin group of drugs has been a real advance in the management of cerebral and other forms of pernicious malaria.

Chloroquine, amodiaquine, sulphadoxine-pyrimethamine, all can be combined with artemisinin drugs.

Due to the risk of development of resistance to artemisinin it is better to avoid monotherapy with this groups of drugs.

Fansidar

It is a long acting sulfonamide drug. Each tablet contains 500 mg sulphadoxine and 25 mg pyrimethamine. It is schizonticidal with a half life of 100 hrs or more. It can be given as an adjunct to quinine for suppressive therapy. It is effective against resistant *Pf* malaria. 3 tablets are given as a single dose. *Pf* may develop resistance to Fansidar.

Metakelfin

This is also schizonticidal. It contains sulphalene 500 mg + pyrimethamine 25 mg. Action is similar to that of Fansidar. 2-3 tablets may be given as single dose against resistant *P. falciparum*

Mefloquine

This is a quinoline methanol compound structurally resembling quinine. It is available for oral use. It is effective against all species of parasites. Dose is 15-25 mg/kg bw up to a maximum of 1g twice day given at 6-hourly intervals. The half life is 14-40 days. Mefloquine should not be given simultaneously with quinine.

Lumefantrine

This is an aryl amino alcohol similar to quinine. It acts on the intra-erythrocytic forms of the parasites. Each tablet contains 120 mg of the drug. Dosage is 1 tablet initially followed by 2 tablets at 8 hours, 3 tablets at 24 hours and 4 tablets at 48 hours.

Halofantrine

This is a phenanthrene methanol compound, active against multi-drug resistant *Pf*. The drug has a long half- life (1.3-6.6 days). The dose is 8 mg base/kg bw for 3 doses. In non-immunes the drug has to be repeated after 15 days.

Causal Prophylactic Drug

Pyrimethamine: This is a time-honoured drug used for more than seven decades. It is a weak schizonticide. It inhibits development of the sexual cycle of the parasite in the mosquito. This unique action helps to interrupt the transmission of the disease by the vector and hence the name *causal prophylactic*. It is available as 25 mg tab for oral use.

Drug used for Eradication

Primaquine is the available drug- It is an 8- aminoquino-line- each tablet contains 2.5 or 7.5 mg given orally in a dose of 15 mg/day for 14 days. It eradicates the exo-

erythrocytic cycle in the liver. It is also a weak schizonticide. It has gametocidal action.

Due to its gametocidal action it is given for all species of parasites even though *Pf* has no well defined exo-erythrocytic cycle. Primaquine is given orally as a single dose of 45 mg for its gametocidal action on *Pf*. The drug is available with the governmental malaria offices for free supply. Primaquine is toxic. It causes methemoglobinemia and hemolysis in G-6-PD deficient individuals.

General Directions for Treatment

Since several drugs are available and the disease spectrum differs depending upon the species of parasite and immune status of the individual the treatment has to be individualized, even though general consensus is available.

Non-immunes have higher morbidity and mortality. Therefore they require more powerful drug combinations. Pernicious forms of *Pf* demand combination therapy, with full supportive treatment without any delay. Delay in treatment leads to higher mortality and residual disability.

Overt Attack of Malaria

Drug of choice: Chloroquine is the drug of choice if parasites are sensitive. Pregnancy is not a contra-indication for chloroquine.

If *Pf* is resistant to chloroquine, artesunate+any powerful schizonticidal drug should be used.

Pernicious Forms

This demands parenteral administration of quinine. Quinine can be given safely during pregnancy also.

If the organisms are resistant *Pf*, artesunate drugs are to be added. Later, oral administration can be instituted. Specific supportive measures should be added depending on the system involved.

Multi drug resistant Pf has to be treated with Artesunate/Quinine+antibiotics – ciprofloxacin, amoxycillin or tetracycline. *Pf* is developing resistance to artemisinin derivatives in areas where it is widely used. Hence these drugs have also to be used with caution.

Recent report on a comparative study of dihydroartemisinin-piperaquine combination with artesunate-mefloquine for treatment of multi-drug resistant *Pf* malaria in Myanmar showed that the former combination was an equally effective, but less expensive drug regimen (\$ 1.5 vs \$ 3.0). Success rates were the same irrespective of whether the drug administration was supervised, or not.

Dose administered

group (1) dihydroartemisinin 2.1 mg/kg bw and piperaquine 16.8 mg/kg bw daily oral for 3 days

group (2) mefloquine 25 mg base/kg bw single dose on day 1 and artesunate 4 mg/kg bw daily oral for 3 days

PREVENTION OF MALARIA

The departments of Health under the central and state governments have dedicated sections for control of malaria. Under the direction and technical and monetary help from the WHO, UNICEF, UNDP, World Bank and several other non governmental funding agencies including Bill and Melinda Gates Foundation, there are global efforts for control of the major infectious diseases- malaria, tuberculosis and AIDS in several countries- mainly African countries. India is also a beneficiary. The main thrust is on making available effective drugs, research on drug resistance of parasites, diagnosis, provision of preventive strategies such as insecticide-treated nets, interrupting transmission by the vector and development of anti-malaria vaccine. Already vaccines are at the stages of field trial. It is advisable that all doctors take the recommendation of the department of health in their areas, about the drug combinations, provision for supply of free medicines and epidemiological information available locally.

Reduction of malarial endemicity depends on the following strategies

1. Treatment of cases and eradication of the reservoir
2. Anti-vector measures
3. Individual protection by insecticide impregnated sleeping nets
4. Patient education on malaria and its prevention

Drug Prophylaxis

Drug prophylaxis is essential for the following categories of persons to prevent malarial infection.

1. Visitors including tourists entering malarious areas
2. All pregnant women in endemic areas
3. Patients having organ failure and risk of renal failure.

Drug Schedule

- a. If the prevalent *Pf* parasite is chloroquine sensitive: chloroquine 300 mg/oral once a week-start the drug one week prior to entry into the area and continue for 4 weeks after leaving the area.
- b. Area endemic for chloroquine resistant *Pf*: mefloquine 250 mg base once a week to be started 3 weeks earlier to entry and continued for 4 weeks after leaving the area.

Alternate schedule. Chloroquine 300 mg/week + doxycycline 100 mg/day.

To be started 2 days prior to entry and continued for 4 weeks after leaving the area (Table 64.7).

Note: Anti-malarial drugs available in the Indian market

TABLE 64.7

Special antimalarial drugs available in India			
Drug preparations	Manufacturer	Name of preparation	Formulation
Artesunate	Cadila Lab	Falcigo	Tablets 100 mg
	IPCA	LARIAGO	Tablets 100 mg
	"	"	IV or IM vials
Artemether	IPCA	LARITHER	120 mg/vial
			Injections IV.IM.

			capsules 40 mg.
	THEMIS	E-mal	150 mg oil-based
	chemicals		preparation /for
			deep IM injection;
Proguanil	IPCA Lab	Laveran	100 mg tablets
Primaquine	IPCA Lab	MALARID	7.5 and 15 mg tab
Fansidar	IPCA Lab	LARIDOX	500 mg +
		Pyralfin	pyremethamine 25 mg
Mefloquine	INFAS	MEFLOTAS	250 mg tab

Chloroquine and quinine are available freely, being produced by several drug manufacturers.

Leishmaniasis

V.P. Gopinathan, K.V. Krishna Das

GENERAL CONSIDERATIONS

Infection by the protozoan parasite of the genus *Leishmania* causes leishmaniasis. This may take several forms. In India, the infection is prevalent in almost all states sporadically. In the northern states it occurs in endemic and epidemic forms. The main clinical presentations seen in India are visceral leishmaniasis (kala-azar), post kala-azar dermal leishmaniasis and the primary cutaneous forms — tropical sore; known by different names. India contains 70% of the global burden of visceral leishmaniasis WHO has categorized leishmaniasis as a category 1 disease (i.e.) emerging and uncontrolled.

The parasite affects mainly the reticuloendothelial organs and the related endothelial cells primarily. Several vertebrate species may be affected by leishmania. In India, humans form the main reservoir of infection. In the Mediterranean areas, Africa and America other animals also harbour the parasites.

- a. *L. donovani* is the main species that causes visceral (VL) and post kala-azar dermal leishmaniasis in India. In other countries other species also produce the disease.
- b. *L. tropica*, *L. major*, *L. aethiopica* that cause oriental sore the primary cutaneous form
- c. *L. amazonensis* - Mucosal form,

All these species are morphologically similar but not immunologically. The parasite exists in two forms

- i. amastigote form, oval or rounded and nonmotile present in reticuloendothelial cells and
- ii. promastigote leptomonad or flagellate form seen in the vector – phlebotomus sand flies in which they develop and become infective in 7 days (Figs 64.6 to 64.9).

Visceral Leishmaniasis (VL)

Syn: Kala-azar

This is a prolonged febrile illness associated with progressive emaciation, anemia and hepatosplenomegaly caused by *Leishmania donovani* which parasitises the reticuloendothelial cells in the spleen, liver, bone marrow and other viscera. This disease has been in existence in India for centuries causing endemics and epidemics from time to time in the northern states. The disease exists in a smaller scale in several pockets in India and has been reported from almost all states including Kerala. The name **kala-azar** (black fever) is derived from the dark

Fig. 64.4: Kala-azar situation in India

pigmentation that develops in the victims of visceral leishmaniasis. The parasite (L.D body) was discovered in 1903 simultaneously by Leishman in England and Donovan in Chennai. Recent work has shown that *L.tropica* may also produce visceral leishmaniasis occasionally.

Epidemiology

Though VL is endemic in more than 60 countries, most of the symptomatic visceral disease (> 90 %) is reported in rural areas of India, Nepal, Bangladesh, Brazil and Sudan, other African countries, Mediterranean countries, S. America and China. Rural surroundings and poverty favour the transmission of the disease. Contributory factors include:

- Altitude below 700 m
- High rainfall and humidity
- Alluvial soil
- Abundant vegetation and
- Rural settings

The previous decade witnessed a severe outbreak of visceral leishmaniasis in Bihar and the neighbouring states, which caused heavy mortality and morbidity.

With an organized centrally sponsored control program launched in endemic areas (1990-91), the disease declined at the rate of 70% annually. By 2003, deaths also could be reduced considerably by improved registration, follow up and intensified treatment strategy. At present the disease is more prevalent in Bihar and north eastern states where resistance to conventional pentavalent antimony compounds is reported to be about 60%, requiring other drugs for treatment (Fig. 64.4).

In the Mediterranean region, infants and children are almost exclusively affected. In other endemic areas including India, though the disease is more frequent in children and young people, older age groups are also susceptible. Males are affected more than females. Conditions which favour the multiplication of the main vector sandfly in India -*Phlebotomus argentipes*- and the presence of susceptible population determine the endemicity. Sand flies bite their victim during sleep. Over 20 species of sand flies can transmit the parasite in other parts of the world. Only female sand flies act as vectors. In India, kala-azar is a disease of humans and animal reservoirs are not reported. In other endemic areas dogs, raposa (a fox-like mammal) and rodents harbour the parasite. These form a natural reservoir from which man is infected. The parasites circulate in blood engulfed by macrophages and these are taken up by vector sandflies which suck blood and transmit them to others during their bites.

Transmission

Amastigotes of *L. donovani* reach the stomach of sandflies along with the blood meal. The parasite develops into the

flagellate leptomonad forms in the midgut of the vector. Within 5-7 days the organisms multiply heavily and extend anteriorly to the proboscis. During subsequent bites the promastigotes in its proboscis and pharynx are introduced into the bite wound. In the dermis the promastigotes become amastigotes and these are taken up by the macrophages. The parasite multiplies in the cytoplasm of the macrophages and when the host cells rupture, they are liberated into the tissue spaces. These are taken up by other macrophages and further proliferation occurs. Foci of parasitic multiplication consisting of parasitized macrophages, histiocytes and lymphocytes are formed. The parasitized macrophages pass into the circulation to reach several organs and develop further.

Pathology

The parasites *Leishmania donovani*, known commonly as Leishman-Donovan bodies (LD bodies) are the amastigote forms, which are found within the cytoplasm of macrophages and other RE cells, in the affected tissues and within monocytes and neutrophils in circulation. Maximum affection is in spleen, liver and bone marrow. In the Indian cases lymph nodes are less commonly involved. Most conspicuous changes are seen in the spleen, the liver and the bone marrow. The spleen is moderately enlarged and soft in an average case, but occasionally it may become very large and firm. Splenic infarcts and perisplenitis may occur in very chronic cases. Malpighian corpuscles are atrophic, macrophages containing LD bodies are seen in large numbers in the splenic pulp. Plasma cells, histiocytes and lymphocytes are seen in large numbers in the lesions. Extramedullary hematopoiesis may develop at times.

The liver is enlarged, pale, and shows fatty changes. Histology shows the Kupffer cells distended with LD bodies, vascular congestion and fatty change in the hepatocytes. The portal tracts show cellular infiltration and parasitized macrophages.

The bone marrow becomes hyperplastic. Yellow marrow in the shafts of long bones is replaced by cellular red marrow. Parasitized macrophages are seen in large numbers in the RE cells. Plasma cells may be increased. At times the lymph nodes, adrenal cortex and the intestinal mucosa may show parasites within macrophages. Lymph node involvement is more characteristic of the African and Mediterranean varieties.

Immunological Changes

In general cell mediated immunity (CMI) is impaired, especially so in those with malnutrition. Specific IgM and IgG antibodies are produced. These are not protective. Cellular immunity, dependent on T-lymphocyte is protective. With the production of gamma interferons (γ -IFN) and proliferation of natural killer cells immunity

Fig. 64.5: Patients with advance kala-azar— note the gross splenohepatomegaly and emaciation—adult 26 years

develops whereas TH2 lymphocytes producing interleukin 4 (IL-4) and interleukin 10 (IL-10) induce susceptibility. Even in cases which have been clinically cured, the parasite may still persist in vacuoles in the cytoplasm. Co-infection with HIV further lowers the CMI. It returns to normal with successful therapy.

CLINICAL FEATURES

There is wide variability in the clinical spectrum, depending on the host's immunity. Many cases may remain subclinical even while harbouring the parasites. The incubation period is usually 2-6 months and the onset may be insidious as in typhoid or abrupt as in malaria. Initially the disease may resemble typhoid fever, malaria or tuberculosis. Pyrexia and apyrexia may alternate for 2-3 weeks and fever may show double spikes on many days. This double spike of temperature is very suggestive diagnostically.

Progressive hepatosplenomegaly and anemia develop. Despite pyrexial spells, patients continue to feel 'well' without recognizing the fever. They may be having good appetite. The spleen and liver enlarge slowly and steadily, spleen reaching even upto right iliac fossa. These organs are usually non-tender. Mild or moderate lymphadenopathy may occur (Fig. 64.5).

As the disease progresses, weight loss, anemia (normocytic or microcytic), abdominal distension, and skin pigmentation develop. Emaciation, thin dry lusterless and brittle hair, dry rough skin, pigmentation around the face, pedal edema and bleeding tendency are late characteristic features. Death is due to bleeding, malnutrition and or intercurrent infection.

Fig. 64.6: *Leishmania donovani*—Leishmanial form (LD body) seen *in vivo* in man—general morphology (diagram)

Laboratory Investigations

Diagnosis is established by the demonstration of LD bodies in the bone marrow, splenic pulp, or lymph node aspirate. Marrow and splenic material are diagnostic in more than 95% of cases. Less commonly, an experienced observer may detect LD bodies in blood monocytes and neutrophils. LD bodies appear as oval or round 2-4 μ intracytoplasmic bodies. They have blue cytoplasm, pinkish red or violet nuclear structures, and rod like kinetoplast. In the majority of cases due to rupture of the macrophages during preparation of the slide, they are seen outside the cells (Fig. 64.7).

Associated features are leukopenia, thrombocytopenia, anemia, reversal of serum albumin globulin ratio and raised alkaline phosphatase. Features of hepatic dysfunction appear in advanced cases. The protein alterations are rise serum IgG and IgM with lowering of C3 complement levels. Reduction of eosinophils in peripheral blood was considered to be suggestive of the diagnosis of kala-azar.

Napier's aldelyde test is a simple bed side test which has been in vogue for more than seven decades. Though it lacks specificity, the ease with which it can be done in almost all hospitals, especially in rural settings may be a

Fig. 64.7: *Leishmania donovani* in macrophages and outside cells (diagram)

Fig. 64.8: Leishmaniasis-leptomonad form seen *in vitro* cultures and in the vector—diagram. Note (1) nucleus (2) kinetoplast (3) flagellum

Fig. 64.9: Bone marrow smear LD bodies ($\times 1000$)

reason to employ this test in endemic areas even at present. Two drops of commercial formalin (formaldelyde 40%) is added to 1 mL of patients' serum. In a positive test, the serum becomes opaque, solid and white within 1 hour to 24 hours, depending upon the rate of positivity.

Culture of organism *Leishmania* can be grown in NNN medium using bone marrow or splenic aspirate material.

Direct agglutination tests using the antigen prepared by Harith et al has been found to be 100% sensitive and specific in early cases.

Ref: Jha TK et al JI. Ass Phys India 449.1996.

Anti – K 39 antibody demonstrable by a strip test is a very reliable diagnostic test in kala-azar and post-kala-azar dermal leishmaniasis. This can be done as a ready-to-use immuno chromatographic strip test which has been developed. In the Bihar epidemic this test using finger prick blood has been found to be extremely useful, giving positive results within five minutes and with specificity reaching 90-100 %, thereby enabling diagnosis early in the disease under field conditions.

Molecular Tests

Identification of the parasite DNA by PCR from blood or material collected from local lesions is a very reliable confirmatory test, available in advanced laboratories.

Skin test – leishmanin test of Montenegro has been used to elicit delayed hypersensitivity. It is negative in active kala-azar and PKDL, while it is positive in the primary cutaneous form. With the treatment of kala-azar and

recovery, the test becomes positive, indicating recovery of immunological function as well.

Diagnosis – Any chronic pyrexial disease associated with splenohepatomegaly occurring in an endemic area should raise the possibility of visceral leishmaniasis. Sporadic cases have been reported from all parts of the country, including a pocket in Trichur District of Kerala.

Differential Diagnosis

All chronic prolonged febrile illnesses and conditions producing hepatosplenomegaly enter the differential diagnosis. Important among these are enteric fever, malaria, acute military tuberculosis, brucellosis, septicemia, acute leukemias, and lymphoma. In India many places are endemic for malaria and leishmaniasis and these infections may co-exist.

Course and Prognosis

Untreated, the majority of patients suffer from chronic, recurrent febrile episodes, they undergo wasting and 70-80% die. Complications such as pneumonia, dysentery, hemorrhage, septicemia, *cancrum oris* and *noma* may develop and prove fatal. Co-infection with human immunodeficiency virus complicates the picture further.

Management

It is broadly divided into specific, supportive and symptomatic measures. Supportive treatment includes improvement of nutrition, treatment of concurrent infections and in selected cases, blood transfusion.

Specific therapy – The specific drugs are the time-honoured pentavalent antimonials and aromatic diamidines, still used in areas where the parasite is sensitive. These drugs are effective and relatively cheap giving cure rates up to 95%. Pentavalent antimonial drugs in common use are sodium stibogluconate, (Solustibostan, Stibatin and Pentostam) and methyl-1- glucamine antimoniate (Glucantime). Among the aromatic diamidines, pentamidine isethionate is more freely available and hence more commonly used in India. Other drugs include amphotericin B, paromomycin and miltefosine which are all highly effective even against resistant organisms.

Sodium stibogluconate is given as daily intramuscular injections initially in a dose of 5 mg/kg and increased up to 20 mg/kg for upto 28 days. Children and infants tolerate only lower doses. The drug is given under close medical supervision. Only up to a maximum of 300 mg /day for children and 200 mg /day for infants is given. Side effects are not infrequent. These include unpleasant and rarely life-threatening adverse effects such as sudden death,

cough, chest pain, abdominal colic, pain in the arms, vomiting, faintness and collapse. After a few injections allergic reactions may develop. Cardio - and hepatotoxicity, leukopenia, and thrombocytopenia may develop later. Delayed hypersensitivity reactions include fever, arthralgia and vague ill health. *In the Bihar epidemic only 30-40% of cases where sensitive to antimonials and therefore other drugs had to be employed.*

Pentamidine isethionate is available for IM or IV injection in doses up to a maximum of 3-4 mg/kg/bw daily or at longer intervals for 20-30 days. The full dose is reached after smaller test doses. Anaphylactic reactions may occur and resuscitative measures should be available at hand. Adverse side effects include nausea, diarrhea, vomiting, hyperglycemia and cardiotoxicity. A temporary diabetic state may occur in a few.

Other Drugs

More effective and safer drugs have been introduced though they are considerably more expensive. These include amphotericin-B, paromomycin, miltefosine and gamma interferon.

Amphotericin-B or its lipid formulation has been used with cure rates above 93%. The initial dose is 1 mg/kg bw given IV diluted in saline. The dose is gradually increased upto 2 mg/kg bw the total dose not exceeding 20 mg/kg bw over twenty days.

Liposomal amphotericin B: has been employed in doses of 1-3 mg/kg bw IV for 5 days. It gives better cure rates (90-100 %). As an alternative a single dose of 5-7.5 mg/kg bw given IV has been employed with 90% success rates. Adverse side effects include allergic reactions, anemia, hypokalemia, azotemia and others.

Paromomycin sulphate is an aminoglycoside which is less expensive and with only mild toxicity. It is given IV/1M in doses of 15-20 mg/kg for 21 days. It gives a cure rate of 93-97%. Adverse effects include ototoxicity infrequently, and local reaction at the injection site.

Miltefosine (Hexadecyl phosphocholine)

An oral drug, miltefosine has been developed with 98% cure rate. Adults are given 100 mg (50 mg 2 caps) daily for 28 days. Children are given the drug at a dose 2.5 mg/kg. Cure rates reach up to 100%. It is avoided in pregnancy, being teratogenic in experimental animals. Adverse side effects include nausea, vomiting, diarrhea, increase in liver enzymes and rise in serum creatinine.

Recombinant gamma interferon (γ - IFN) when given in a dose of 100 mg/m² body surface along with antimonials may improve immunity, and restore susceptibility of the parasite. It may reduce the incidence of future recrudescence.

Targeted delivery of drugs: Incorporation of antimonials or diamidines into liposomes help to increase the concentration of the drug at the local sites and to deliver higher doses to the phagosomes of the infected macrophages which contain the parasites. The therapeutic activity increases several folds even upto 700 times that of the parent drug, without increase in toxicity. Cure rates are much higher and duration of treatment is less.

The final word on the optimal management of visceral leishmaniasis is not available yet, considerable work is going on towards this goal. Availability of miltefosine has rendered the treatment of kala-azar simple and highly effective.

Results with Treatment

Successful treatment abolishes the fever in 2-4 weeks, the spleen becomes impalpable in three weeks, and anemia and leukopenia improve. Relapses may occur, usually within six months of apparent relief. Remission for periods exceeding six months indicate cure. Parasitological cure can be confirmed by appropriate tests. In many cases parasite may still remain dormant in the macrophages subclinically. This is not an indication for continuous therapy.

Prevention

Problems in the control and the spread of leishmaniasis are 1. prevalence of the vector, 2. resistance to pentavalent antimony, cost and the side effects of drugs, the inherent tendency for recrudescence, and 3. co-infection with HIV. Early detection of asymptomatic infection with the use of anti k 39 antibody by immunochromatographic strip test has helped early diagnosis. Use of insecticide (pyrethroid) impregnated bed nets (with narrow mesh < 25 holes/cm²), spraying of houses with insecticide, treatment of those with post kala-azar dermal leishmaniasis and regular follow up of treated groups form the essence of control programmes. Insecticide impregnated nets have to be repeatedly re-charged with insecticide. Nets with incorporated insecticide are effective for their life-time.

Prophylactic vaccines are not available yet.

POST-KALA-AZAR DERMAL LEISHMANIASIS

Syn: PKDL-Dermal Leishmanoid of Brahmachari

Definition

It is a chronic granuloma of the skin caused by *Leishmania donovani* following recovery from kala-azar. Maximum number of cases have been described from India and Bangladesh. In other endemic regions PKDL is rare or absent.

Etiology

PKDL develops as a sequel in 5-10% of cases of kala-azar, usually manifests 6 months to 5 years after apparent

cure. There is breakdown of cell-mediated immunity in the host so that the parasites in the dermis are not eliminated even after the visceral disease has been suppressed by chemotherapy or natural resistance.

Pathology

The lesions consist of granulomas in the dermis made up of parasitized macrophages, lymphocytes and plasma cells. The lesions do not ulcerate.

Clinical Features

Hypopigmented macules: Macular or erythematous lesions develop which are hypopigmented and flush with the surface, varying in size from pinpoint to large patches. These may involve the whole body leaving the regions of the belt, axillae and neck unaffected. The face, extensor surface of the limbs and lateral parts of the back show predilection. The whole face, and in rare instances the whole body may be affected.

Nodular lesions are commonly seen on the chin, other parts of the face except the ears, trunk, limbs, genitals and rarely the mucous membrane of the tongue and lips. Occasionally large tumour-like masses may appear on the face, limbs and trunk. The majority of cases of PKDL show more than one type of lesion. Constitutional disturbances are not present.

Laboratory Features and Diagnosis

Serum antileishmanial antibodies can be detected with standardized and sensitive assays. Diagnosis is confirmed by demonstrating LD bodies in the “slit and scrape material” obtained from the skin lesions, and stained by Leishman’s stain. Further, *L. donovani* may be grown in NNN medium from material aspirated from the nodules. The flagellate form (promastigote) is readily demonstrable after 7-10 days of incubation. PCR studies on material obtained from local lesions also give confirmatory evidence.

Differential Diagnosis

PKDL has to be differentiated from lepromatous leprosy, leucoderma, pityriasis versicolor, dermatitis, lupus erythematosus and neurofibromatosis.

Treatment

It responds to pentavalent antimonials as in the case of kala-azar. Three to four courses may be required.

Prognosis

If left as such, the lesions progressively worsen, and heal with heavy scarring. Cosmetic deformity results. With treatment, 50% clear completely and others may show

considerable improvement. Nodules and erythema readily respond, but the hypopigmented macules are more resistant.

CUTANEOUS LEISHMANIASIS

Cutaneous leishmaniasis is primary infection of the skin caused by direct inoculation of the parasites at the site of lesions by the appropriate vector sand flies. These are seen both in the old world and the new world. In India and the neighbouring countries the parasites are mainly *L. tropica* and *L. major*. In the American varieties the parasites are the *L. mexicana* species complex and the viannia sub-genus including *L. (V) braziliensis*. The parasites remain at the site of the ulcers or nodules, without causing systemic invasion, since cell mediated immunity is high.

Generally, the lesions are localized. They may be entirely cutaneous, e.g. oriental sore or mucosal, e.g. viannia sub-group. Diffuse cutaneous lesions may occur, e.g. *L. aethiopica* and *L. mexicana* complex species in other regions. Man and animal reservoirs such as gerbil provide the source of infection. Infection produces substantial immunity and, therefore, adults show resistance, whereas most of the victims are children. At the site of inoculation of pro-mastigotes lesions develop leading to granulomatous ulcers which are indolent and very chronic existing for several months to years. They are known by various synonyms such as *oriental sore*, *Delhi boil*, *Baghdad boil*, and others.

Oriental sore is a chronic granulomatous lesion of the skin and subcutaneous tissue which ulcerates to form an indolent ulcer. It is caused mainly by *L. tropica* and *L. major*.

The disease is present in the western part of India, Pakistan, Afghanistan, Iran, Iraq, the whole of Arabia, Egypt, Mediterranean region, coastal states of Africa, Sudan, Ethiopia, Niger, and asian parts of Russia.

The vectors are female sandflies belonging to several species in different areas. In India and Pakistan *Phlebotomus papatasi* is the main vector. Local lesion develops with the formation of a granulomatous ulcer. The organism remains at the ulcer site and can be demonstrated in imprint smears or aspirated material.

Clinical Features

Two patterns are seen. In the desert and semi-desert regions, the lesions are moist and tend to ulcerate early and the incubation period is 1-6 weeks. In the urban type, ulcerations is late and the lesions tend to be dry. In this form the incubation is prolonged to 8-24 weeks.

The ulcers are multiple and occur on exposed parts such as face, ears, extremities and the trunk. Early lesions start as itchy papules which enlarge to form nodules and ulcerate to form circular ulcers with clear cut margins.

The ulcers are covered with thin adherent scabs. Regional lymph nodes may enlarge due to spread. Bacterial infection supervenes in due course. The ulcers heal spontaneously in about six months to one year and produce deep scarring and depigmentation.

Diagnosis

In persons living in endemic areas and in those who have recently visited such areas the characteristic lesion should suggest the diagnosis. Other ulcerating lesions such as lupus vulgaris, leprosy, syphilis and rodent ulcer have to be differentiated. The organism can be demonstrated in smears made from scrapings of ulcer margin or in the tissue obtained for biopsy from the depth of the ulcer. The organism can be cultured in NNN medium from material obtained from the lesion.

Treatment

Local treatment is indicated when the sores are only a few. This consists of infiltration of the ulcer base by sodium stibogluconate 100 mg/mL solution. Infiltration is done at intervals of 3-4 days repeatedly and all the lesions heal by repeated sessions. A single small sore may heal with a single infiltration but larger sores heal only with 3-6 infiltrations. Oral drugs such as ketoconazole, 200-400 mg oral daily and itraconazole 100-200 mg oral daily are effective. Paramomycin, when applied as a local ointment gives relief in many cases. When the lesions are numerous or not easily accessible to infiltration therapy, systemic administration of sodium stibogluconate or methyl glucamine antimoniate is resorted to. The lesions heal with one or two courses of injections.

Prevention

Oriental sore can be prevented by adopting anti - sandfly measures, but these are difficult to implement under desert and semi-desert conditions. An ingenious method adopted by natives is to introduce the infective material in an area which is concealed. Natural immunity occurs when this lesion heals and further ulcers do not develop.

Vaccines against leishmania are being developed in several laboratories in India. Results are awaited.

American Cutaneous and Mucocutaneous Leishmaniasis

Syn: Espundiasis

Cutaneous and mucocutaneous leishmaniasis is prevalent in many countries of central and south America from Mexico to northern Argentina with the exception of Chile. The causative organisms are species of Viannic subgenus, especially *L. braziliensis* and *L. mexicana*. These different species show difference in isoenzyme patterns. They are not common in India.

Other Forms of Jungle Leishmaniasis

Several locally occurring forms of mucocutaneous leishmaniasis have been described in jungle regions lying between latitudes 22°N and 30°S. The causative organisms are species of viannia subgroups especially *L. braziliensis* and *L. mexicana*. They produce destructive lesions in the nasopharynx and nose leading to perforation of the nasal septum leading to deformity and disfigurement.

Lesions resemble those of oriental sore histologically. The organisms cause zoonoses among various species of rodents and are transmitted to man by sand flies. *Leishmania mexicana* leads to ulceration of the pinna of the ear and other exposed parts and this is known as “**chicleros ulcer**”, seen in persons who go into forests to collect gum. The pinna may be destroyed over several years.

African Trypanosomiasis

Syn: Sleeping Sickness

K.V. Krishna Das, V.P. Gopinathan

African trypanosomiasis or sleeping sickness is caused by two subspecies of *Trypanosoma brucei*, *T. gambiense* and *T. rhodesiense*. These hemoprotezoa are transmitted by the bite of infected tsetse flies (*Glossina*).

Geographic distribution: *Trypanosoma brucei gambiense* is found in West Africa, Congo, Southern Sudan and Uganda. *Trypanosoma brucei rhodesiense* is found in Central and Eastern Africa. Endemicity is closely related to the distribution of the vector tsetse flies and the reservoir hosts. The disease is not present in India.

Trypanosomes are hemoflagellates seen as actively motile spindle shaped organisms in peripheral blood. In Leishman stained preparations trypanosomes measure $14-33 \times 1.5-3.5$ microns. They possess a central nucleus and a kinetoplast situated near the posterior end. A flagellum arises from the blepharoplast situated close to the kinetoplast and passes forwards along the free margin of the undulating membrane and becomes a free flagellum protruding forward from the anterior end. Trypanosomes are seen actively moving in the plasma in fresh preparations. *Trypanosoma gambiense* and *Trypanosoma rhodesiense* are morphologically similar, but the latter is more virulent in laboratory animals (Figs 64.10 and 64.11).

Incidence

20,000 to 30,000 people are infected by Trypanosomes each year.

Transmission

The vectors are mainly *Glossina palpalis* (*G. fuscipes*) and *G. tachinoides* for *Trypanosoma gambiense* and *G. morsitans*, *G. pallidipes* and *G. swynnertonii* for

Fig. 64.10: Trypanosomes—General morphology. Note the nucleus (1), kinetoplast (2), undulating membrane (3) and the flagellum (4)

Fig. 64.11: Trypanosomes in peripheral blood
1. *T. cruzi*, 2. *T. gambiense*

Trypanosoma rhodesiense. Both sexes of tsetse flies suck blood and transmit the disease. They live for 2-5 months.

T. gambiense* and *T. rhodesiense are a widespread parasites of several herbivorous animals in endemic areas and these form the reservoir. Humans form the major reservoir for *T. gambiense* and animals form the major reservoir for *T. rhodesiense*.

Tsetse flies get infected by feeding on infected animals or man. The parasites multiply in the gut of the fly and pass anteriorly to the proventriculus and the salivary glands. The infective metacyclic forms develop and multiply there further and pass into the proboscis after 3-7 weeks. The fly remains infective for its life. The metacyclic forms are introduced into the host during the next bite. The metacyclic forms transform into trypanosomes within 48 hours and multiply in the tissue space. Ultimately, they pass to lymph nodes and the blood stream and then reach several organs.

Pathology

Lymph nodes and the central nervous system (CNS) show maximal lesions. There is localized or generalized lymph node enlargement. The nodes are congested and show hemorrhagic areas which contain trypanosomes. Later, these undergo fibrosis. In liver, Kupffer cell hyperplasia occurs with portal infiltration, but clinical hepatosplenomegaly is rare. Pancarditis occurs because of extensive cellular infiltration and fibrosis.

Affected organs show infiltration of the blood vessels by monocytes, macrophages and plasma cells causing endarteritis. This increases vascular permeability.

In the CNS the main lesion is leptomeningitis seen over the brain and spinal cord. Histologically there is perivascular cuffing with lymphocytes and plasma cells. Later, trypanosomes invade the brain tissue, particularly the frontal lobe, pons and medulla. Parasites are seen in the cerebrospinal fluid during the meningitic stage. Other changes include rise in pressure, moderate rise in protein and lymphocytosis. Complement-mediated hemolytic anemia may develop in some. IgM class antibodies are demonstrable in the serum and CSF.

Clinical Features

The incubation period varies from one to three weeks. Though the symptoms of *T. gambiense* and *T. rhodesiense* infections are broadly similar, the rhodesian type is usually more severe and runs a more acute course with a higher mortality. The initial lesion is the formation of a painless nodule at the site of bite (*trypanosomal chancre* or *trypanids*). This nodule occurs 5-15 days after the bite. *Trypanosomes* are seen in this lesion. Irregular fever and parasitemia occur within (1-2) weeks. Lymphadenopathy occurs usually after 3 weeks of the bite. Cervical, femoral and axillary groups of lymph nodes enlarge. Lymph nodes are more pronounced in the posterior triangle of the neck in *T. gambiense* infection. Enlargement of these groups of lymph nodes is called "*Winterbottom's sign*". The spleen is often enlarged. Anemia develops in due course due to slow inanition and hemolysis. Fever, lymphadenitis, anemia and debility continue for several months.

The CNS involvement is late in the gambian type while symptoms of the CNS involvement develop within a few months in the rhodesian type. The whole course runs over 2-3 years, but the course is shorter in the rhodesian type and death may occur in 6-9 months.

Several unusual manifestations may develop. These include circinate erythematous skin rashes, localized edema over the face, eyelids and neck, ulnar hyperaesthesia (Kerandel's sign) neuralgic pains, formication, myocarditis, pericardial effusion and jaundice. The sleeping sickness stage sets in when the parasites enter the CNS. The debility and languor increase, the gait becomes slow, shuffling and swaying, the speech becomes slurred, and tremors of the tongue and lips develop. The patient may become demented. Mask-like vacant expression, drooping of eyelids, tendency to fall asleep during day time and restlessness at night are all seen in endemic areas. The patient becomes severely emaciated and serious complications like pneumonia, dysentery, hyperpyrexia, convulsions and coma may supervene and prove fatal. Though untreated cases of sleeping sickness are generally fatal, the gambian type may recover spontaneously at times (Table 64.6).

TABLE 64.6

Comparison of disease caused by *T. Brucei gambiense* and *T. Brucei rhodesiense*

	<i>T.B. gambiense</i>	<i>T.B. rhodesiense</i>
Disease produced	Gambian sleeping sickness	Rhodesian sleeping sickness
Distribution	West and central Africa	East Africa
Vector	Glossina palpalis or tachinoides (riverine tsetse)	Glossina morsitans (Savanna tsetse)
Reservoir	Humans and domestic animals	Wild animals
Course	Slow—months to years. Less acute course	More rapid—up to one year. More acute course
CNS symptoms	More characteristic	Less marked
Results with treatment	Good	Not satisfactory
Chemoprophylaxis	Useful	Not reliable

Diagnosis

History of residence in an endemic area, irregular fever, enlargement of cervical lymph nodes and hepatosplenomegaly should point to this diagnosis. Trypanosomes are demonstrable in peripheral blood, lymph node aspirate and cerebrospinal fluid. Serological Tests such as indirect fluorescent antibody test and ELISA are helpful. Newer tests based on proteomics signature analysis are available. These are more specific and reliable for diagnosis and follow-up.

Drug Treatment

Early cases limited to blood and lymph nodes respond to suramin which is a derivative of urea. Dose is 20 mg/kg bw given IV as a 10% solution on days – 1, 3, 7, 14 and 21. the drug is nephrotoxic. Anaphylactic reaction may develop.

Late cases with neurological involvement respond to melarsoprol (Mel – B) which is a trivalent arsenical, combined with BAL (British anti lewisite). The drug has to be administered under supervision due to adverse side effects. The drug is quite effective in curing even late cases with neurological involvement. Resistance of the parasite to arsenicals may develop. Other drugs which are also effective include difluoromethyl ornithine (efflornithine) given in a dose of 200–400 mg/kg bw daily IV for 4 weeks and nitrofurazone given in a dose of 10 mg/kg given 8h orally for 10 days. With treatment, clinical and parasitological clearance occurs even in late cases. Patients should be watched for 2 years to ensure cure.

Prevention

Anti –tsetse fly measures including proper clothing and insect repellent creams (Di -meepol or diethyl benzamide and elimination of the reservoir hosts are effective. Drug prophylaxis with suramin or pentamidine are also available.

American Trypanosomiasis

Syn: Chagas Disease

K.V. Krishna Das, V.P. Gopinathan

GENERAL CONSIDERATIONS

The Brazilian Physician – Carlos R. J. Chagas discovered *Trypanosoma cruzi* in 1909. Chagas disease is caused by *Trypanosoma cruzi* (schizotrypanum) which is transmitted by species of reduvid bugs to man. It is seen in all countries of central and south America (Fig. 64.11).

Trypanosoma cruzi is a broad trypanosome about 20 µ in length and is C-shaped. The motile stage of the parasite is found only for a short period after infection. It soon develops into the leishmanial form that multiplies in the cells of mesenchymal origin. Reduvid bugs of the genera *Triatoma*, *Rhodinus*, and *Eratyrus* are the principal vectors. These bugs inhabit the floor and walls of rural houses. These come out at night and suck blood from the sleeping inhabitants. During the blood meal they defecate (Fig. 64.12). Reservoir hosts are formed by dogs, cats, opossums and armadillos. Reduvid bugs are infected by taking blood meal and in 6-15 days infective metacyclic forms are passed in feces. Organisms enter the body when the feces is smeared on to the bite wound. Other methods of transmission also exist. Infected mothers can transmit the disease to the fetus, giving rise to congenital Chagas disease. Spontaneous abortion may occur in many, but 2-5% of babies may manifest infection at birth.

Other vehicles for transmission of infection are blood or donated organs from infected individuals. Migration of population has led to introduction of this disease into several parts of the world which were free.

Fig. 64.12: Reduvid bug

Incidence

An estimated 16 -18 million people are infected in 18 Latin American countries. Chagas disease results in 45,000 to 50,000 deaths per year. Major cause of death is cardiac involvement. This disease is not reported from India.

Pathology

At the site of inoculation, the organisms multiply and produce a local lesion-Chagoma. They are seen in the blood stream for a short period. They are taken up by macrophages later. *Trypanosoma cruzi* multiplies and produces focal lesions in the cardiac and skeletal muscles and neuroglia. Cardiomyopathy develops as a result of cardiac involvement. From the foci of multiplication active trypanosomes enter the blood stream and are demonstrable.

Granulomatous lesions occur in the spleen, liver and lymph nodes. CNS involvement in children leads to meningoencephalomyelitis. Chronic Chagas disease manifests several years or decades later in 10-30% of cases. The direct effect of the parasite as well as immunological processes account for the late results. Common presentation is as cardiomyopathy. Pathological changes include biventricular enlargement, thinning of ventricular walls, apical aneurysm, mural thrombi and varying degrees of heart block. Parts of the alimentary tract are also affected.

In the esophagus and colon dilatation occurs giving a picture of acquired achalasia cardia and megacolon seen. The alimentary lesions are due to destruction of the Auerbach's plexus.

CLINICAL FEATURES

In children *Chagas disease* occurs in an acute form, presenting with fever, rash. without itching, and the rash clears in several days. Symptoms of the acute phase may also include malaise, myalgia, headache, asthenia, and anorexia. Mortality in the acute phase, is low (<5%) and it is due to acute myocarditis and/or meningoencephalitis, Children younger than 2 years suffer more.

Chagoma (furunculoid and peeling cutaneous lesion) which is nodular occurs at sites of entry of the parasite through the skin, generalized lymphadenopathy, myocarditis and rarely meningoencephalitis develop. The Romaña sign develops in 20-50% of cases in which the route of entry is through the conjunctiva. It is a painless, periophthalmic, unilateral edema of both palpebral conjunctiva, frequently accompanied by conjunctivitis and local lymph node enlargement. It persists for 30-60 days. The manifestations of the acute disease resolve spontaneously within 3-8 weeks in approximately 90% of individuals who are infected.

They enter the chronic, latent or indeterminate asymptomatic phase of the disease. A direct progression from the acute phase to the symptomatic chronic form of Chagas disease occurs in fewer than 5% of patients. In the chronic type cardiomyopathy and achalasia cardia and atonic dilation of the colon and the small intestine are seen. Approximately two thirds of cases develop cardiac manifestations leading to arrhythmias, cardiac failure, thromboembolic phenomena, and sudden death. In the endemic areas of south and central America Cardiomyopathy due to Chagas disease used to be a common cause of cardiovascular death among patients aged 30-50 years.

Involvement of the gastrointestinal tract leads to megaesophagus and/or megacolon in approximately one third of chronic cases, these chronic lesions do not resolve spontaneously.

Diagnosis

Direct microscopic examination of blood smears will demonstrate rapid movements of live *T. cruzi*. Quantitative Buffy coat also can be done for demonstration of parasite. Immunological tests such as detection of *T. cruzi* specific antibodies, indirect hemagglutination test, immunofluorescence and ELISA are also available. PCR test has been developed to demonstrate the parasite antigen.

ECG may show arrhythmias, heart block especially RBB and block of the anterior branch of the bundle of His.

Affection of the other systems can be demonstrated by appropriate tests.

Treatment

In acute phase, Benznidazole is the drug of choice. Benznidazole (Rochagan) is given as an oral dose of 6 mg/kg for 30-60 days. This has to be given under supervision. Primaquine has been found useful in a dose of 15 mg daily for about 6 months in acute Chagas disease. At present Nifurtimox (Lampit) a nitrofurantoin, is available for oral use. The dosage is 8-10 mg/kg/day for adults and 15-20 mg/kg/day for children and the drug has to be administered for 120 days. Cure rates of 80% in acute and 90% in chronic cases have been claimed. The drug is toxic and hence has to be given under supervision. Permanent lesions occurring in others organ systems demand management on their own merits.

Posaconazole which is a systemic antifungal agent shows promise as an anti *T. Cruzi* drug.

Control

Improvement in housing and sanitation, and use of insecticides limit the spread of the reduvid bugs. Treatment of active cases and attention to the animal reservoir reduce the reservoir pool.

Balantidiasis 386

Toxoplasmosis 387

Cryptosporidiosis 389

Amebiasis

GENERAL CONSIDERATIONS

Fedor Aleksandrovich Losch in Russia first described amoebiasis in 1875. The term amebiasis includes all lesions caused by infection by the protozoan parasite *Entameba histolytica*. These amebae cause ulcerative lesions in the large intestine causing dysentery and from there they spread to several organs to produce necrotic lesions. There is a great tendency for the intestinal infection to become chronic and persistent for long periods. *E.dispar* is morphologically identical to *E. histolytica*, but nonpathogenic. It is genetically different. It is a commnsal. However, *E. histolytica* can also remain in the bowel for many years without causing major symptoms.

Amebiasis is worldwide in distribution, but it is very prevalent in tropical climates. In many parts of India, the infection rate used to be as high as 40 to 50%. Chronic carrier state, poverty, insanitary disposal of excreta, unhygienic food handling, and proliferation of flies are responsible for this high prevalence. Though all age groups are susceptible, adults suffer more often.

Due to the wide prevalence of intestinal parasitism and want of full information on the prevalence of other chronic gastrointestinal disorders such as irritable bowel syndrome and motility disorders there was a general tendency to overestimate the prevalence of intestinal amebiasis. In areas where the environmental sanitation has improved and the use latrines is popular the prevalence of amebiasis has considerably fallen. Intestinal endoscopic studies done in many institutions reveal that at present amebic lesions are relatively less common.

Parasitology

Amebae are widely distributed in nature. The common pathogen is *E. histolytica*. It exists in two forms—the *cyst* and the *trophozoite*. The cysts are round or oval in shape and measure 10 to 15 μ in diameter. In iodine-stained preparations the cysts show one, two or four nuclei depending on their maturity. Cysts resist adverse environment. In addition to the nucleus, one or more rod-like structures called chromidial bars, and a glycogen mass are also seen. Cysts are formed in the bowel when the environment becomes unfavorable for the trophozoite and are then passed out in feces. Cysts are responsible for transmission of the disease from person to person. The vegetative form (trophozoite) is actively motile by the aid of pseudopodia. It measures 20 to 50 μ in diameter. Invasive trophozoites are identified by the presence of ingested erythrocytes within them. Amebae multiply by binary fission. The trophozoite is the invasive form and is responsible for all lesions. A large number of trophozoites is seen in the feces of dysenteric patients. Trophozoites and cysts occur in the feces of carriers. Outside the body, the trophozoites survive only for an hour or so. Normal gastric juice destroys them in the stomach. Cysts survive external environment for long periods.

Transmission

Humans are the only reservoir for *E.histolytica*. Cysts are passed in the feces of cases and carriers. These are ingested along with food or water. Cysts resist acid

digestion in the stomach. Excystation occurs in the intestines, Trophozoites develop from cysts and they establish themselves in the colon, feeding on the bacteria and desquamated epithelial cells. They multiply by binary fission. These non-invasive forms may persist for long periods without producing any symptoms. Under favourable conditions these become invasive.

PATHOLOGY

Intestinal amebiasis: The invasive trophozoites adhere to colonic mucosa with the help of specific lectins and ulcerate the mucous membrane and penetrate deep into the submucosal layers of the colon. The basic pathological process is a lytic necrosis of tissue. This is due to an extra cellular cysteine kinase enzyme causing proteolytic destruction of the tissue, producing flask shaped ulcers. *E. histolytica* which produce lytic enzymes kills host cells which come into contact with them. The host cells become immobile on contact with *E. histolytica*, and the cells die. *E. histolytica* can also induce apoptosis in host cells. The cellular response consists of mononuclears and a few polymorphs. Amebae are seen in the invading margins of the lesions. Cecum, ascending and descending colon, and rectum are the sites of predilection. The appendix may be involved. The terminal ileum may be affected rarely. The ulcers have undermined edges and are covered by dense yellow or brown slough. The mucous membrane between ulcers is healthy. Ulceration may extend to blood vessels causing severe hemorrhage at times. Perforation of the bowel may occur, but it is rare. Sometimes **ameboma** or amebic granuloma develop due to repeated infection by ameba and bacterial pathogens. The acute inflammatory process has a tendency to subside spontaneously. In many patients chronic infection persists with microscopic lesions which harbour *E. histolytica* for many years. The lesions may heal in a few cases. Persistence of the chronic lesions accounts for the carrier state.

E. histolytica infection is associated with transient immunosuppression. Activated macrophages form the major defence against invasive amebae. Tumour necrosis factor (TNF) which is a cytokine derived from macrophages has parastical properties. The resistance against invasive amebiasis is mainly cell mediated immunity .

Extra-intestinal Lesions

Amebic liver abscess: Invasive amebae reach the liver through the portal blood stream from the colon which is the primary seat of infection. In the liver they multiply and cause colliquative necrosis of liver cells to produce abscess. Possibly malnutrition, alcoholism and consequent immunosuppression favour the development of liver abscess. Unlike pyogenic abscess, the wall of the amebic abscess is made up of necrotic and compressed liver tissue

and it is devoid of granulation tissue. Active amebae are found near the expanding margins. The pus is made up of necrotic tissue which shows amorphous material and erythrocytes. It is sterile on culture. In most cases the colour of the pus is reddish brown or chocolate. Amebae are seen only rarely in the pus aspirated from the center of the abscess, they are more often demonstrable in the pus aspirated from near the walls on subsequent occasions. The site of the abscess is more commonly the right lobe. It is usually single and may attain very large size. The abscess may enlarge progressively and spread by contiguity to the chest wall, colon, diaphragm, pleura, and pericardial cavities. Amebic abscess does not impair hepatic-function significantly. Jaundice is generally mild or absent, but pressure over a major hepatic duct can give rise to obstructive jaundice. On aspirating the pus the liver tissue comes into apposition and complete healing occurs without structural damage or fibrosis.

During acute amebic dysentery, the liver may enlarge as a result of diffuse inflammation caused by the products of inflammation of the colonic tissue and bacteria reaching the liver in the blood stream. The hepatic lesion clears up with cure of the dysentery. This lesion should not be mistaken for liver abscess.

Other foci for embolic lesions include the lungs, brain, spleen and other tissues. Direct invasion of the skin by active vegetative amebae leads to extensive spreading necrotic ulceration-cutaneous amebiasis.

CLINICAL MANIFESTATIONS

The incubation period varies from a few weeks to months.

Spectrum of illnesses caused by E. histolytica

Intestinal amebiasis

1. Asymptomatic infection
2. Symptomatic non-invasive infection
3. Acute proctocolitis (Dysentery)
4. Toxic megacolon
5. Chronic non dysenteric colitis
6. Ameboma
7. Peri anal ulcers

Extra intestinal amebiasis

1. Liver Absces
2. Pleuro -Pulmonary involvement
3. Pericarditis
4. Peritonitis
5. Brain abscess
6. Genito urinary disease

ACUTE AMEBIC DYSENTERY

This presents with sudden or subacute onset of lower abdominal pain and diarrhea with blood and mucus in stools. The frequency ranges from 3 to 10 in a day. At times watery diarrhea with large amounts of blood and

mucus may occur. Constitutional symptoms are mild and these include low grade fever and vague discomfort. Palpation of the abdomen reveals colonic tenderness and mild hepatomegaly. The feces is semisolid or liquid, showing fecal matter mixed with blood and mucus. Microscopic examination shows erythrocytes, a smaller number of leukocytes and trophozoites of *E. histolytica*. In the majority of cases, the condition subsides after several weeks even without treatment, to exacerbate again with dietary irregularity, psychological stress or other factors. Complications are rare but in a few cases extensive destruction of mucosa and submucosa may lead to severe hemorrhage and occasionally perforation. Rectal prolapse, intussusception and colonic stricture may develop in some. **Amebomas** may develop in the cecum or other parts of the colon and these may be mistaken for tumours. These resolve completely with specific treatment.

Non-dysenteric Amebiasis

This is a common mode of presentation in endemic areas. The condition starts insidiously with abdominal discomfort, flatulence, intermittent diarrhea with constipation, and the presence of mucus in stools. Asymptomatic intervals and periods of dyspepsia alternate for many months or years. Vague general symptoms like feverishness, mild depression, fear and anxiety may be prominent. Physical examination may reveal palpable tender cecum and sigmoid and sometimes tender hepatomegaly. An amebic granuloma (*ameboma*) may be felt as a sausage-shaped mass in the right iliac fossa and this may be mistaken for malignancy or tuberculosis. Mucosal ulcers may be seen on sigmoidoscopy. Examination of the mucus collected by sigmoidoscopy may show the active trophozoites. Repeated examination of fresh stool or sigmoidoscopic specimen may be necessary to establish the diagnosis. Sigmoidoscopic biopsy reveals the ulceration and the parasite in the mucosa.

HEPATIC AMEBIASIS

Hepatic involvement used to be very common, almost all patients give a history of alcoholism. Around 50% of patients suffering from hepatic amebiasis give history of dysentery. Liver involvement manifests as insidious onset of pain in the right hypochondrium or right lower chest with fever, chills and sweating. Loss of weight and anemia may be pronounced. In the early stage the liver is enlarged as a whole. The pathological process is not inflammatory, but it consists of multiple necrotic lesions caused by amebae diffusely distributed in the liver. In this stage the organ is enlarged as a whole and it is acutely tender. This stage may persist for varying periods and may resolve either spontaneously or with treatment, without

proceeding to abscess formation. At present the occurrence of liver complications has come down.

In those in whom abscess develops, the liver is considerably enlarged and tender. When the abscess spreads to the abdominal wall, there is superficial edema and severe local tenderness. The majority of liver abscesses are in the right lobe. Left lobe lesions are palpable over the epigastrium. Diaphragmatic involvement causes pleuritic pain in the right lower chest. Physical examination reveals diminished air entry, impaired percussion note and crepitations over the lower part of the right chest. Jaundice is rare. Blood shows mild to moderate leukocytosis (about 12-14.000/cmm) with polymorphonuclear cells dominating the field. The ESR is usually high. Fluoroscopy reveals elevation of the right dome of the diaphragm and diminished movement. Ultrasound, CT scan and isotopic scanning help to locate the site of the abscess.

Complications of liver abscess include rupture into neighbouring organs or cavities leading to peritonitis, right sided empyema, bronchohepatic fistula, and pericarditis. Untreated, the mortality may go up to 10%.

Cutaneous amebiasis occurs over the genitalia, perianal region, opening of sinuses and around colostomy wounds. Rarely metastatic lesions from the liver develop in the lungs and brain. Rupture of a liver abscess into the peritoneum causes the clinical picture of an acute abdominal emergency with shock.

Differential Diagnosis

Amebic dysentery has to be differentiated from bacillary dysentery, ulcerative colitis and tuberculous enterocolitis. Ameboma may closely resemble carcinoma. Chronic intestinal amebiasis may be mistaken for irritable bowel syndrome, diverticulitis, neurasthenia or malabsorption state. Hepatic amebiasis is a common cause of prolonged fever in the tropics and when liver enlargement and tenderness are not marked, it resembles enteric fevers, brucellosis or tuberculosis.

In an endemic area, enlargement and tenderness of the liver should suggest the diagnosis of amebic liver abscess. Other conditions such as alcoholic liver disease, primary and secondary tumours of the liver, subdiaphragmatic abscess and pyogenic liver abscess have to be differentiated. In case of doubt the diagnosis is confirmed by ultrasonography and later, aspiration. Prompt response to antiamebic drugs is a point suggesting a diagnosis of hepatic amebiasis.

Laboratory Diagnosis

Examination of the feces – Fresh stool examination by light microscopy invariably reveals *E. histolytica* in dysentery. Active *E. histolytica* shows characteristic ameboid movement and ingested erythrocytes. In chronic amebic colitis cysts are present in feces in varying numbers. These can be identified in saline preparations

Fig. 65.1: *Entameba histolytica* in stools (diagram)

1. Trophozoite (vegetative motile form) with ingested erythrocytes
2. Uni- and bi-nucleated cysts
3. Chromatoid bars and glycogen vacuole
4. Mature cyst with four nuclei

but cellular details are better demonstrable in iodine stained specimen. Unlike bacterial dysentery, the feces does not contain innumerable leukocytes. Plenty of erythrocytes are present. Stool occult blood may be present in invasive intestinal disease. Stool enzyme immunoassay also will be useful (Figs 65.1 and 65.2).

E. histolytica has to be distinguished from the non-pathogenic *Entameba coli* by the following features.

	<i>E. histolytica</i>	<i>E. coli</i>
Saline wet smear		
1. Movement	Progressive	Non-
2. Ingested RBC	Present	Nil
Iodine stained preparation		
Nuclear Chromatin	Central	Eccentric
Number of nuclei in the cyst	1 or 4	1,2 upto 8
Chromidial bars	Short and thick	Filamentous

Apart from feces, vegetative *E. histolytica* can be demonstrated in the following specimen.

1. Liver abscess pus.
2. Sputum in pulmonary amebiasis.
3. Discharge from cutaneous amebiasis.

Serological tests – These tests are mainly used in extraintestinal disease. Indirect hemagglutination antibody test is positive in 95% of extraintestinal and 70% of intestinal amebiasis. Other tests also have been developed. Indirect immunofluorescence is positive in more than 60%

Fig. 65.2: *Entameba coli* in stools (diagram)

1. Trophozoite
- 2, 3 and 4. Uni-, bi- and quadrinucleate cysts with glycogen vacuole and chromidial bars
5. Mature cyst with eight nuclei

of cases. Countercurrent electrophoresis and agar gel diffusion are other methods employed.

Imaging studies: ultrasonography – A single lesion in the posterosuperior aspect of the right lobe of the liver is commonly seen. But, multiple abscesses may also occur in some patients. Deep seated abscess may be missed on clinical evaluation. Multiple abscesses should suggest the possibility of pyemic etiology.

CT scan – In cerebral amebiasis, CT may show irregular lesions without surrounding capsule or enhancement.

Other investigations – Blood counts may show mild anemia, leucocytosis, elevated ESR and elevated alkaline phosphatase.

Endoscopy – Rectosigmoidoscopy and colonoscopy may reveal small mucosal ulcers covered with yellowish exudates, and the intervening mucosa appears normal. For demonstrating vegetative amebae the fresh mucus exudates should be examined as a saline preparation, microscopically.

In chronic intestinal amebiasis the feces show amoebic cysts, when the disease is quiescent. With acute exacerbation, trophozoites appear from time to time. Charcot-Leyden crystals may be seen as a result of chronic bleeding foci. These crystals are needle shaped, refractile, and are made up of lysophospholipase.

TREATMENT OF AMEBIASIS

Drug treatment consists of amebicidal drugs. These may act on the parasites found in the lumen of the gut or on the invasive forms seen in the tissues. They are grouped as luminal amebicides and tissue amebicides. Some drugs, however, have action on both sites.

The most effective amebicides in current use are given in the following table.

1. Metronidazole 400 mg 3 times/day orally for 10 days (or) 800 mg tds for 5 days.
2. Tinidazole 600 mg 2 times daily for 5 days orally
3. Diloxanide furoate 500 mg 3 times daily for 10 days
4. Chloroquine 500 mg 2 times daily for 2 days
250 mg BD for 2–3 weeks

1. **Metronidazole:** This drug has effect on both trophozoites and cysts. It is well-absorbed after an oral dose to produce adequate tissue levels. It is effective for the treatment of acute and chronic intestinal amebiasis and in hepatic amebiasis. In severe cases the drug can be used intravenously in a dose of 500 mg twice a day as an infusion. Though side effects are not serious, they are common. These include distaste in the mouth, anorexia, nausea, abdominal discomfort, vertigo, dizziness and ataxia. Peripheral neuropathy may develop rarely. The drug is generally avoided during pregnancy on account of its possible teratogenic effects in laboratory animals.

2. **Tinidazole:** This drug belongs to the group of nitroimidazole derivatives, structurally related to metronidazole. The therapeutic spectrum is similar to metronidazole, but the drug is more potent, it is also better tolerated.

* Newer drugs in this group with more prolonged action are being introduced, e.g., Secnidazol 2 g single dose for intestinal amebiasis and 1.5 g as a single daily dose for five days for hepatic amebiasis.

3. **Diloxanide furoate:** It is a safe drug effective only on the intestinal forms of the parasite. It is used in the treatment of acute and chronic intestinal lesions in doses of 500 mg tds oral for 10 days. In amebic dysentery, the symptoms subside in 5-7 days. In chronic intestinal amebiasis clearance rates approximate 80-90%.

4. **Chloroquine:** It has amebicidal properties in hepatic lesions. This is brought about by the high tissue concentration of the drug obtained in the liver. It is effective in the treatment of hepatic amebiasis along with metronidazole or tinidazole. It has no action on the trophozoites or cysts in the intestine.

Acute amebic dysentery: Metronidazole, which produces symptomatic relief in 3-5 days, is the drug of choice. General management consists of the treatment of fluid and electrolyte imbalance, especially potassium loss. The diet should be soft, low residue type with high caloric value. After the full course of treatment, stool examination should be done to ensure parasitological cure.

Chronic intestinal amebiasis: When symptoms are mild and chronic, metronidazole or diloxanide furoate are the

drugs of choice. A single course may bring about parasitological cure in 80-90% cases. Repeated courses are required to completely eliminate the infection in most cases. Even with repeated courses some cases may prove to be resistant.

Hepatic amebiasis: Metronidazole and chloroquine are administered in full doses. During the acute phase metronidazole 500 mg infused IV twice a day till the pain and tenderness subside and then followed up by oral dosage is ideal. Addition of chloroquine is optional. Large abscesses should be aspirated 2-3 days after starting drug therapy.

Aspiration should be done at the site of maximum tenderness or edema of the chest wall. Ultrasonography helps to locate the exact site of the abscess for aspiration. Since there is no granulation tissue to wall off the cavity in amebic liver abscess, needle aspiration is adequate to remove the pus and favour healing. Most of the cases clear up with two to three aspirations. Emergency aspiration has to be done if the abscess threatens to rupture or has just ruptured. In case of left lobe abscesses aspiration under ultrasonographic guidance may be necessary to achieve full drainage.

The main complications of aspiration are hemorrhage, vasomotor collapse and introduction of infection into the cavity. Secondary infection should be treated with full doses of broad spectrum antibiotics. In uncomplicated liver abscess the pus is chocolate coloured or yellow, odorless, sterile and does not show predominance of pus cells on microscopy. When the abscess is infected the pus is yellow or greenish, foul smelling and microscopic examination shows predominance of pus cells. Gram staining and culture help in demonstrating the organisms. Small liver abscesses may resolve with medical treatment even without aspiration. In all cases of hepatic amebiasis a course of intestinal amebicides should be given to prevent relapse of the hepatic lesions and to clear the carrier state.

Other lesions: Amebic lesions of the brain, lung and skin respond to a course of metronidazole or tinidazole.

Dehydroemetine is indicated if the response is unsatisfactory. The dose is 60 mg/day by IM injection. The drug is toxic particularly causing myocarditis. A course should not exceed a cumulative dose of 600-900 mg. The drug is seldom used now.

Resumption of alcohol intake predisposes to relapse of liver abscess.

Asymptomatic cyst passers: It is advisable to treat them with metronidazole to avoid the risk of future hepatic amebiasis and to eradicate the carrier state. A full course of metronidazole or tinidazole given for 5-10 days clears 80% of cases. Repeated courses are needed for better results. Diloxanide furoate, either singly or in combination with metronidazole can also be employed with success.

Results of treatment: Both acute and chronic intestinal amebiasis respond satisfactorily to drug therapy. In endemic regions reinfection is quite common, unless proper hygienic measures are instituted. Complications like gut perforation and amebic peritonitis carry a high mortality if treatment is delayed. Prompt supportive measures and therapy with antiamebic drugs and antibiotics considerably improve the outlook. Mortality due to liver abscess is about 10% if the condition is not diagnosed and treated in time. Prompt treatment gives very satisfactory results. The liver recovers completely without residual damage. Amebic abscess of the brain clears up with specific therapy and other symptomatic measures, but it is fatal if missed.

Prevention: The most important steps are to observe food hygiene, provide safe drinking water and arrange for sanitary disposal of human excreta. Ordinary chlorination of drinking water does not kill the cysts. Cooks and food handlers should be periodically examined and the infection eradicated. Fruits and vegetables can be rendered safe by washing with soap and peeling off the skin wherever possible.

Primary Amebic Meningoencephalitis

K.V. Krishna Das

General Considerations

Some species of free-living soil amebae of the genus *Naegleria* may produce primary amebic meningoencephalitis, which is a rapidly fatal disease. The organisms are carried in the nose and throat to asymptomatic carriers. It is seen worldwide, occurring sporadically. The disease is present in India.

Naegleria gruberi is the common pathogen. The genus *Hartmanella* (syn: *Acanthamoeba*) can also affect man. In most of the cases a history of swimming or bathing in contaminated water may be obtained. The organisms enter through the roof of the nose and spread up the cribriform plate to reach the subarachnoid space. The brain is edematous and covered by a blood stained purulent exudate, especially in the basal cisterns. Amebae are also seen invading the grey matter.

Clinical Features

The incubation period is 2-14 days after a possible exposure. The clinical picture resembles acute meningitis. The CSF is under tension and it is turbid or blood stained. Microscopy shows erythrocytes, numerous polymorphs and motile amebae containing ingested erythrocytes which may be mistaken for macrophages. The species of ameba can be identified by suitable staining. CT scan shows generalized cerebral edema with increased vascularity in post-contrast study suggestive of meningitis.

Azithromycin in the dose of 7.5 mg/kg/day for 5 days has been tried with partial success. Amebic meningoencephalitis is associated with high mortality within 2-5 days. Present treatment is not fully satisfactory. In addition to meningoencephalitis occasionally granulomatous amebic encephalitis may develop. This is caused by *Acanthamoeba* species and *Balamuthia mandrillaris*, particularly in immunocompromised subjects.

Treatment

Amphotericin B given intravenously in a dose of 0.25 mg/kg daily for 8 days is partially effective against *Naegleria*. The drug can also be given intrathecally in a dose of 0.5 mg diluted in 5 mL of CSF, thrice a week.

Acanthamebae (*Hartmanella*) are free-living amebae seen in soil and water. These become pathogenic to immunocompromised hosts. They gain entry through the nasal mucosa, abrasions on the skin or eyes. Pathogenicity is similar to that of *Naegleria*.

Further reading: Tungikar SL et al. Primary amebic meningoencephalitis JAPI 2006; 34: 327-9.

Giardiasis

K.V. Krishna Das

Giardiasis is infection of the small intestine by the flagellate protozoon—*Giardia intestinalis* (*G. lamblia*). In the tropics and subtropics, this parasite is very widely prevalent, particularly in children.

Giardia lamblia is a flat pear-shaped organism 12-18µ in diameter with eight flagella, two nuclei and a large ventral sucker placed anteriorly. These flagellates are found in large numbers in the duodenum and jejunum in between the villi, and attached to them by their suckers. Occasionally biopsy specimens may show *giardia* between villi. With the aid of the flagella, giardia moves actively and this helps to identify the organisms in fresh stools or duodenal aspirates. Cysts are formed which are passed in feces (Fig. 65.3).

Transmission occurs by ingesting the cysts along with food and water. Infection rates are high in closed communities. New immigrants and travellers may get the infection from endemic areas. Hypochlorhydria and hypogammaglobulinemia predispose to heavy infection.

Pathogenesis

Though the exact mechanism is not known, it is possible that a large number of flagellates adhering to the mucosal surface may reduce the area for absorption. In addition, irritation of the brush border of the villi, alteration in bacterial flora in the small intestine; and invasion of the submucosa have been suggested as contributing factors. Many cases show increased intestinal motility.

Fig. 65.3: *Giardia lamblia* seen in stools (diagram)

1. Actively motile form
2. Cyst

Clinical Features

Presenting symptoms range from mild abdominal discomfort to explosive diarrhea. Some infections may be asymptomatic but the majority are subacute or chronic. Nonspecific symptoms include failure to thrive, abdominal pain, epigastric distress, intermittent diarrhea and general ill-health. Features of malabsorption may occur, especially in children and this should suggest the possibility of giardiasis.

In some outbreaks explosive diarrhea with watery foul smelling stool may be the presenting symptom. Giardiasis is a frequent cause for traveller's diarrhea in endemic regions. The acute attack lasts for 3-4 days but in children the course may be prolonged for weeks or months and it results in malabsorption state. Many cases go into spontaneous remission and carrier state develops in them.

Diagnosis

Giardiasis is a common cause of diarrhea in children and vague abdominal discomfort in adults. Fresh feces should be examined for identifying the motile flagellate. Presence of the active flagellate in fresh stool or in the duodenal aspirate confirms the diagnosis. In many cases mixed infection with *Giardia* and other intestinal pathogens like *E. histolytica* or helminths is common. Clinical severity does not always correlate with the number of parasites seen in feces. In mild infections, repeated examination and concentration methods (formol-ether concentration method or Zinc sulphate floatation) may be required to establish the diagnosis. In some cases, when feces do not show the parasites, duodenal aspiration has to be done for recovering them. Presence of cysts indicates the carrier

state. These can be identified by examining iodine-stained preparations of feces.

Treatment

The drug of choice is metronidazole in a dose of 15 mg/kg/day given for seven days. In 80-90% of cases the infection is eliminated. In resistant cases this course can be repeated. Single administration of metronidazole in a dose of 30 mg/kg repeated after a week is also effective and it may be more suited for mass treatment on account of better patient compliance. Chloroquine 250 mg thrice a day for 5 days and tinidazole are also effective.

Giardiasis can be prevented by improving food hygiene and environmental sanitation. Heavy chlorination of water supply is required for killing giardia cysts.

Balantidiasis

K.V. Krishna Das

Balantidiasis is infection by *Balantidium coli* which affects the large intestine of man. *Balantidium coli* is a large ciliate (200 $\mu \times 80 \mu$), seen actively motile with the help of numerous cilia, in fresh specimens of stools. The cysts are rounded and smaller (Fig. 65.4). These are seen in carriers. Infection occurs when cysts are ingested. It is primarily a pathogen of pigs. Malnourished persons with low gastric acidity are more commonly infected. Compared to giardiasis and amebiasis, incidence of balantidiasis is very rare in India, but it is encountered from time to time.

Pathology

Balantidium coli primarily invades the colonic mucosa and produces flask-shaped ulcers which resemble amebic ulcers. Proteolytic enzymes and hyaluronidase are secreted by the organism. The mucosa shows infiltration by lymphocytes and polymorphs around the ulcers. Secondary infection and hemorrhage may occur as complications. In fulminant cases necrosis of the colon

Fig. 65.4: *Balantidium coli* in stools (diagram)

1. Trophozoite—motile ciliate
2. Cyst

and perforation may result rarely. In addition to the colonic lesions, uterine, vaginal, and vesical lesions may also develop at times.

Clinical Features

These resemble cases of mild to moderately severe amebic dysentery. Mild infections may be asymptomatic.

Diagnosis

It is established by demonstrating the active parasite in feces or sigmoidoscopic aspirate material. Presence of cysts indicates the carrier state.

Treatment

Tetracycline given in divided doses of 10 mg/kg daily for 10 days eliminates the infection. Many cases show a tendency towards spontaneous remission and development of carrier state. Metronidazole is also effective but the results are not consistent.

Toxoplasma gondii

K.V. Krishna Das, V.P. Gopinathan

Infection by *Toxoplasma gondii* causes toxoplasmosis. This parasite undergoes its full life cycle only in cats and other canine hosts but it affects many mammals, birds, and reptiles chickens lambs and pigs may be affected. The parasite was first discovered in 1908 in a North African rodent—the gondii. *Toxoplasma gondii* is a crescent shaped organism $4.6 \times 2 \mu$ size demonstrable by Giemsa or Wright stain. It is seen intracellularly in endothelial cells, monocytes or tissue cells. It may be seen free in tissues and tissue fluids.

T. gondii is a sporozoan parasite which is intracellular. In its life cycle there is a sexual cycle in the intestinal epithelium of cats and other feline hosts. Immature oocysts develop into mature infective sporozoites in the environment within 2-3 days. When humans and other intermediate hosts ingest them trophozoites (also known as tachyzoites) are released. They invade the cells of the gastrointestinal mucosa and then disseminate through the circulation to most of the organs. In the nucleated cells the parasite proliferates. This leads to death of the host cell. If the host develops immunity the trophozoites encyst. Each cyst contains about 3000 organisms. Encystment protects the organisms. They persist through the life-span of the host. The dormant organism within the cysts are called bradyzoites. They are morphologically identical to tachyzoites, but they multiply slowly and are functionally different.

Fig. 65.5: Old choroido retinitis

Human infection is acquired by ingesting the oocysts passed in cat's feces or contaminated meat of animals and birds. *Toxoplasma gondii* may be found in the milk of infected animals. Transplacental transmission to the fetus from the mother occurs if she gets infection during early pregnancy. At times the maternal infection may be silent. Other rarer modes of transmission include inoculation of infected material into skin, blood transfusion, organ transplantation and entry through the respiratory tract. The disease is worldwide in distribution and limited serological surveys reveal that it is prevalent in India.

Pathology

The congenital form occurs in 3-5% of babies of infected mothers. If the fetus is affected heavily transplacentally during early pregnancy, abortion or stillbirth may result. If the fetus is affected in late pregnancy, the baby is normal at birth but symptoms develop after a few months. Lesions are seen widespread in the CNS, eyes, heart, lungs and adrenals. The parasite disappears from all tissues except the CNS and retina. Brain and spinal cord show extensive areas of necrosis, cyst formation and patchy calcification. Retina shows choroidoretinitis (Fig. 65.5).

In the acquired form, the parasite gets disseminated through the blood and lymphatics from the intestinal epithelium. Lymph nodes and spleen are commonly affected. Other tissues such as the liver, lungs, skeletal muscles, myocardium, meninges, and brain may also be involved.

Clinical Features

Congenital toxoplasmosis presents predominantly with neurological involvement. The child develops chronic encephalomeningomyelitis which results in hydrocephalus, microcephaly, convulsions, tremors, focal paralysis and contractures. Eye lesions include micro-

TABLE 65.1

Lesions in the different forms of toxoplasmosis

Congenital	Acquired
	Often asymptomatic detected by serological survey
a. Hydro- or micro- cephaly	a. Maculopapular rash
b. Convulsions	b. Fever
c. Ocular palsies	c. Hepatomegaly
d. Bilateral Choroido- retinitis	d. Lymphadenopathy-tender non-suppurative, anterior, and posterior cervical groups
e. Hepatosplenomegaly	e. Encephalitis
f. Jaundice	f. Myocarditis
g. Maculopapular rash	g. Choroidoretinitis rare, unilateral
h. Cerebral calcification	h. Pneumonia

6

phthalia, nystagmus, blindness and bilateral choroidoretinitis. In cases with meningoencephalitis, cerebrospinal fluid is xanthochromic with rise in protein and mononuclear cells but with normal sugar. *Toxoplasma gondii* may be demonstrable. Other manifestations such as hepatosplenomegaly with jaundice, thrombocytopenic purpura, lymphadenopathy and rashes have been described.

Unlike congenital toxoplasmosis, acquired toxoplasmosis may be symptomless in the vast majority, detectable only by serological tests (Table 65.1).

Symptomatic cases may occur in two forms—acute and chronic. The acute form presents frequently with fever, aches and pains, cough, pneumonitis, profound malaise and maculopapular rash. Rarely jaundice, myocarditis and meningoencephalitis may develop. In the chronic form there is generalized painful lymphadenopathy which is more marked in the cervical region, lymphocytosis with atypical lymphocytes in peripheral blood, hepatomegaly and rarely unilateral choroidoretinitis. In persons with latent infection or those who have undergone remission, depression of immune status of the individual results in recrudescence.

Toxoplasmosis in AIDS

Toxoplasmosis is one of the frequent opportunistic infection in HIV positive individuals. It mainly affects central nervous system. Toxoplasmosis occurs when CD₄ count falls below 100 cells/mL. It presents with fever, headache, focal neurological deficits like hemiparesis, aphasia and seizures. It also presents with pneumonia, pericarditis, and choroidoretinitis. For further details see chapter 48, pp 271.

Diagnosis

Strong clinical suspicion is necessary for recognizing the condition. Since the manifestations are protean,

toxoplasmosis should be considered in the differential diagnosis of a wide range of clinical situations. Demonstration of *T. gondii* in the CSF, lymph gland aspirate or in biopsy specimens, confirms the diagnosis. The organism can be recovered by inoculating the infective material into laboratory animals like mice, hamsters and guinea pigs. Isolation of the organism points to acute lesion.

When acute *T. gondii* infection is suspected in a pregnant woman, the diagnosis should be pursued. Toxoplasmosis usually is diagnosed on the basis of antibody detection. In acute infection, IgM and later IgG antibody levels generally rise within one to two week. IgM antibodies indicate the occurrence of recent infection. IgG antibodies develop later and persist for considerable periods.

Toxoplasmosis in Pregnancy

When a pregnant woman is found to be infected with *T. gondii*, the next step is to determine whether the fetus is infected. It is done by demonstrating polymerase chain reaction (PCR) testing of amniotic fluid to diagnose congenital toxoplasmosis. PCR testing of amniotic fluid is safer and more sensitive than fetal blood sampling, and it allows earlier confirmation of fetal infection. However, false-positive and false-negative tests may occur with PCR tests.

Other investigations like complement fixation test, neutralizing antibody test, indirect hemagglutination test and ELISA test are also available. The IgM-immunofluorescent antibody (IgM-IFA) test is particularly useful to detect recent infection. Immunocompromised subjects may not show rise in antibody titer. Ocular toxoplasmosis can be diagnosed by funduscopy on seeing typical lesion, associated with the positive serological tests.

The cerebral lesions can be visualized by contrast enhanced CT scan and MRI which show single or multiple ring-enhancing lesions near the basal ganglia, brainstem and subcortical region with space occupying effect, and surrounding edema.

In the investigation of pregnant women and neonates for infection, toxoplasmosis is always looked for.

Course and Prognosis

The lymphatic form tends to be mild and chronic which runs over several months, but is ultimately self-limiting. Congenital toxoplasmosis and acquired neurological lesions are associated with high mortality and morbidity. Congenital toxoplasmosis is a major cause of developmental anomalies.

Treatment

The organism is susceptible to a combination of pyrimethamine (daraprim) 25 mg/day and sulphadiazine

1 g every 6 hours for 14 days. Pyrimethamine is a folate-antagonist, and therefore, megaloblastic anemia may develop during prolonged therapy. In children the dose of pyrimethamine is 2 mg/kg. In acute cases large doses of pyrimethamine—i.e., a loading dose of 200 mg, followed by a maintenance dose of 25-75 mg/day, and sulphadiazine 100 mg/kg daily in three divided doses may be needed. At this dose, folinic acid 10 mg should be given daily to prevent the development of megaloblastic anemia. The course of treatment has to extend for 4-6 weeks.

Clindamycin is also effective and this can be combined with the standard drugs in resistant cases. The dose is 1200 mg/day in divided doses. Other drugs effective against *T. gondii* include azithromycin (250 mg bd) given with pyrimethamine (25 mg) or atovaquone monotherapy. In *Ocular toxoplasmosis* oral corticosteroid therapy given in addition to pyrimethamine—sulphadiazine is beneficial.

Treatment of Toxoplasmosis in Pregnancy

Women who are seropositive should be advised to take spiramycin 1 g qid for 4-6 weeks before undertaking pregnancy. This drug is safe for use during pregnancy. If the clinical features and laboratory investigations confirm that a pregnant woman has an active infection, the next step is to determine whether the fetus is infected. Prenatal tests including amniocentesis and ultrasound may help to determine whether the fetus is infected. If the fetus is infected. The mother is given pyrimethamine and sulfadiazine after the first trimester along with folinic acid in doses of 20 mg/day. Pyrimethamine is teratogenic and hence contra indicated in the first trimester of pregnancy. Other effective drug schedules include azithromycin + pyrimethamine or atovaquone monotherapy.

Cryptosporidiosis

K.V. Krishna Das

This is caused by infection by *Cryptosporidium parvum*. Cryptosporidia are coccoid protozoa. Distribution is world-wide. Domestic animals such as cattle, sheep, pigs and horses act as reservoir hosts. Infection occurs by

ingesting the oocysts. This infection has been reported in Kerala. In a study of stools in 148 diarrheal patients *C. parvum* was seen in 1.5% of cases. Maximum prevalence was in children below 2 years of age and in immunocompromised patients.

On reaching the small intestine, infective sporozoites are released from the oocysts. They undergo asexual development in the apical enterocytes of the small intestine. After two cycles of development sexual stages develop, with the formation of zygotes and more oocysts. The oocysts sporulate, mature fully in the gut and are passed in feces, ready to infect other hosts. Incubation period after ingestion ranges from 3-11 days.

Clinical Features

Onset is with acute watery diarrhea associated with fever and general malaise. In healthy individuals the disease runs a benign course and is self-limiting.

Cryptosporidiosis is a common opportunistic infection in AIDS. In such patients the disease runs a more aggressive down-hill course, leading to severe weight loss and general debility. Toxic dilation of the colon may occur in a few.

Diagnosis

Demonstration of oocysts using concentration techniques and modified Ziehl-Neelsen staining help to establish the diagnosis.

Treatment

No specific drug was available. Clindamycin, erythromycin, and spiramycin may reduce the severity of diarrhea.

In AIDS patients zidovudine clears the infection temporarily. Nitazoxanide in a dose of 7.5 mg/kg bw controls the disease when given for 5-7 days. This is a thiazolide drug, the active metabolite being tizoxanide. Adverse side effects are minimal.

Helminthiasis: General Considerations

R.K. Shenoy, K.V. Krishna Das

Chapter Summary

General Biology 390

Pathogeneis 390

6

General Biology

Helminths constitute the most widespread parasites affecting humans all over the world. In India the problems of helminths is a serious one leading to considerable morbidity, mortality and economic retardation. *Ascariasis*, *ancylostomiasis*, *schistosomiasis* and *filariasis* are the most widespread helminthic parasites affecting extensive geographical belts and millions of people. The three main soil transmitted helminths *Ascaris lumbricoides*, *Trichuris trichura* and the hookworms-*Nectar Americanus* and *Ancylostoma duodenale* are common in most parts of India, where the soil is contaminated by human feces.

In many poor communities helminthiasis may be evident even at the age of 1 year, it reaches its maximum by the age of 10-12 years and then its severity declines. Helminths affecting man can be divided into *three groups* - *roundworms (nematodes)*, *tapeworms (cestodes)* and *flukes (trematodes)*. The helminths have well developed reproductive, excretory and nervous systems and many also possess alimentary tracts. They have complex life cycles and for the majority of parasitic helminths, the reproductive and transmission cycles require the presence of two or more hosts. Both the adults and the larvae are capable of producing disease depending on the parasite. Several mechanisms operate to produce lesions in different helminthic infections, examples of which are mentioned under pathogenesis. Allergy plays a part in producing symptoms during the stages of larval development. In many infections mild to moderate eosinophilia may develop. This reflects the immunological reaction of the host. Eosinophils have a protective role. They are seen to accumulate around helminthic larvae and destroy them, e.g. filaria.

Pathogenesis

Pathogenetic mechanisms in helminthiasis

1. Competition for nutrients in small intestine, e.g. *Ascaris lumbricoides* adults, *Diphyllobothrium latum*. They derive their nutrition by absorbing nutrients that pass through the intestines. Hook worms and whip worms get their nutrition and oxygen from the blood that traverse their intestinal tracts.
2. Ingestion of host's blood and causing blood loss from the intestine, e.g. Hook worms, *Trichuris trichura*.
3. Adults undergoing development in host's tissues and giving rise to tissue lesions, e.g. *Strongyloides stercoralis* and *Trichinella spiralis* in submucosa of small intestine, schistosomes in blood vessels, *Fasciola hepatica* in biliary passages, *Paragonimus westermani* in lungs.
4. Dilation of lymph vessels caused by adult parasites, which later becomes prone to secondary bacterial infection resulting in clinical disease, e.g. *Wuchereria bancrofti* and *Brugia malayi* filariasis.
5. Larval forms producing tissue lesions, e.g., migrating phase of round worms, hook worms and strongyloides producing pulmonary and other tissue lesions; larval forms of *Echinococcus granulosus* (hydatid cysts), *Taenia solium* (cysticercosis), *Trichinella spiralis* in muscles and *Onchocerca volvulus* in skin and eyes.
6. Tissue irritation by eggs, e.g. schistosomes.
7. Irritation by the presence of adults, e.g. *Enterobius vermicularis* over the perianal region, *Ascaris lumbricoides* in the intestinal tract, biliary passages and respiratory tract.
8. Allergic manifestations - both local and systemic, e.g. Loeffler's syndrome caused by larval forms of nematodes, larva migrans caused by *A. braziliense* and *Strongyloides*, tropical pulmonary eosinophilia caused by filariasis.
9. Give rise to severe functional damage to intestines to produce malabsorption state, especially in

immunocompromised hosts, e.g. strongyloidiasis, trichuriasis and ascariasis. Ascariasis may lead to lactose intolerance and malabsorption of Vit A.

- 10. Toxic effects due to absorption of the metabolites or products of dead worms e.g. round worms, microfilaria.
- 11. Risk of malignancy: Constant irritation by the adults or the ova in the tissues or natural passages has been associated with higher incidence of cancers in these sites, e.g. *Opisthorchis viverini* in Thailand, Laos and Malaysia and *Clonorchis sinensis* in Japan increase the risk of cholangiocarcinoma 25-50 times. *Schistosoma hematobium* is associated with the increased incidence of cancer of urinary bladder.

With the introduction of sanitary latrines and potable water supply, the prevalence of intestinal helminths has come down considerably in several communities, especially in Kerala but in many parts of India the soil transmitted helminths infection is very rampant. The problem with regard to tissue helminthiasis, especially lymphatic filariasis remains the same and larger and larger areas of India are now identified to be endemic for the disease.

Host parasite interaction: Several factors contribute to the survival and persistence of these worms in the human host. The worms produce anti-proteolytic substances which help them to escape the digestive enzymes. They modify the immune mechanisms of the host so as to avoid acute and formidable reactions in the host, thereby, enabling them to complete their life span in the human host including residence, feeding, and reproduction. Except *Enterobius vermicularis* and *Strongylus stercoralis* the others do not multiply in the same host. Increase in number is mainly due to continuous infection.

Helminths secrete substances which make them refractory to host immunity. Whip worms produce anti-inflammatory cytokines. They induce production of cytokines (interleukins 4,5,10 and 11), parasite specific immunoglobulin and nonspecific immunoglobulin E, and also expansion and mobilization of mast cells, eosinophils and basophils (TH₂ immune response).

Diagnosis

Helminthiasis is diagnosed in the vast majority of instances by the demonstration of the adults, larvae or eggs in appropriate specimens. Indirect methods include immunological tests like immunoelectrophoresis and enzyme-linked immunosorbent assay.

Treatment

Many subjects harbouring worms acquire heavy worm loads due to the long-life span of the parasites and

repeated infection. Effective anthelmintics can produce temporary reduction or elimination of the worm-load, but reinfection occurs if the subject continues to live in the same environment. Even regular periodic deworming fails to eradicate intestinal helminths from communities, unless simultaneous steps are taken to improve environmental sanitation.

Prevention

Strict personal hygiene, proper disposal of excreta and provision of potable water supplies are most important to ensure freedom from intestinal helminthic infestations. Whereas vector control assumes importance in infections caused by tissue nematodes. More recently mass drug administration to ‘at risk’ population in endemic countries is adopted as a measure to prevent transmission of filarial infection.

Important points

- 1. Helminths infecting man belong to the class nematodes, cestodes and trematodes.
- 2. Pathogenesis ranges from simple competition for nutrients to risk of malignancy.
- 3. Availability of broad-spectrum anthelmintics like albendazole and praziquantel has improved the ease and efficacy of treatment.
- 4. Good personal hygiene, vector control and mass drug administration are important to prevent different types of helminthic infections.

Choice of Drugs for Helminthiasis		
Worm	First choice of drugs	Alternatives
Round worm	1. Albendazole 2. Mebendazole 3. Pyrantel pamoate	1. Levamisole
Hook worm	1. Albendazole 2. Mebendazole 3. Pyrantel pamoate	1. Levamisole
Thread worm	1. Albendazole 2. Mebendazole 3. Pyrantel pamoate	—
Strongyloides stercoralis	1. Ivermectin 2. Thiabendazole	1. Albendazole 2. Mebendazole
Whipworm	1. Albendazole 2. Mebendazole	—
Trichinella spiralis	1. Thiabendazole 2. Albendazole	1. Mebendazole
Filariasis	1. Diethyl carbamazine	1. Ivermectin 2. Albendazole 3. Doxycycline
Tapeworm	1. Praziquantel 2. Albendazole	1. Niclosamide 2. Mebendazole
Hydatid disease	1. Albendazole 2. Mebendazole	—
Guinea worm	1. Metronidazole	—
Flukes	1. Praziquantel	1. Albendazole

Chapter Summary

Ascariasis	392
Hookworm Infection	393
Trichuriasis	395
Strongyloidiasis	396
Enterobiasis	397
Trichinosis	398
Larva Migrans	399

Ascariasis

Ascariasis is worldwide in distribution and is caused by the nematode *Ascaris lumbricoides*. In India it is one of the most widely distributed intestinal parasite.

Morphology and Habitat

The worm measures 20-35 cm in length. The female is larger than the male. The females lay several thousand eggs every day. The eggs are elliptical, 30-40 μ x 50-60 μ in size with an outer dense mammillated shell and a smooth translucent inner shell. They are passed in feces. They become embryonated and infective in the soil in 2-3 weeks and they can remain viable under optimum conditions for years.

Life Cycle

Embryonated eggs are ingested with food or water and the larvae hatch out in the small intestine (Fig. 67.1). They penetrate the intestinal mucosa to enter the venules or lymphatics and travel to the lungs, where they develop for about 10 days. They then enter the alveoli to be coughed up and swallowed. During the pulmonary phase the larvae undergo four moultings and become resistant to gastric acid. The larvae grow and mature in 2-3 months. Life span of this worm is 6-15 months.

Pathogenesis

During the stage of larval migration, pulmonary symptoms like cough, wheezing and hemoptysis may occur

Fig. 67.1: Ova of *Ascaris lumbricoides* (diagram)
(a) Embryonated, and (b) Non-embryonated

(*Loeffler's syndrome*) and used to be a common cause of respiratory symptoms in children.

The adult worms ingest nutrients from the small intestine and lead to nutritional deprivation. Large number of adults may form tangled masses and obstruct the small intestines. The worm may migrate to ectopic sites like the stomach, nasal cavity, biliary tree, pancreatic ducts, respiratory passages, female genital tract or others.

Absorption of the products of living and dead worms lead to the development of allergy and toxic symptoms.

Clinical Features

Those due to larvae: Respiratory symptoms such as cough, hemoptysis or wheezing may develop 1-5 days after swallowing the eggs. Eosinophilia may be present. Clinical severity depends upon the worm load and reactivity of the host.

The liver may be enlarged and histology may show centrilobular necrosis. Rarely larvae may reach the brain, giving rise to convulsions. Other organs may also be affected.

Those due to adult worms: Light infestations are asymptomatic. Moderate worm loads produce abdominal pain, pica, diarrhea, abdominal distention and grinding of the teeth (bruxism). Infected children have voracious

appetite but they remain malnourished despite adequate intake of food. Migration of worms to biliary ducts or pancreatic ducts lead to obstruction. In heavy infection the masses of worms may lead to intestinal obstruction and they may be palpable.

Diagnosis

It is made from the history of passing round worms in the stool or the children may vomit round worms. Diagnosis is confirmed by demonstrating the characteristic ova in feces. In the rare event of infection by male worms alone, ova may not be present in feces. During the stage of larval migration, the diagnosis has to be presumptive.

Treatment

The adult worms respond to a variety of anthelmintics.

Effective, safe and polyvalent anthelmintics are preferred at present. In more than 30% of patients multiple helminths occur, common combination being roundworm, whipworm and hookworm and broad spectrum anthelmintics are more advantageous in them. Benzimidazole drugs which include albendazole and mebendazole bind to nematode β tubulin and inhibit parasite microtubule polymerisation which causes death of adult worms which may take a few days to complete.

Albendazole in single dose of 400 mg for adults and 200 mg for children is the drug of choice due to its safety, ease of administration and easy availability. **Mebendazole** in a dose of 100 mg twice a day for three days is another equally effective alternative. The worms are killed, and are eliminated in a partly digested manner. There is no danger of irritation of worms, exacerbation of symptoms or other untoward effects. The eradication rate of round worms after single dose reaches 80-90% and above 95% after two doses given at weekly interval. Albendazole is ideal for mass therapy in community practice on the merit of its effectiveness, ease of administration and safety. Adverse side effects include gastrointestinal upsets, nausea, vomiting, abdominal pain, dizziness and rarely granulocytopenia. Albendazole is contraindicated during pregnancy.

Pyrantel pamoate, in a dose of 11 mg/kg given as a single dose at bedtime is a limited broad-spectrum anthelmintic active against roundworm, hookworm and pinworm. The drug eliminates the worms in up to 50% of subjects. It is safe in children.

Ivermectin 200 μ g/kg in single oral doses is also effective against round worms.

Children with intestinal obstruction are managed conservatively with intravenous fluids, gastric suction and antibiotics for 24 hrs. If the mass of worms remains in the same position in the presence of severe abdominal colic and tenderness or if the general condition

deteriorates as indicated by rising pulse rate and toxemia etc. surgery is indicated. The worms are manipulated to break the mass without opening the intestine. Delayed surgery carries a high mortality.

Prevention

Improvement in nutritional status of children, health education, especially pertaining to personal hygiene and environmental sanitation reduce the infection rates. Mass deworming campaigns are helpful in endemic areas to reduce worm loads temporarily but reinfection within months is the rule.

Important points

1. No direct human-to-human transmission since *Ascaris* ova have to develop in the soil before they become infective.
2. There is a pulmonary phase in the developmental cycle.
3. No multiplication of roundworm in humans and the worm load depends on the number of eggs ingested.
4. Clinical symptoms could either be due to the larvae or the adult worm.
5. After administration of albendazole usually intact worms are not seen in the stools, as the dead worms are partly digested.

Hookworm Infection

Syn. *Ancylostomiasis*

Hookworm infection is prevalent in hot damp areas throughout the tropics and subtropics. Two species of hookworms - *Ancylostoma duodenale* and *Necator americanus* are seen to parasitize the small intestine of man. *Ancylostoma* is more harmful than *Necator* because it is more persistent in the environment and causes heavier blood loss. *Ancylostoma* is seen in the tropical and temperate zones whereas *Necator* is more widespread in the tropics.

In the rural communities in India, the prevalence for hookworm in adults ranges from 10 to 35%. In children with increasing age the prevalence rates also increase being 0.5% at 1 year of age to 10% in the 12th year. In 60-70% of affected persons *Ascaris lumbricoides* and *Trichuris trichura* may also be present. In almost all parts of India, Far East, Africa and South America both types of hookworms are seen. In South India, *N. americanus* predominates. Some persons show a special predilection to acquire and sustain different intestinal nematodes.

Morphology and Habitat

Man is the natural host. The adults remain in the small intestine. Eggs are passed in feces.

Adult worm of *Ancylostoma duodenale* is 8-13 mm long and is thread-like in thickness. The buccal cavity has

four pointed hook-like teeth. *Necator americanus* is smaller than *A. duodenale*. The buccal cavity contains two chitinous cutting plates (Figs 67.3 and 67.4).

The worms attach to the intestinal villi of the jejunum and duodenum by their mouthparts. They produce bleeding points from which the blood passes through the alimentary canal of the worm continuously. This blood is required for the nutritive and respiratory functions of the worm. Hook worms produce pathogenesis- related proteins which prevent clotting by combining with platelets and inactivating them. In addition, factors that inhibit factor Xa, V11a, and tissue factor are also secreted. Thus the worms ensure a continuous flow of blood through their intestinal tract. The loss of blood caused by a single ancylostome is estimated to be 0.1-0.2 mL per day. *Necator* causes a blood loss of 0.01-0.03 mL. Worm loads above 40 can give rise to significant iron deficiency anemia over a period of time if there is added malnutrition as well.

The fertilized female can lay up to 20,000 eggs a day. The eggs measure 40-60 μ and are embryonated when passed. *Necator americanus* lays fewer eggs than *A. duodenale*, but the eggs are larger (60-70 μ) (Fig. 67.2).

Rarely two other species of hookworms- *A. cyclonicum* and *A. braziliense* may infect man. *Ancylostoma cyclonicum* is a hookworm of cat found in the Far East, which occasionally reaches maturity in humans. *Ancylostoma braziliense* is a hookworm of dogs and cats, which may also infect man but does not reach maturity.

Life Cycle

Eggs are passed in feces and within 5 days they hatch in warm moist soil. The rhabditiform larvae come out and they moult twice on the third and fifth days and develop into filariform larvae, which develop a sheath. These are infective to man. The larvae can persist in the soil for two months, feeding on bacteria and other organic matter. On coming into contact with the skin of man, the sheath is shed and the larvae penetrate into the subcutaneous tissues and enter the lymphatics and venules.

Fig. 67.2: Hookworm eggs. Note the segmented embryo (diagram)

Fig. 67.3: Adult worm mouth parts A duodenae

Fig. 67.4: Hookworms—Buccal capsules. (1) Necator americanus, (2) Ancylostoma duodenale—diagram

Within three days of entry into the skin, the larvae pass through the right side of the heart and the pulmonary capillaries to enter alveolar spaces. Foci of inflammation develop in the lungs. Then they enter the bronchi and pass up the trachea, larynx and back of the pharynx to be swallowed. In the oesophagus a third moulting occurs and a terminal buccal capsule is formed. In the small intestine they attach to the villi and grow into adults in 3-5 weeks. Average life-span of the worm is 2 years, but sometimes it may exceed 10 years.

Clinical Manifestations

Skin: The site of entry of the larvae becomes itchy and sodden. It ulcerates and becomes secondarily infected (ground itch). Common site for this lesion is the web of the toes.

Lungs: Larval migration through the lungs may lead to allergic symptoms, malaise, eosinophilia, dyspnea, cough and hemoptysis - *Loeffler's syndrome*.

Intestinal tract: Mild infections are usually asymptomatic. When the worm load is heavy, considerable blood loss occurs from the intestine. This leads to iron deficiency anemia, which is aggravated by coexistent malnutrition. Vague abdominal symptoms like pain resembling peptic ulcer or chronic intestinal amoebiasis may develop.

Heavy infection, apart from severe anemia, leads to stunted growth, apathy, reduction of learning abilities in children, frequent absence from work and school, diminished productivity, impairment of immune responses, frequent respiratory infections and increased susceptibility to tuberculosis.

Diagnosis

The diagnosis is established by demonstrating the ova in feces. Ova of *A. duodenale* and *N. americanus* are indistinguishable. The feces gives positive reaction for occult blood. The worm load can be quantitated by egg counting using Kato-Katz cellophane thick smear technique or by Stoll's method when there is heavy infection. Each worm produces 30 eggs per gram of feces per day. Identification of species is carried out by examining the adult worms passed after a vermifuge.

Treatment

Specific treatment can be administered directly if the hemoglobin is above 7 g/dL. In severely anemic patients proper diet and iron supplements are given to raise the hemoglobin to 5 g/dL or more before administering the anthelmintic. Though this is a golden rule to be followed in outpatient practice, specific anthelmintic treatment can be started much earlier using *albendazole* or *mebendazole*, which are considerably less toxic. Elimination of the worms leads to quicker recovery of the nutritional status as well.

Albendazole 400 mg single dose causes partial elimination of the worms along with other nematodes. Repeated doses may be required for complete elimination. The drug is best absorbed when given along with a fatty meal. It is available as 400 mg tablets and 200 mg suspension. Children above 2 years can be given the full doses. Younger children should be given 200 mg. Since the drug reaches several tissues it may act on tissue forms of helminths as well. *Albendazole* has become more acceptable for mass therapy on account of its effectiveness, safety and convenience of dosage. The side effects are mild including gastro intestinal upset, allergy, headache, alopecia and rarely convulsions. *Albendazole* is contraindicated in pregnancy due to risk of teratogenicity.

Mebendazole is given in the dose of 100 mg twice daily for three consecutive days after food (for adults). It is poorly absorbed from the intestine and therefore its

effects is mainly on the adult worms. This drug produces clearance of 80 % of worms in a single course and almost complete clearance if two courses are administered at an interval of 2 weeks. Due to risk of teratogenicity the drug is contraindicated during pregnancy and infancy.

Pyrantel pamoate, which is also a broad spectrum anthelmintic, given in a single dose of 11 mg/kg body weight is very effective in clearing the infection.

Prophylaxis

Personal measures include the use of proper footwear and sanitary disposal of excreta.

Important points

1. Ancylostomiasis is a geo helminth infection where skin lesions may be present at the site of larval entry.
2. There is a pulmonary phase during larval migration.
3. Clinical manifestations are mainly due to blood loss.
4. Occult blood may be present in stools in heavy infection.
5. Protective footwear, completely covering the feet is important in preventing transmission.

Trichuriasis

Syn: Whipworm infection

Trichuris trichiura is worldwide in distribution. It is especially prevalent in the tropics. The prevalence rate in India varies from 6 to 25 %, in different communities. There is considerable geographical variation. Co-infection with roundworm and hookworm is very common.

Morphology and Habitat

The adult worm measures 30 to 50 mm in length, the females being larger than males. The anterior three fifths is slender and filiform and the posterior two fifths is bulky and fleshy. The worms are seen in the caecum and large intestine with their anterior ends introduced into the mucosa to suck blood (Fig. 67.6).

The eggs are barrel-shaped, translucent, 20-50 μ in size, thick-walled, and possess knob-like ends (Fig. 67.5).

Life Cycle

The eggs become embryonated and infective in three weeks after being passed. They are ingested. Hatching occurs in the small intestine. The larvae get attached to the intestinal villi and after variable periods migrate to the large intestine where they mature in about 3 months. Though not exactly known, the lifespan of the worm is probably several years. The adults suck blood and lead to blood loss though in a smaller degree than hook worms. With the elimination of hookworms from many

Fig. 67.5: *Trichuris trichuria*—ovum (diagram)

Fig. 67.6: *Trichuris trichuria*—adult. Note the slender anterior end (A) and the thick posterior end (B)

communities, whipworms have emerged as a major cause of intestinal blood loss.

Clinical Manifestations

Mild infections pass unnoticed and the diagnosis is made by routine examination of feces. Heavy infection, which is common in children and certain susceptible subjects, is accompanied by nausea, vomiting, diarrhea and dysenteric symptoms. Diarrhea with mucus and even blood-streaking may occur. Rectal prolapse may develop. Malabsorption leads to wasting and stunting of growth in children. Iron deficiency anemia may develop.

Diagnosis

Demonstration of the eggs in feces establishes the diagnosis. Adult worms may be seen hanging from the walls of the colon on sigmoidoscopy.

Treatment

Albendazole, the drug of choice, given in a single dose of 400 mg gives a clearance rate of 30 to 90%. Administration for 2 to 3 days continuously increases the clearance rate and this may be required in heavy infection.

Mebendazole 100 mg tablets twice daily for three consecutive days produces a cure rate of 50 to 80%. Repeated courses improve the clearance rate. This drug should be used with caution in children and pregnant women.

Ivermectin, a newly introduced anthelmintic, is also effective against trichuriasis.

Important points

- 1. Trichuriasis is a geo helminth infection.
- 2. There is no phase of larval migration.
- 3. Like hook worm infection, trichuriasis can cause blood loss and anemia.
- 4. Severe infections may be associated with symptoms of dysentery.

Strongyloidiasis

Strongyloidiasis is infection of the small intestine by *Strongyloides stercoralis*. Adult females are small measuring 2 mm in length. They live in the mucosa of the duodenum and lay eggs.

Life Cycle

The eggs are laid inside the mucous membrane. Soon the eggs hatch and the rhabditiform larvae enter the intestinal lumen by breaking the mucosa. These larvae are seen in fresh stools and their spring-like movement is diagnostic. *Strongyloides stercoralis* is known to take one of three life cycles (Figs 67.7 and 67.8).

- 1. **In the soil:** They develop into the infective filariform stage within three to four days. The larvae penetrate human skin to enter the blood vessels. An alternate mode of infection is accidental ingestion of infective larvae. They pass through the lungs and after a period of development, they are coughed up and swallowed. In the small intestine they mature and copulate. The fertilized female burrows into the mucosa of the jejunum while the males are passed in feces. Life span of the worm is not clearly known.
- 2. **Free living cycle:** *Strongyloides stercoralis* can develop as free-living worms in the soil. The

Fig. 67.7: Larva of *Strongyloides stercoralis* (diagram) (1) Gravid female, (2) Egg containing larva

rhabditiform larvae in soil may develop into free-living adults, which reproduce in the soil independent of the human host. Under favorable conditions, the free-living larvae can change into filariform larvae, which can enter the human skin and initiate a new cycle.

3. **Autoinfection:** By this life cycle the worm perpetuates itself without leaving the host. The rhabditiform larvae change into filariform larvae in the large intestine or in the perianal skin. The latter penetrate the mucosa or skin to enter venules and reach the pulmonary circulation and develop further. In this way the infection can persist in an individual for long periods even after leaving the endemic area.

Clinical Features

Clinical symptoms depend on the severity of infection and reactivity of the host. Mild infections may be asymptomatic. In immunocompromised subjects hyperinfection occurs which may be fatal.

Larval Migration

Local allergy and infection may appear at the site of penetration by the larvae. The progress of the larvae through the skin and subcutaneous tissue (**cutaneous larva migrans**) may produce linear streaks of urticaria, which progress at the rate of a few centimeters every hour. Crops of these urticarial lesions recur for considerable periods. Larva migrans caused by *Ancylostoma braziliense* and *A. caninum*, move at the rate of 1-2 mm/hour. The pulmonary phase of the larvae may be associated with cough, fever, breathlessness and asthmatic symptoms. Hemoptysis may occur rarely.

Symptoms Attributed to the Adult Worm

Heavy infection may cause epigastric pain, nausea, vomiting, and diarrhea. When the worm load is very high symptoms of enterocolitis develop. Meningeal irritation is seen in a few cases.

In immunocompromised individuals strongyloidosis may take a severe and fatal form of hyperinfection; may present as malabsorption syndrome or chronic diarrhea resembling Crohn's disease. Elimination of larvae in feces may be episodic and therefore the diagnosis may be missed by single examination of feces. Diagnosis can be confirmed by biopsy of small intestine. Extensive dissemination of the larvae can present with respiratory, cardiovascular, hepatic and central nervous manifestation rarely.

Diagnosis

It is established by demonstrating the larvae or adult worms. Larvae can be demonstrated in fresh fecal

samples. The larvae may be detected in the sputum during the pulmonary phase of migration. Accidentally the duodenal aspirate may reveal the larvae and intestinal biopsy may bring out the adult worm. During the phase of larval migration moderate to high eosinophilia may be seen. ELISA detecting antibodies to the excretory-secretory antigens of the parasite is shown to be highly specific and sensitive.

Treatment

Once the infection is diagnosed, treatment must be given, irrespective of the symptoms. *Ivermectin* is the drug of choice. It is given in doses of 200 µg/kg orally for 1 to 2 days. Cure rates reported range from 82-98%.

Thiabendazole, which is available as tablets or suspension is the alternative drug. This is given in a dose of 25 mg/kg twice a day for 3 days. *Thiabendazole* is generally safe, but vomiting and vertigo may occur at times, which are self-limiting. Clearance of the worms occurs in over 80 % of cases. Repetition of the drug after 3 months may be necessary if the larvae are demonstrable in feces or allergic manifestations persist.

Albendazole in a dose of 400 mg orally once a day is also effective. Repetition of 3 doses at weekly intervals gives higher clearance rates.

Prevention

The general principles mentioned in the case of hookworms are applicable in the case of strongyloides, but treatment has to be repeated to eradicate the infection due to the phenomenon of autoinfection.

Important points

1. *Strongyloides stercoralis* is known to have three different life cycles.
2. Infection tends to be severe and fatal in immunocompromised host.
3. Apart from lungs, larval migration can occur through the skin.
4. Only larvae (not ova) are seen in the stools.
5. Ivermectin is the drug of choice.

Enterobiasis

Syn: Oxyuriasis, Threadworm, Pinworm, Seat worm

Enterobiasis is caused by *Enterobius vermicularis* (also known as *Oxyuris vermicularis*), the adults of which inhabit the large intestine, especially the cecum, rectum and anal canal. The infection occurs worldwide and is seen more in children.

The female is 8-13 mm long and has the thickness of a thread. The male is 2-5 mm long. The egg, which contains a well-formed larva when passed, is plano-convex, 20 x 50µ in size and is infective when laid (Figs 67.9 and 67.10).

Fig. 67.9: *Enterobius vermicularis*—adult (diagram)

Life Cycle

The gravid female comes out of the anus to lay eggs in the perianal and perineal skin, usually during sleep. Intense itching results in scratching and the ova contaminate fingers of the host. These are swallowed accidentally by the same host or may be spread to others. The ova hatch in the intestine and the larvae migrate to the colon to mature. Life-span is 4-6 weeks. This infection can perpetuate itself in the same host for long periods.

Clinical Features

The patient may complain of passing pinworms in stools. Symptoms are produced by the adult female, which migrates to lay eggs. It results in perianal pruritus and excoriation due to scratching. In females, severe pruritus vulvae and mild vulvitis may develop. Children may suffer from nocturnal enuresis, insomnia and allergic manifestations.

Diagnosis

The condition can be diagnosed by observing the worms in the perianal region while the child is asleep or on the surface of the feces. Ova can be demonstrated by examining a scotch-tape swab prepared from the perianal skin. A cellophane tape is applied to the un-cleaned perianal region in the morning, with the sticky side up, to collect the ova. After removal it is placed on a clean glass slide, sticky side down with a drop of toluene over the slide and examined under the low power of the microscope to detect the eggs.

In heavy infections, material collected by digital examination of the rectum shows the ova.

Course

The infection is self-limiting if autoinfection is prevented, otherwise it persists for long periods due to reinfection. Members of the same household get cross infection.

Treatment

Single dose oral treatment with mebendazole 200 mg, albendazole 400 mg or pyrantel pamoate 10 mg/kg are all effective. The parasite can be eradicated from the household only if all affected persons are treated simultaneously. Some persons have a particular predilection to get the infection repeatedly. In them repeated deworming may be required.

Important points

1. Threadworm infection presents with nocturnal, perianal pruritus and in females pruritus vulvae.
2. Ova are not seen in stools and are demonstrated only by scotch tape technique.
3. Because of direct human infection members of whole household need to be treated.
4. Repeated courses of treatment necessary due to high incidence of reinfection.

Trichinosis

Syn: *Trichiniasis, Trichinellosis*

This is only rarely seen in India. Trichinellosis is caused by *Trichinella spiralis*, a nematode parasite of several animals such as the rat, pig, polar bear etc. Infection in humans occurs when meat containing infective larvae is ingested without proper cooking. The disease has been reported from many parts of Europe, North and West USA, African countries and China.

Common mode of infection is through partially cooked pork sausages. The pig acquires infection by eating infected rats or the offal of infected pigs. Both adults and larvae are seen in the same hosts, but two hosts are required to complete the life cycle.

Morphology and Life Cycle

The adult female varies in size from 3- 4 mm × 40-60 μm. The male is only half this length. When meat containing viable larvae is ingested, the larvae escape in the intestinal lumen, penetrate the mucosal cells of the duodenum and grow into adults in 5-7 days. After fertilization, the female discharges larvae, which embolize to many tissues. Those reaching the muscles encyst themselves in an oval capsule measuring 0.8 mm, grow, mature and become infective after 16 days. They remain viable for 6 months and thereafter die and become calcified. Each female may liberate 1000-1500 larvae during its lifespan. The male lives for about a week, while the female lives for 3-16 weeks. Intercostal muscles,

pectoral muscles, diaphragm and shoulder girdle muscles are heavily affected.

Clinical Features

Symptoms depend upon the heaviness of infection. Mild infection may be asymptomatic. Within the first 1-2 days after ingestion, fever, abdominal pain, nausea, vomiting and diarrhea may develop. Larval dissemination starts around the seventh day and is marked by urticarial rash, remittent fever, edema of the eyelids, conjunctivitis and subungual splinter hemorrhages. Neurological manifestations include polyneuritis, polio-like paralysis, myasthenia, meningoencephalitis and psychosis. The CSF does not show any abnormality. Myocarditis may occur. This is characterized by persistent tachycardia and congestive failure. In 20 % of cases ECG shows ST-T wave changes and conduction defects.

Diagnosis

Eosinophilia is a constant finding in the early stages. ESR is invariably normal. Serum muscle enzymes are elevated. Skin test using the larval antigen is not useful to diagnose active infection since it remains positive for even up to 20 years after infection. Useful serological tests are ELISA, Immunofluorescent test and bentonite flocculation test. Muscle biopsy from the deltoid or gastrocnemius shows encysted or calcified larvae and evidence of myositis (Fig. 67.11).

The acute stage of larval migration has to be differentiated from other conditions characterized by allergic manifestations and muscular pains such as dermatomyositis, other forms of polymyositis, polyarteritis nodosa, serum sickness and food poisoning.

Treatment

Available anthelmintic drugs are not proved to be effective once the parasite invades the muscles. They may be more effective during the intestinal phase of infection. Thus

albendazole 400 mg twice a day for 10 days; mebendazole 200-400 mg thrice a day for 10 days or thiabendazole 25 mg/kg given twice daily for 5-7 days are all effective. During the phase of muscle invasion, antihistamines, corticosteroids and analgesics may be required for obtaining symptomatic relief. The overall mortality is around 2 %.

Prevention

The larvae in meat can be destroyed by proper cooking or deep-freezing at -18°C for 24 hours.

Important points

1. Trichinellosis is rare in India.
2. This parasitic infection has to be differentiated from common collagen vascular diseases.
3. Eosinophilia associated with normal ESR is suggestive of *Trichinella spiralis* infection.
4. Anthelmintics are not proved to be of use in the muscle invasion phase.

Larva Migrants

Visceral Larva Migrants

The term “*visceral larva migrants*” is used to denote the manifestations produced by larvae of non-human ascarids, when they migrate through human tissues. Most often the ascarids of dogs and cats-*Toxocara canis* and *Toxocara cati*-are the common offenders. Possibly larvae of other helminths also may be causative. Though larvae migrate in human tissues for variable periods, the adults do not develop in man. The larvae migrate in the pulmonary and visceral capillaries evoking a granulomatous reaction in various organs. They die and the life cycle is terminated at this stage in non-canine hosts. However, in female dogs the larvae pass transplacentally into the fetus *in utero* and into the puppies through milk while suckling. The adults develop in the puppies. They eliminate the eggs in feces in the first few months.

Children between the age of one and four, who are in close contact with puppies, are at high risk of infection. The infection is acquired by ingesting dirt containing the ova. The larvae are liberated in the jejunum and they migrate into tissues like liver, lungs, heart, brain, ocular structures, kidneys and muscles.

Clinical Features

In the majority of cases the condition is asymptomatic. In a few, symptoms such as fever, cough, wheeze, abdominal pain, and pallor develop. Central nervous system may be involved leading to headache, visual disturbances, strabismus and convulsions. CSF pleocytosis with eosinophil predominance may occur. Nodular eruptions and urticaria may develop as skin manifes-

Fig. 67.11: *Trichinella spiralis* larva is striated muscle biopsy (diagram)

tations. Eye lesions include exudative endophthalmitis and retinal granuloma. These may impair vision considerably. Some children develop hepatomegaly.

Leukocytosis with marked eosinophilia is common during acute phase of infection. ELISA detecting larval antibodies is highly specific and sensitive.

Treatment

Visceral larva migrans is self-limiting, since the encysted larvae die out after varying periods. Involvement of liver, lung, brain or eyes calls for treatment.

Available anthelmintics are not proved to be effective in *visceral larva migrans*. Albendazole, mebendazole, thiabendazole and ivermectin are tried empirically. Albendazole 400 mg twice daily or mebendazole 200-400 mg twice daily are given for 21 days. Thiabendazole is given in a dose of 50 mg/kg body weight in divided doses daily for 2-3 days.

Antihistamines and corticosteroids are required to suppress the allergic response. Pulmonary lesion, chorioretinitis and neurological involvement are indications for corticosteroids. Ocular lesions may progress further even after specific anthelmintic therapy and, therefore, prolonged follow-up is necessary in such cases.

Larva migrans can be prevented by proper deworming of newborn pets and avoiding contamination of children's playground with the excreta of these animals.

Cutaneous Larva Migrans

The larvae of *Ancylostoma braziliense* and *A. caninum* (dog's and cat's hookworms) and *Strongyloides stercoralis* cause creeping eruption. The larvae, which are present in soil penetrate the intact skin and enter the tissues. In the subcutaneous tissues, they cause multiple, intensely pruritic serpiginous tracts. While the larvae of *A. braziliense* and *A. caninum* progress forwards at a rate of 2-3 mm per hour, those of *S. stercoralis* progress a few cm at a time. At the anterior end of the eruption the larva is present and a bleb may form. Since the larvae ultimately die, the lesions are self-limiting. The eruptions due to strongyloides tend to persist for several years, if left untreated.

Treatment

Albendazole 400 mg given orally for 5 days or ivermectin 200 µg/kg single dose are the treatment of choice on account of their safety. Antihistaminics help to suppress the pruritus.

Important points

1. Larva migrans in humans is mostly caused from accidental infection by helminths from animals.
2. Marked eosinophilia is common during active infection.
3. Anthelmintics are generally not proved to be effective.
4. *S. stercoralis* can cause rapidly progressing cutaneous larva migrans.

Chapter Summary

General Considerations	400
<i>Taeniasis saginata</i>	401
<i>Taeniasis solium</i> and Cysticercosis	402
Echinococcosis	404
<i>Diphyllobothriasis latum</i>	405
<i>Hymenolepis nana</i>	406
<i>Hymenolepis diminuta</i>	406
<i>Dipylidium caninum</i>	406

General Considerations

Cestodes or tapeworms are segmented flat ribbon-like hermaphrodite worms that inhabit the small intestines of men or animals. The head (scolex) is at the anterior end and the body (strobila) is made up of segments. The head is small in size and it is provided with suckers, which help the worm to attach to the intestinal mucosa. The scolex contains hooklets in some species. The body consists of a short neck and a chain of successive segments

(proglottids). Every proglottid is a complete hermaphrodite unit. The proglottids are formed near the head as the worm grows. The segments near the head are immature, the intermediate ones are mature with fully developed gonads and the distal ones are gravid, filled by the uterus containing numerous eggs. Cross-fertilization occurs between adjacent segments. Tapeworms have no body cavity or digestive tract. Nutrients are absorbed by the surface. They require 2 or 3 hosts for completion of their life cycle. More than 30 species have been found to infect man but only six of them are common. These are *Taenia solium*, *T. saginata*, *T. echinococcus*, *Diphyllobothrium latum*, *Hymenolepis nana* and *H. diminutum*.

Taeniasis saginata

Syn: Beef Tapeworm, Unarmed Tapeworm

Taeniasis saginata is infection caused by *Taenia saginata*. This is the commonest among the large tapeworms found in man and is distributed worldwide. Prevalence is highest in areas where beef is a major source of meat. The adult worm grows to a length of 10 meters and may consist of over 2000 segments. It lies free in the jejunum and ileum, the head being attached to the mucosa. The scolex is 2 mm in diameter and bears no hooklets, but has four suckers. The gravid segments are actively motile and they come out in chains along with feces or wriggle out singly due to their intrinsic muscular action. The uterus has about 20 lateral branches.

The eggs are spherical measuring 30-45 μ in diameter and the egg shell is thick, striated and bile-stained. The embryo or onchosphere bears six hooklets and it remains viable for 4-8 weeks. The adult worm may live for 10-25 years.

Life Cycle

Man is the definitive host and *cattle and llamas* form the intermediate hosts. Eggs passed in feces contaminate soil. These are ingested by grazing cattle. The onchospheres are liberated in the intestine and they penetrate the mucosa, enter the blood stream, and reach various muscles, mainly those of the heart, tongue, shoulder, neck and loins. On reaching these sites the onchospheres lose their hooks and grow into the cystic stage known as *cysticercus bovis* in 60-70 days. The cysticercus is ovoid, measures 8 $\times$ 5 mm and contains a single sprouting scolex. Cysticercus remains viable for 1-3 years within the muscles. Heavily infected meat is easy to distinguish by the presence of numerous cysts.

On ingesting undercooked meat, the cyst wall is digested and the head attaches itself to the intestinal mucosa and rapidly grows to reach the adult size in 6-8 weeks. A host usually harbors only one or two worms.

Fig. 68.1: *T. Saginata* diagram
1. Scolex. 2. Gravid proglottide, and 3. Ovum

Clinical Features

Majority is asymptomatic, though vague symptoms such as abdominal pain, diarrhea and increased appetite may occur in a few. The motile segments emerging out of the anus may cause pruritus and anxiety to the host. Appendicitis and biliary obstruction have been reported rarely.

Diagnosis

History of passing segments and seeing the segments in feces confirm the diagnosis. The species can be identified by observing the number of lateral branches of the uterus. An easy method is to press the segment between two glass slides and to hold it against light. *Taenia saginata* segment has more than 15 lateral branches, whereas *Taenia solium* has only less than 13.

Eggs can be demonstrated by microscopic examination of the feces or by examining perianal scotch tape swab. The eggs of *T. saginata*, *T. solium* and *T. echinococcus* cannot be differentiated from each other (Fig. 68.1).

Treatment

Both niclosamide (Yomesan) and praziquantel are effective against *T. saginata*. Niclosamide kills the scolex and segments on contact. Four tablets, each of 0.5 g, are given as a single dose to be thoroughly chewed in the morning with a gulp of water. The worm is passed partially digested 24-36 h later. If the whole worm including the scolex is not passed, the worm re-grows and segments reappear in stools within 3 months. In this case the drug is repeated in the same dose.

Praziquantel in a dose of 10-15 mg/kg body weight given as a single dose orally is adequate to dislodge the intestinal adult worm in almost all cases. The drug is generally safe. Side effects include dizziness, headache, vomiting and allergy. It is available as tablets of 500 mg and 600 mg. It is expensive, costing Rs. 330 per tablet.

Prevention

Taenia saginata infection can be prevented by avoiding infected beef, inspection of slaughterhouses and proper disposal of excreta.

Important points

1. *T. saginata* is the longest tapeworm infecting humans
2. Passing motile segments in stools is diagnostic.
3. Morphology of ova does not help to differentiate the different tapeworms.
4. There is no tissue invasion in humans

Taeniasis solium and Cysticercosis

Syn: Pork Tapeworm, Armed Tapeworm

The adult of *Taenia solium* inhabits the small intestine of man. The larval stage of *T. solium* may remain encysted in several tissues. This condition is called cysticercosis. *Taenia solium* is seen all over the world, especially in those countries where pork is a major source of meat. With the availability of computed tomography (CT) and magnetic resonance imaging (MRI) of brain, more and more cases of cysticercosis are being diagnosed in many parts of India. *T. solium* is present in all areas, though it is less common than *T. saginata* (Fig. 68.2).

Morphology

The adult worm is 3 meters in length and the proglottids are less than a thousand in number. The scolex is globular and 1 mm in diameter. It bears a rostellum with a row of hooklets and four suckers. The name solium is derived from the shape of the rostellum, which resembles the conventional figure of the sun.

The gravid uterus has a main stem with 8-10 compound lateral branches on either side. The worm has

Fig. 68.3: *T. solium*—*cysticercus cellulosae* (diagram)

a long life span anecdotally stated as extending up to 25 years but, actually may be only up to five years. Eggs are indistinguishable from those of *T. saginata*. Larvae are found encysted in tissues. The cyst is oval in shape (5 × 20 mm) and contains an invaginated scolex (Fig. 68.3).

Life Cycle

Man is the definitive host. Pigs and occasionally man form the intermediate hosts. Segments containing eggs passed in the feces are eaten up by pigs. The hexacanth embryos liberated in the intestine of the pig penetrate the gut wall and reach several tissues through the blood stream. Muscles of limbs, tongue and neck are affected more. Within 60-70 days the embryos develop into cysts called *cysticercus cellulosae* (bladder worm). The cysticerci live up to 8 months after which they die. Heavily infected pork is known as “measly pork”. Man gets the infection by eating undercooked infected pork. The larvae are liberated in the intestines. They attach to the jejunal mucosa and grow into adult worms in 2-3 months after which segments are passed in stools.

Clinical Manifestations

Intestinal infection leads only to minimal symptoms or none at all. The patient may complain of passing segments in strips and this may lead to anxiety.

CYSTICERCOSIS

When man ingests the eggs or when the gravid segments with ova reach the stomach by reverse peristalsis, the eggshell is digested and larvae escape. The liberated embryo penetrates the mucosa. The larvae are disseminated to various tissues in the circulation and they develop into cysticerci. Cysticercosis is the result of a complex encounter between a highly sophisticated parasite and an elaborate immune response. This can lead to rapid elimination of the parasite in some cases. In others the parasites persist and grow. The cysts are found mostly in the subcutaneous tissues, eyes, brain and bones and they

Fig. 68.2: *T. solium* (diagram)

1. Scolex, 2. Gravid proglottide. and 3. Ovum

remain viable for three years. Viable cysts do not cause any tissue reaction. When they die, the cysts swell up and provoke foreign body reaction in the tissues and general symptoms in the form of fever, eosinophilia, arthralgia and muscular pain. Ultimately, the cysts get calcified and can be seen in X-rays. The disease may be seen in strict vegetarians as well.

NEUROCYSTICERCOSIS

This has emerged as a common cause of seizures and intracranial space occupying lesion in many parts of India. The cysts developing in the nervous system may be situated in the parenchyma of the brain, subarachnoid space, meninges, ventricles or rarely in the spinal cord. They may present with focal or general neurological manifestations such as epilepsy, focal neurological deficits referable to brain or spinal cord, rise in intracranial tension and progressive or intermittent hydrocephalus. The commonest presentation is late onset epilepsy. The cysts in the brain do not calcify readily as in other tissues. In the eyes, the cysts provoke uveitis and retinal hemorrhage and they can be seen by ophthalmoscope. In the skin and muscles they are palpable as small nodules. Sometimes affected muscles undergo pseudo hypertrophy.

The advent of CT has revealed that cysticercosis exists in all communities irrespective of their dietary habits.

Diagnosis

T. solium is diagnosed by observing the gravid segments or eggs in feces. The gravid segment show distinctive features. The ova of all the taeniae are identical morphologically. Examination of the feces is quite adequate to diagnose the infection in almost all cases. Sophisticated tests to detect specific copro-antigen by ELISA are available. So also specific DNA based studies are available to detect carrier state.

Cysticercosis is suspected by history and clinical examination. Calcified cysts may be seen by radiological examination of soft tissues. Occasionally ocular cysticerci can be seen at funduscopy. CT scan and MRI scan are excellent methods to visualize cysticerci, which give diagnostic patterns. Both CT and MRI are reliable methods to diagnose neurocysticercosis and to follow up treatment results. Parenchymal cysticerci appear as multiple cortical and subcortical circumscribed lesions about 1 cm in diameter with perilesional edema appearing as a ring lesion. Contrast enhancement suggest active inflammation. The differential diagnosis includes tuberculosis and fungal infections. ELISA to detect antibodies to cysticercal antigens is helpful in diagnosis. Enzyme linked immunoelectrotransfer blot (EITB) is shown to be more specific and sensitive.

Treatment

Niclosamide is effective in killing the adult worms in a dose of 2 g, but the worm is disintegrated and this may liberate the ova. Due to the risk of cysticercosis, this drug is better avoided. Praziquantel in a single dose of 15-20 mg/kg is effective against the adult. It is preferable, since it has action against cysticerci too.

Treatment of Neurocysticercosis

The drug of choice is *albendazole* given orally in a dose of 15 mg/kg/day for 8 days. It is a benzimidazole compound, which is readily absorbed from the gut. *Albendazole* prevents glucose uptake by the parasite membrane, thereby leading to energy depletion. It reaches high concentration in most of the tissues and so it exerts wormicidal effects in tissue forms of helminths. It is easily available in India, cheaper than praziquantel and safe. The success rate is 80%. *Albendazole* can be safely administered with anticonvulsant drugs without affecting their efficacy.

Being embryotoxic and teratogenic, albendazole is contraindicated in pregnancy. Toxic effects include abdominal pain, nausea, vomiting, dizziness, headache, rashes, pruritus, leukopenia, alopecia, eosinophilia, jaundice and nonspecific rise of hepatic transaminases.

Praziquantel which is also a broad spectrum anthelmintic is effective against cysticerci when given in a dose of 50 mg/kg/day for 15 days. The success rate is 60-70%. It exerts its action by producing muscular paralysis and destroying the scolices. It is not freely available in India, but it can be procured for special cases, but at much higher cost than albendazole.

Treatment using albendazole or praziquantel should be started only after hospitalizing the patient. This is necessary since the dying parasites induce inflammatory reactions in the surrounding tissue resulting in features of meningism or signs of raised intracranial tension. These reactions require measures to reduce the inflammation and raised tension, along with antiepileptic drugs.

In late cases, where arachnoiditis and hydrocephalus have set in, results may not be fully satisfactory even after eradicating the cysticerci.

Symptomatic measures include the control of seizures by anti-epileptic drugs, control of cerebral edema and anti-inflammatory drugs. Rarely surgery may be required to relieve obstructive hydrocephalus. Corticosteroids are indicated when there is raised intracranial tension, signs of meningoencephalitis or ocular cysticercosis.

Prevention

The infection can be prevented by cooking pork thoroughly and by proper disposal of human excreta.

Important points

1. Cysticercosis can occur both in vegetarians and non-vegetarians.
2. Neurocysticercosis is a common cause of epilepsy and focal neurological deficits in endemic areas.
3. A high index of suspicion is required to make a clinical diagnosis of neurocysticercosis.
4. Treatment with albendazole or praziquantel should be given after hospitalization due to risk of inflammation induced by the dying parasites.

Echinococcosis

Syn: Dog Tapeworm or Hydatid Worm

Definition

Infection of human tissues by larval form of *Echinococcus granulosus* and less commonly *E. multilocularis* is termed echinococcosis. The disease is worldwide in distribution. It is more common in sheep-rearing countries both in the tropic and temperate zones. Close contact between man, dog and sheep favors this infection. *E. granulosus* is widely distributed in India and the disease is seen endemically or sporadically.

Morphology

The adult worm is small, measuring only 3-6 mm in length. The scolex bears four suckers and rostellum with two rows of hooklets. There are only three segments. The last segment is mature and gravid. Dogs pass the ova in their feces. The ova resemble those of *T. saginata* and contain the infective embryo. Larval forms occur within hydatid cysts. A single metastasized larva settles in tissues and grows to form a hydatid cyst. The germinal layer of the hydatid cyst gives rise to successive generations of embryos, ultimately leading to the development of several thousand infective larvae from a single egg (Figs 68.4 and 68.5).

Life Cycle

Definitive hosts are the dogs, wolves, jackals and other canines. Intermediate hosts are sheep, pigs, goats and humans. Sheep are the optimum intermediate hosts and they serve to perpetuate the natural life cycle of the parasite. The eggs passed in dog feces are ingested by the intermediate hosts. The embryos are liberated in the intestines. They penetrate the mucosa and enter the portal radicles to reach the liver. The larvae are arrested mainly in the liver and lungs but some may escape into the systemic circulation to reach other viscera like the brain, bones and kidneys. Within 3-6 weeks they grow into vesicles 5-10 mm in diameter and these are known as hydatid cysts (hydatids = drops of water). They grow to reach large sizes and the parasite multiplies in number.

Fig. 68.4: *Echinococcus granulosus*
(A) Adult, and (B) Ovum

Fig. 68.5: Hydatid cyst (diagram)
1. Outer wall, 2. Brood capsules, and 3. Scolices

The hydatid cyst has a thick fibrous outer wall and an internal germinal layer, from which brood capsules containing budding scolices arise. These may separate from the capsule and float inside as daughter cysts. The hydatid fluid is a clear colorless fluid, which is highly antigenic. On keeping it a granular deposit forms at the bottom (hydatid sand), which contains free scolices and brood capsules.

When the hydatid cyst or scolices are ingested by the definitive hosts, they attach to the intestinal mucosa and grow into adults. Each animal may harbor many worms.

Clinical Features

Infected dogs are asymptomatic. In human hydatid disease, symptoms are due to allergic reactions and mechanical compression of the surrounding tissues. Local symptoms depend on the site and size of the cyst. Clinical features are those of an enlarging mass. Common presentation is with hepatomegaly, hemoptysis or neurological symptoms. In about 75% cases the right lobe of the liver is the seat of large cysts. Lungs, brain, orbits and bones are affected not uncommonly. An interesting physical finding is the hydatid thrill, which is elicitable by percussion over large hydatid cysts, particularly over the liver region. Place three fingers of the left hand firmly over the enlarged liver and percuss on the middle finger with the right hand, and feel the sensation over the other

Fig. 68.6: X-ray chest hydatid disease left lower zone

two fingers, produced by the movement of the free floating daughter cysts in the cyst cavity. This is called hydatid thrill.

Allergic manifestations occur either as non-specific allergy such as urticaria, eosinophilia or rashes. Sometimes rupture of a cyst and entry of the fluid into tissues evoke anaphylactic reactions.

Diagnosis

Strong clinical suspicion is necessary to suggest the diagnosis of hydatid disease.

1. **Blood:** Mild eosinophilia is invariably present.
2. **Casoni's reaction:** This intradermal test using sterile hydatid fluid used to be an important diagnostic test which was in vogue till three decades ago. It is no longer used because of poor specificity and cross reaction with other helminths.
3. **Immunological tests** such as hemagglutination test using sensitized sheep red cells and immunofluorescence are useful for screening.
4. **Immunoelectrophoresis and ELISA techniques** are specific, though technical difficulties restrict their wide use.
5. **X-rays:** The cysts are radiopaque and are seen as sharply outlined masses in the lungs (Fig. 68.6).
6. **Imaging:** Ultrasonography gives the most valuable information about the nature of the mass and its contents. CT and MRI are also useful imaging techniques. Calcification of the cyst wall on CT is suggestive of hydatid cyst. Isotope scans of the liver bring out cold areas.

Closed aspiration as a diagnostic procedure is generally contraindicated since escape of the contents may result in anaphylactic shock and secondary infection.

Treatment

Planned surgery offers the best chance of cure for symptomatic cysts as drug therapy fails to clear the mass fully. Due to problems associated with surgery, presently ultrasound guided percutaneous aspiration and infusion of scolical agents like ethanol or hypertonic saline followed by re-aspiration of the contents is recommended for uncomplicated cysts.

Albendazole, which is the drug of choice, is effective in sterilizing the scolices and reducing the size of the cysts. This drug is given pre-and post-operatively to sterilize the cysts and to prevent recurrence due to spillage during surgery. The dose is 800 mg given orally as two doses for 30 days. Pregnancy is a contraindication for this drug. Concurrent administration of corticosteroids help to reduce systemic reactions.

Praziquantel 50 mg/kg/day for 2 weeks is shown to destroy the protoscolices within the cysts but has no action on the germinal layer.

Prophylaxis

Care should be taken in handling dogs. Domestic dogs should be regularly dewormed. Monthly treatment with praziquantel 5 mg/kg eliminates *T. echinococcus* and *Hymenolepis nana* in dogs. Oxbendazole which is a vetnary drugs given a dose of 30mg/kg bw given orally, eradicates the infection in animals in > 95%.

Contamination of children's playgrounds with dog's feces should be avoided.

Important points

1. Hydatid cyst should be considered in the diagnosis of an otherwise asymptomatic space occupying lesion in the liver and lungs.
2. Ultrasound and CT findings are diagnostic, especially calcification in the cyst wall.
3. Aspiration of the cyst is associated with risk of spillage of the contents and anaphylactic shock.
4. Planned surgery is the definitive treatment since albendazole alone does not clear the cyst completely.

Diphyllobothriasis latum

Syn: *Diphyllobothrium latum*, fish tapeworm

Infection by *Diphyllobothrium latum* is extremely rare in India. It is more common in the USSR, Baltic regions, Switzerland and Japan. The adults are seen in human small intestine and may range in length from 3-10 meters. The eggs are operculated. Two intermediate hosts are required for completing the life cycle, the fresh water cyclops and fresh water fish. Man gets infected by eating uncooked fish. The parasite may compete for vitamin B₁₂ in the intestine, leading to vitamin B₁₂ deficiency in the host.

Both niclosamide and praziquantel are effective vermicides.

Hymenolepis nana

Syn: Dwarf Tapeworm

This is the smallest tapeworm found in man, measuring 1-4 cm in length. Children acquire infection by swallowing eggs. The larvae hatch out and grow in the small intestine. Niclosamide and praziquantel are very effective in clearing the infection.

Hymenolepis diminuta

This tapeworm is a parasite primarily affecting rats and mice. Man is accidentally infected by consuming the infective larva present in fleas, along with cereal grains. Both niclosamide and praziquantel are curative.

Dipylidium caninum

This is a tapeworm seen in cats and dogs. Many get infected accidentally by consuming the infective larvae present in fleas. Niclosamide and praziquantel are effective drugs.

Comparative morphology of the pathogenic tapeworms is given in Figure 68.7.

Fig. 68.7: Comparative diagram of tapeworms. (1) *T. solium*, (2) *T. saginata*, (3) *T. echinococcus*, (4) *H. nana*, (5) *D. latum*, and (6) *H. diminutum*. (A) Scolices, (B) Proglottides, (C) Eggs and (D) Larvae

Trematode (Fluke) Infections

R.K. Shenoy, K.V. Krishna Das

Chapter Summary

General Characteristics 406
Fascioliasis 407
Heterophyiasis 407
Clonorchiasis 408
Schistosomiasis 408

General Characteristics

Trematodes (flukes) are flat leaf-shaped unsegmented worms, which have a long life span. Except schistosomes all are hermaphrodites. Compared to the other worms, human fluke infection is rare in India.

The common features are:

1. Majority of them gains entry through the digestive tract except schistosomes;
2. Intermediate host is a snail and the infective metacercaria encyst on vegetables or develop in some aquatic animals which are ingested; and
3. The eggs are operculate except in the case of schistosomes.

General Life Cycle

Man and other mammals form the definitive hosts. Intermediate hosts are fresh water snails or molluscs. In addition, some have also a second intermediate host such as fresh water fish or a crustacean. The eggs hatch out

General characteristics of some of the common pathogenic trematodes		
Species of Flukes	Hosts	Habitat of adult
Intestinal flukes		
<i>Fasciolopsis buski</i>	Pig, occasionally dog, man	Duodenum and jejunum
<i>Heterophyes heterophyes</i>	Cat, dog, fox, man	Small intestine
<i>Metagonimus yokogawai</i>	Fish eating mammals, pelican, man	Small intestine
<i>Gastrodiscoides hominis</i>	Pig, man	Caecum and colon
Liver flukes		
<i>Clonorchis sinensis</i>	Dog, pig, cat and man	Biliary passages
<i>Opisthorchis felineus</i>	Dog, cat, fox, several other animals and man	Biliary and pancreatic passages
<i>Fascila hepatica</i>	Sheep, cattle, rabbit, man	Liver and biliary passages
Lung flukes		
<i>Paragonimus westermanii</i>	Tiger and other crab eating animals, man	Lungs
Schistosoma		
<i>S. haematobium</i>	Man	Urinary tract
<i>S. mansoni</i>	Man	Intestines, liver
<i>S. japonicum</i>	Man and other animals	Intestines, liver, lungs, brain

when liberated into water and give rise to the motile ciliated embryos called miracidium. These penetrate the body of particular species of snails and develop into sporocysts in the liver or lymph spaces. Rediae develop from the sporocysts. The rediae either develop into cercariae or a second generation of rediae. Asexual multiplication occurs at this stage and the number of parasites increases. The cercariae escape from the snails and either encyst as metacercariae over water plants or are taken up by the second intermediate hosts. Infection to man occurs due to ingestion of metacercariae on contaminated vegetables or by eating uncooked fish or crustacea (Table 69.1).

Fascioliasis
Syn: Sheep liver fluke

Fascioliasis is infection by *Fasciola hepatica*. It is essentially a parasite of cattle and sheep and is worldwide in distribution. Infection among cattle is not uncommon in India but human infection is less common.

Morphology, Life Cycle and Pathogenesis

This fluke measures 3.5 × 1.5 cm. The eggs measure 140 × 80 µm. They are operculate and are passed in feces. The snail vector is *Limnaea truncatula*. The cercariae encyst on aquatic vegetation. Man gets the infection by eating contaminated watercress. When ingested, the parasites excyst in the intestine and penetrate the wall to enter peritoneal cavity. They enter the liver by piercing the capsule. In the liver they mature into adults in the bile ducts. Ova appear in feces 3-4 months later.

Clinical Features

During parasitic invasion prolonged fever, abdominal pain, tender enlargement of the liver, urticaria and eosinophilia develop. Thereafter, the disease remains latent for months to years. The third stage is one of obstruction of the bile duct leading to jaundice and biliary cirrhosis.

Treatment

Triclabendazole given orally in a dose of 10 mg/kg body weight in 2 single doses, 2 days apart is the drug of choice. Bithional in a dose of 30-50 mg/kg given orally on alternate days for 10-15 days or Praziquantel in a dose of 75 mg/kg daily in three divided doses for 5 days is also effective.

Important points

1. Infection by *Fasciola hepatica* is one of the causes of obstructive jaundice and biliary cirrhosis.
2. Triclabendazole is the drug of choice.
3. In endemic regions watercress should not be eaten raw.
4. Cooking destroys the parasite.

Heterophyiasis

Heterophyes heterophyes is a small fluke found in large numbers in the small intestine of man, dog, cat and wolf. It is distributed widely in the Far East and Egypt. In India, it is occasionally seen in visitors or immigrants. The operculated eggs measure 13-16 µm in size and are passed in feces. They resemble those of *Clonorchis sinensis*. The snail vector is *Pironella conica*. The second intermediate hosts are the mullets and other types of fish, which are

infective when eaten raw or improperly cooked. Inflammatory reactions occur at the point of attachment to the intestinal mucosa. Heavy infections lead to diarrhea and abdominal pain. Ectopic worms and ova in the heart had been reported. These unusual sites are reached through the blood stream.

Treatment

Praziquantel given in a single oral doses of 20 mg/kg body weight clears the infection.

Clonorchiasis

Syn: *Chinese liver fluke*

Infection of the biliary passages by *Clonorchis sinensis* causes clonorchiasis. This disease is prevalent in the Far East among fish eating mammals such as dogs, cats, pigs and man. In India it has been reported among the Chinese immigrants.

Morphology, Life Cycle and Pathogenesis

This fluke is 11-20 x 3-4 mm in size. Eggs measure 30 to 16 µm and are passed in stools. The snail vectors belong to the *Bythinia* species. The cercariae are ingested by fresh water fishes (more than 40 species), which form the second intermediate hosts. Metacercariae develop in their muscles. When such fishes are ingested uncooked, the cyst wall is digested and the larvae are set free in the duodenum. They pass up through the ampulla of Vater to the smaller biliary passages and sometimes the pancreatic ducts. In course of time the biliary epithelium proliferates and the ducts dilate to form cystic cavities. The liver is enlarged and biliary cirrhosis, suppurative cholangitis and rarely malignancy may occur as complications.

Clinical Features

Include diarrhea, hepatomegaly, recurrent jaundice and eosinophilia.

Diagnosis

The eggs can be demonstrated in the feces or duodenal aspirate.

Treatment

Praziquantel in a dose of 75 mg/kg given in three divided doses for 1-2 days is curative. Bithionol given orally in doses of 50 mg/kg on alternate days for 2-3 weeks is also effective.

Important points

1. There are two intermediate hosts in the life cycle of *Clonorchis sinensis*
2. Clonorchiasis clinically presents with obstructive jaundice from cholangitis, biliary cirrhosis.
3. Chronic infection may predispose to the development of cholangio-carcinoma.
4. Proper cooking of fish prevents infection.

Schistosomiasis

Syn: *Bilharziasis*

Definition

Infection by *Schistosoma hematobium*, *S. mansoni* or *S. japonicum* constitutes schistosomiasis. *Schistosoma hematobium* affects the urinary tract. *S.mansoni* affects the large intestine, liver, lungs and also spinal cord. *S. japonicum* affects mainly the small intestine and upper part of large intestine, but the liver, lungs and the central nervous system are also affected frequently. *S. hematobium* and *S. mansoni* parasitize only man whereas *S. japonicum* may also affect other animals such as the dog, cat, rat, field mouse and cattle. More than 200 million people are affected by the worm, worldwide.

Morphology and Life Cycle

The life cycle of all the species is similar. Definitive host is man. Eggs are discharged in urine or feces. The eggs hatch out immediately in water and liberate free-swimming miracidia, which penetrate specific snail hosts within 24 h (genus *Bulinus* for *S. hematobium*, *Biomphalaria* for *S. mansoni* and *Oncomelania* for *S. japonicum*). Two sporocyst generations develop within the snail. Cercariae are formed within 4-6 weeks. These escape from the snail into water and remain infective for 2-3 days. A snail infected by one miracidium can shed thousands of cercariae daily for months. The cercariae penetrate intact human skin and the oral mucous membrane when there is a thin film of water. Infection is acquired by contact with fresh water containing the cercariae. After entry, the cercariae lose their tails and they reach the peripheral venules and lymphatics. Within 24 hours, they pass through the lungs, diaphragm and liver. Then they enter the systemic circulation. The parasites finally reach the portal venous system and develop into adult worms. The adult worms measure 1-2 cm in length and have a life span of 4-30 years. The male is broader and holds the female within its fold. The female is longer and more slender and cylindrical than the male (Fig. 69.1). Within 4-6 weeks of infection they reach their destination through the venules draining the pelvic viscera and start laying eggs. *Schistosoma japonicum* passes through the superior mesenteric vein and *S.mansoni* passes through the inferior mesenteric veins. Finally, they both reach the submucosal vessels of the intestine. *Schistosoma japonicum* affects the small intestine and the ascending colon, while *S. mansoni* lodges in the descending colon and rectum. *Schistosoma hematobium* reaches the bladder and other pelvic organs. They feed on blood and globulins by anaerobic glycolysis.

The females lay about 3000 eggs daily in the terminal blood vessels. The eggs contain ciliated miracidium larvae which secrete proteolytic enzymes which help them to

Fig. 69.1: Adult schistosome (A) Male, and (B) Female

migrate into the lumen of the bladder or the intestine. The worms slowly retreat as the terminal vessels get progressively blocked. The eggs remain viable for 1 week. The eggs of *S. hematobium* containing miracidia appear in urine. The eggs of *S. mansoni* and *S. japonicum* are passed in feces (Fig. 69.2).

Epidemiology

Though schistosomiasis is one of the more widespread helminthic infections affecting about 200 million people in 71 countries, it is only rarely reported from India. There is a pocket of infection by *S. hematobium* in Maharashtra state. Highest prevalence is in Africa and the Middle East. *Schistosoma hematobium* and *S. mansoni* occur in Africa, Middle East and South America. *Schistosoma japonicum* is prevalent among the field workers in China, Japan, Philippines, Celebes, Lagos, Thailand, Vietnam and Myanmar. Newer areas have become endemic with the construction of dams and irrigation projects.

Pathology and Pathogenesis

Eggs are laid in the tissues, but many are discharged into the lumen and are passed in urine or feces. About 50% of the eggs are retained in the tissues. The eggs produce proteolytic enzymes which lead to typical eosinophilic inflammatory and granulomatous reactions, leading to

Fig. 69.2: Ova of schistosome (A) *S. hematobium*, (B) *S. japonicum* and (C) *S. mansoni*

fibrosis. Granulomatous lesions occur especially in liver, intestines, urinary bladder, uterus and lungs, resulting in complications. The tissue reaction is determined by the intensity of infection and the reactivity of the host. Ultimately further reinfection is limited by immunity developed by the host in endemic areas.

Clinical Features and Complications

Three phases are recognizable.

1. **Earliest lesion** is caused by penetration of the skin by cercariae. It results in itching and papular rashes at the sites of penetration (**swimmer's itch, cercarial dermatitis**). This phase is more common in infections caused by non-human schistosomes.
2. In about 4-6 weeks the **second stage** starts with fever, severe toxemia and allergic reactions. Marked eosinophilia develops in about 4-6 weeks. This stage is called **Katayama syndrome**. This serum sickness like reaction is seen during oviposition and it is most severe in *S. japonicum* infection.
3. **Late complications** are seen three months to several years after the initial infection. These are due to granulomatous lesions and fibrosis occurring in various organs. The manifestations of this stage differ in the three species.

Schistosoma hematobium (*Genitourinary schistosomiasis*) affects the urinary bladder, ureters and the prostate in males, whereas vagina, cervix and uterus are also involved in females. Urinary symptoms predominate depending on the stage of the disease. *S. hematobium* infection predisposes to vesical carcinoma.

Schistosoma mansoni infection (*Intestinal schistosomiasis*): The early stage is characterized by abdominal pain and dysenteric symptoms. The lesion extends to the liver due to retrograde passage of eggs into the portal system and the liver. Periportal fibrosis resulting in presinusoidal portal hypertension develops in the liver. Massive splenomegaly may occur. The ova may reach all organs through the portal-systemic collaterals. The ova in the brain lead to neurological symptoms. *Schistosoma mansoni* infection favors the development of carrier state for *Salmonella typhi*. There is no rise in the risk of cancer.

***Schistosoma japonicum* infection (Katayama disease, Asiatic schistosomiasis):** Since this worm produces more eggs than the others, its pathogenicity is greater. Major pathological lesions are seen in the small intestine, mesentery and ascending colon. This leads to ulcerations, fibrous thickening, and polyp formation. Early symptoms are abdominal pain and bloody mucoid stools. Cirrhosis liver develops with all its attendant complications. Five percent of cases develop ectopic foci of infection, especially in the lungs and central nervous system. Symptoms include Jacksonian epilepsy, focal paralysis, paraplegia and coma. Embolization of eggs in the pulmonary circulation leads to obstruction of small arterioles resulting in pulmonary hypertension. Granulomas develop in the lungs, which result in fibrosis. Such patients present with asthma, bronchitis, or pulmonary emphysema.

6

Diagnosis

Schistosomiasis is diagnosed by demonstrating the eggs in appropriate specimens or in tissue biopsy. Concentration technique like Kato-Katz quantitative method is useful to enhance the egg count results. Investigation for *S. hematobium* includes plain X-ray abdomen for bladder calcification, excretory urograms and cystoscopy with biopsy, especially when there are no eggs or miracidia in urine. Rectal biopsy, sigmoidoscopy, barium enema and colonoscopy with biopsy are necessary to diagnose *S. mansoni* and *S. japonicum*. Serological tests like ELISA and Immunoblot are available for diagnosis.

Modern investigations such as ultrasonography, CT and MRI help to assess lesions in the liver, portal venous system, kidneys, bladder, brain and spinal cord. With the availability of these facilities structural lesions can be diagnosed and appropriate corrective treatment instituted.

Treatment

It should be the aim to start treatment early since at this stage lesions are reversible. *Schistosoma hematobium* is most susceptible and *S. japonicum* is more resistant to drug therapy.

Praziquantel

This is an acylated quinoline-pyrazine derivative. It is given as a single oral dose of 30-45 mg/kg and the drug is effective

against the adult worms in all types of infections. Cure rates of 72-95% have been reported and side effects are few, spasmodic abdominal pain being the most common. Being effective in a single dose, it can be utilized for mass therapy. Therefore at present it is the drug of choice. *S. hematobium* responds to 30 mg/kg body weight, whereas *S. mansoni* and *S. japonicum* require above 40 mg/kg for proper response. The drug is available as 600 mg tablets. After a single dose 70-100% of patient cease to discharge eggs. A follow-up dose repeated 6-12 week later ensures killing of developing pre-patent worms as well. Katayama fever is primarily treated with corticosteroids and praziquantel.

Oxamniquine is a quinoline derivative specific for *S. mansoni* infection. It is given orally in a dose of 20-30 mg/kg/day for 3 days. Fever and eosinophilia may develop 2-3 days after completing treatment.

Metrifonate: This is an organophosphorous compound specific for only *S. hematobium*. It is given orally in a dose of 10 mg/kg every 2 weeks for a total of 3 doses.

Preventive measures should aim at:

1. Proper environmental sanitation and health education;
2. Mass therapy with oral drugs to reduce the worm load;
3. Destruction of snails by proper control of water and use of molluscicides and
4. Avoidance of infection by wearing protective clothing.

Important points

1. In schistosomiasis the pathology is caused by the ova deposited in the tissues.
2. *S. hematobium* infection predisposes to vesical carcinoma.
3. *S. mansoni* infection favors carrier state for *Salmonella typhi*.
4. Neurological manifestations are caused by both *S. japonicum* and *S. mansoni*.
5. *S. japonicum* infection may result in pulmonary hypertension.
6. Mass drug administration using praziquantel is one method of parasite control in endemic regions.

Tissue Nematodes

R.K. Shenoy, K.V. Krishna Das

Chapter Summary**Filariasis 411**

General Considerations 411

Lymphatic Filariasis 411**Loiasis 418****Onchocerciasis 418****Other Filarial Infections 419***M. perstans* 419*M. streptocerca* 419*M. ozzardi* 419**Dracontiasis 420****Filariasis**

R.K. Shenoy

General Considerations

Infection by nematodes belonging to the superfamily filarioidea constitutes filariasis. *Wuchereria bancrofti*, *Brugia malayi*, *Brugia timori*, *Loa loa*, *Onchocerca volvulus*, *Dipetalonema perstans*, *Dipetalonema streptocerca* and *Mansonella ozzardi* parasitize man. The distribution of these parasites depends upon the geographical and climatic conditions and the prevalence of the appropriate vector. In India the two species prevalent are *W. bancrofti* and *B. malayi*. The parasites are distributed in different parts of Africa, South America and possibly other areas. The morbidity burden caused by filariasis in India is considerable. Extensive areas are endemic for this disease.

Lymphatic Filariasis

This is caused by *W. bancrofti*, *B. malayi* and *B. timori*. The first two infections are considered in this chapter since *B. timori* is rare and is confined to a few islands in Indonesia. The adult worms living in the lymphatic vessels are responsible for the lesions and hence the name.

Epidemiology

It is estimated that 120 million people throughout the world are infected with *W. bancrofti* or *B. malayi*. Out of this disease burden, India and Sub-Saharan Africa account for about 38% and 34% respectively. Infection by *W. bancrofti* is endemic between latitudes 41° north and 30° south involving most parts of India, Myanmar, Africa, South-East Asia, West Indies, Central America, the Pacific Islands and eastern coastal plains of South America. Infection due to *B. malayi* is restricted to South-East Asian countries and several pockets in India particularly along the coastal and backwater regions of Kerala and Andhra Pradesh. It is now becoming clear that many areas hitherto unsuspected, coastal, midland and even mountainous, are endemic for bancroftian filariasis.

Morphology

The adults of *W. bancrofti* are 4-10 cm long, whereas those of *B. malayi* are only 3-5 cm. The males are smaller than females. The adults are seen coiled in clusters in the lymphatic vessels and their life-span ranges probably from 7-15 years. Periodically, the female worm discharges numerous embryonated eggs (microfilaria) into the lymphatics. These circulate in blood. In India the microfilaria (mf) are most numerous in the peripheral blood at night, whereas in other geographical areas like the Pacific Islands they are present during daytime as well. This phenomenon probably corresponds with the biting habits of the vector mosquitoes and the sleep rhythm of the patients.

When they are not present in peripheral blood, the microfilaria remain in the central parts of circulation in the lungs, liver and spleen. The microfilaria are sheathed, vary in length from 200-300 µ, and are actively motile. The mf of *B. malayi* differ from those of *W. bancrofti* by certain characteristics like increased length of the cephalic space, secondary kinks in the curvature and presence of terminal nuclei in the tail. These help to identify them morphologically. Man is the only known definitive host for *W. bancrofti*, but animals like monkeys and wild carnivores also harbor *B. malayi*.

Life Cycle

The microfilaria are ingested by the vector mosquitoes during blood meals. For *W. bancrofti* many species of *Culex* and some species of *Anopheles* mosquitoes act as vectors. *B. malayi* is transmitted by *Mansonia* and *Anopheles* mosquitoes, the former being more important. The adult worms do not multiply in the host, nor do the larvae multiply in mosquitoes, so that the extent and severity of infection ultimately depend on the number of bites by the infective vector. Further development occurs when the mf are ingested by the appropriate mosquito vectors. In the mosquito the mf shed their sheath, reach the wing muscles, become shorter and thicker, moult twice, and develop further to become the infective form. Depending on the temperature and humidity of the environment and species of the mosquitoes this takes 10-14 days. The infective L3 larvae, which measure 1.4-2 mm x 18-23 μ migrate to the proboscis-sheath to be deposited at the bite wound caused by the mosquito. The larvae enter the skin at puncture sites and reach the lymphatics to grow, mature and mate. Microfilariae appear in circulation 6-12 months after entry of the larva. The severity of infection is determined by the number of adult worms harbored by the host. The microfilaria remain viable for 2-3 months after which they die and are removed by the macrophages of the liver and the lungs (Figs 70.1 and 70.2).

Fig. 70.1: Microfilaria *W.bancrofti*

Fig. 70.2: Microfilaria *B.malayi*

Pathology

The adult worms living in the lymph vessels are responsible for the early changes in these vessels. The severity of the pathology depends on the number of adult worms, their location and the host immune response. At one end of the disease spectrum there are many who, in spite of repeated exposure, do neither have microfilaremia nor any lesions. The largest group of affected individuals are asymptomatic who harbour the adult worms and show mf in their peripheral blood, but without clinical disease. The commonest clinical presentation is lymphedema involving the extremities or occasionally the genitalia in both sexes and rarely breasts in the females. At the other end of the clinical spectrum is tropical pulmonary eosinophilia syndrome, which results from an exaggerated immune response of the host. It is classified under occult filariasis.

Spectrum of disease in lymphatic filariasis

- Endemic normals
- Asymptomatic microfilaremia
- Clinical disease
- Tropical pulmonary eosinophilia syndrome

Recent studies have revealed that the earliest lesion in lymphatic filariasis is dilatation of the lymph vessels harboring live adult worms. This is demonstrable by ultrasound scan and lymphoscintigraphy, in even asymptomatic patients harbouring microfilaria. Dilatation is responsible for the later lymphatic dysfunction and lymph stasis. It predisposes to secondary bacterial infections and development of lymphedema in the affected regions. The alterations in the immune response of the host and the parasite products probably contribute to the lymphatic dilatation (Figs 70.3 to 70.6).

Infection by *Str. haemolyticus* and occasionally other bacteria produces recurrent episodes of acute adenolymphangitis (ADL), also termed acute dermato-

Fig. 70.3: Filarial lymphedema with acute adenolymphangitis

Fig. 70.4: Late stage of filarial lymphedema of leg

Fig. 70.7: Fungal infection in the interdigital web space in a case of filarial lymphedema

Fig. 70.5: Warty excrescences in a filarial foot

Fig. 70.6: Large nodular excrescences in a filarial leg

lymphangio-adenitis (ADLA) because of the sequence of events i.e., inflammation of the skin, lymph vessels and then lymph nodes. These involve the limbs or sometimes

genitalia, where there is underlying lymphatic damage. ADL presents as acute febrile episodes. In most patients with acute ADL attacks, sites of entry for the bacteria are demonstrable in the limb involved (Fig. 70.7). These include fungal infections of the interdigital spaces, minor injuries or other lesions that damage the skin barrier allowing entry of bacteria. Moisture and damp environment favor the development of the skin lesions. This accounts for their greater frequency during rainy season. Repeated ADL attacks lead to progression of the lymphedema and later elephantiasis of the affected region. In elephantiasis the edema is non-pitting. There is thickening of the skin and gross hypertrophy of the subcutaneous tissues. The skin may show warty or nodular excrescences.

In the early stages of lymphedema there is evidence of subacute inflammation in the affected tissues and in the draining lymph nodes. There is predominant polymorphonuclear infiltration. As the disease advances there is further dilatation of lymphatics, proliferation of the lymphatic endothelium and new lymph vessel formation. Late stages of lymphedema show obstructive changes, gross thickening and fibrosis.

The dilation and rupture of the lymphatics lead to oozing of lymph - lymphorrhage. This favors secondary infection. Common sites of lymphorrhage are the scrotum (lymph scrotum) and lower extremities (Lymphorrhage). Rupture of lymph varices around the renal pelvis leads to presence of chyle in the urine (chyluria). Rupture of peritoneal lymphatics leads to chylous ascites i.e. the presence of chyle in the ascitic fluid, which makes it milky. Dilatation leading to dysfunction of lymphatics of the spermatic cord and the para-aortic lymphatics leads to collection of fluid in the tunica vaginalis testes - hydrocele. Similarly chylocele may occur due to the rupture of these lymphatics.

When the adult worms die this leads to granulomatous changes with predominant eosinophilic infiltration. The dead worms may get calcified.

Immunology

Immune mechanisms play the major role in the pathogenesis and clinical manifestations of filariasis. The adult worms remain in the host for long periods without evoking host defense response by producing anti-inflammatory substances. The T lymphocyte responses lead to production of interleukins 4 and 5 (IL4 and IL5). *B. lymphocytes* are stimulated to produce IgE and IgG4 which are associated with eosinophilia. IgG4 blocks the action of IgE, thereby reducing the host immune response. In the tropical pulmonary eosinophilia syndrome the hyperimmune response with high levels of IgE is characterized by increase in eosinophils in the absence of microfilaria in peripheral blood.

6 Role of Wolbachia in Lymphatic Filariasis

Recent studies have shown the presence of endosymbiotic bacteria of the genus *Wolbachia* in the adult filarial worms. *Wolbachia* are required for the homeostasis of their hosts. Destruction of these bacteria by drug intervention results in profound effects on the development, viability and fertility of the adult parasite. The role of these bacteria in the pathogenesis of filariasis and the inflammatory episodes is currently under investigation.

CLINICAL FEATURES

The incubation period is from 5 to 12 months. There are acute and chronic clinical manifestations.

ACUTE MANIFESTATIONS

Attacks of adenolymphangitis (ADL) are the commonest acute clinical manifestations, which may occur both in the early and late stages of the disease. These are characterized by fever, lymphangitis, lymphadenitis or epididymo-orchitis. Fever is usually moderate and intermittent but sometimes it may be high, associated with severe rigor, sweating and delirium. The affected area is painful, tender, warm, red and swollen. Inguinal, axillary and epitrochlear lymph nodes, lower and upper limbs or genitalia are frequently affected. In *B. malayi* infection genital involvement is rare, and lower limbs below the knee and upper limbs below the elbow alone are involved. These acute ADL attacks recur many times a year in patients with lymphedema. Common sites for lymphangitis are the inner aspects of the thighs, legs, and arms. Repeated episodes of lymphangitis lead to distal edema, which resolves initially but later on tends to persist. Other acute manifestations are funiculitis, orchitis and epididymitis. Rarely scrotal pain, abscess formation in the breast in females or lymphadenitis in the abdomen resembling a picture of acute appendicitis or psoas abscess may occur. Hematuria, usually microscopic is seen sometimes in patients with microfilaremia.

Acute manifestations directly caused by adult worm death are usually rare and they occur when the adult worms are destroyed in the body either spontaneously or by drugs like diethylcarbamazine or albendazole. These true attacks of *acute filarial lymphangitis* (AFL) are characterized by formation of small tender nodules at the location of adult worms either in the scrotum or along the lymphatics in the limbs. Lymph nodes may become tender. Inflamed large lymphatics may stand out as long tender cords underneath the skin, usually along the lateral aspect of chest or upper arm and axilla associated with painful restriction of movement of affected limb. Unlike ADL, these episodes are not associated with fever, toxemia or evidence of secondary bacterial infection.

Manifestations of lymphatic filariasis	
1. Early silent phase:	Clinically asymptomatic Microfilaria present in peripheral blood Dilatation of lymphatics demonstrated by ultrasonography and lymphoscintigraphy
2. Acute manifestations:	Acute adenolymphangitis Acute epididymo-orchitis, funiculitis Acute onset hydrocele due to inflammation Abscess formation Acute abdominal lymphadenitis Hematuria
3. Chronic manifestations:	Lymphedema/elephantiasis of extremities, genitalia and breasts Hydrocele Lymph scrotum Chyluria, Chylocele, Chylous ascites Lymph node enlargement Lymphadeno-varix

Chronic Manifestations

The commonest permanent sequel of the disease is lymphedema, which may be pitting on pressure in the early stages. But in later stages it is non-pitting leading on to elephantiasis, which may attain enormous sizes. Lower limbs, external genitalia in males and upper limbs are affected in the order of frequency. In females, the breast and the genitalia may develop elephantiasis at times. This feature is rare in India. Repeated ADL episodes are responsible for the progression of lymphedema.

Hydrocele of the tunica vaginalis is a common manifestation resulting from involvement of the para-aortic group of lymphatics. The skin of the scrotum may be covered with vesicles distended with lymph giving a soft velvety feel known as lymph scrotum. Chylous ascites and chyluria, often associated with hematuria may result from rupture of dilated peritoneal or perirenal lymphatics. Spongy lymphadeno-varix is another chronic manifestation. In this condition, the lymph nodes, usually in the groin are enlarged, soft and spongy, the swelling becoming prominent in erect posture. Usually there is associated lymph scrotum, chylocele or chyluria.

Lymphatic Filariasis in Children

Infection acquired in childhood: It is now known that filarial infection is first acquired mostly in childhood. Lymphedema of the limbs, hydrocoele and ADL attacks are known to occur in children and young adults in endemic areas. Recent studies have indicated the extent of microfilaremia and circulating filarial antigens in children aged 3 years and above. Lymphoscintigraphy has demonstrated lymph vessel dilatation and ultrasound has shown presence of adult worms in lymph nodes and lymph vessels in children. The current understanding is that lymphatic dilatation once established is irreversible and promotes future progression of the disease. Most children with microfilaremia or lymph vessel dilatation are asymptomatic. Acute ADL attacks and lymphedema are later manifestations, which may be the first clinical presentation.

Diagnosis

The diagnosis is evident when a patient presents with unilateral or asymmetrical bilateral edema of the limbs of long duration associated with recurrent febrile episodes of lymphangitis in an endemic area or if there is history of residence in an endemic area. But diagnosis of filarial infection is not possible clinically in the early asymptomatic phase. The following tests help in the diagnosis of lymphatic filariasis in its various stages.

Differences between chylous and pseudochylous urine		
Characteristics	Chylous urine	Pseudochylous urine
a. Appearance	Milky	Cloudy
b. On keeping for hours	Fat containing high triglycerides float on top	Pus and debris settle in the bottom
c. Triglyceride content	>110 mg/dL	<110 mg/dL
d. Mixing with ether, or other fat solvents	Fat dissolves, urine becomes relatively clear	No change
e. Microscopy	RBCs, lymphocytes, fat, microfilaria	Cellular debris, pus cells or malignant cell

Microfilaria Detection Tests

Due to the periodicity of the parasite, mf are detected usually by examination of peripheral blood at night. They are detectable in the early stages of the disease even before clinical manifestations develop. Once lymphedema develops microfilaria are rarely seen in the peripheral blood. But hydrocele may be associated with microfilaremia.

Examination of a blood smear obtained by finger prick method from the patients between 10 PM and 2 AM and stained with Leishman or Geimsa stain helps in the identification of the parasite and species. Motile mf are generally seen in fresh thick wet films and this helps in rapid diagnosis. Concentration methods and techniques to filter the mf through nuclepore membrane filters are available to enable easy detection even when mf counts are low and also to quantify the load of infection.

A moderate rise in eosinophils (up to 20 %) is usually present, though this is not invariable. Chylous urine and hydrocele fluid may show microfilaria.

Sometimes pyuria with disintegration of the cells may superficially appear milky. This is termed pseudochylous urine.

Histological examination of lymph nodes or swellings may reveal the adult worms.

Immunochromatographic Test (ICT)

Both card and ELISA based ICT are highly specific and sensitive for the diagnosis of *W.bancrofti* infection. This is a filarial antigen detection test, which can be done on blood collected even during daytime. This test is positive in early stages of the disease when the adult worms are alive and becomes negative once the worms are dead. This test is not currently available commercially.

For *B. malayi* infection a recombinant antigen-based ELISA and its modification, the ‘Brugia Rapid’ dipstick test, are currently available. This test detects filariasis specific IgG4 antibody in *B. malayi* infection. Both these tests are highly sensitive and specific.

Ultrasonography: Live *W.bancrofti* adult worms can be visualized in the scrotal lymphatics of microfilaremic males by ultrasonography using special techniques. ‘Filarial dance sign’ is the demonstration of the wriggling movements of the live adult worms on ultrasonography.

Lymphoscintigraphy: Another imaging modality of the lymphatics is lymphoscintigraphy. This procedure has shown dilatation of lymph vessels in the limbs of amicrofilaremic, asymptomatic individuals including children. Lymphoscintigraphy is also useful in advanced lymphedema to delineate the pathology in the lymph channels and to determine their patency to plan lympho-venous shunt procedures (Figs 70.8 and 70.9).

Even though several tests are available for laboratory diagnosis, in the present situation in India, the diagnosis has to be arrived at by clinical findings, geographical considerations and probability. The fact that microfilaria are seen in the night blood only in the asymptomatic phase and that too in around 30% of the cases, makes early diagnosis difficult.

Definite differentiation between filariasis due to *W.bancrofti* and *B.malayi* is possible only during the early

Fig. 70.8: A normal lymphoscintigram of the lower and upper limbs after injecting Tc99m tagged Sulphur colloid in the interdigital spaces. The inguinal and axillary lymph nodes are imaged. Normal lymph vessels are not visualized

asymptomatic microfilaremic phase, by examining the morphological characteristics of the microfilaria. The ICT helps in the diagnosis of *W.bancrofti* infection when the adult worms are alive. The table below lists some of the differences between the diseases produced by these two species.

Differences between <i>W.bancrofti</i> and <i>B.malayi</i> infection		
Characteristics	<i>W.bancrofti</i>	<i>B.malayi</i>
a. Global prevalence	106.2 million	12.9 million
b. Global distribution	Tropical regions of Asia, Africa, China, Pacific and Americas	China, India and other South-East Asian countries
c. Distribution in India	12 States and Union Territories	7 States only
d. Incubation period	5 to 12 months	2 to 12 months
e. Sites of involvement	Extremities, Genitalia and breasts	Only extremities: Lower limbs below knee Upper limbs below elbow
f. Immunology tests	ICT card test and ELISA for circulating filarial antigen	Brugia Rapid and ELISA for filariasis specific IgG4
g. Sensitivity to drugs	Less sensitive to DEC	More sensitive to DEC

Mixed infections by both the parasites are encountered occasionally in some endemic regions where both are

Fig. 70.9: Lymphoscintigram showing dilated lymph vessels in both legs of a child with asymptomatic microfilaremia. Dilation of the lymph vessels is caused by the adult worms

known to co-exist, while blood is examined for microfilaria. The diagnosis of mixed infection is possible only at this stage since mf are not generally seen once symptoms appear.

Differential Diagnosis

Filarial aetiology should be considered in the differential diagnosis of the following clinical situations:

- Repeated or single attacks of lymphangitis, lymphadenitis or cellulitis
- Unilateral or asymmetrical bilateral swelling of limbs
- Swelling of the scrotum, funiculitis, epididymo-orchitis
- Fever with chills, rigor and delirium
- Persistent eosinophilia

Lymphedema and elephantiasis are also known to occur in other conditions where there are congenital anomalies of the lymphatics, following irradiation to the lymph nodes for treatment of malignancies or following surgical excision of the lymph nodes. Lymphedema of the legs simulating filariasis may also be seen in late stages of carcinoma cervix or carcinoma of the prostate with pelvic floor secondaries. Rarely still, damage to the lymphatics following absorption of particles like silica in certain geographic areas also result in lymphedema. In all the above situations where there are abnormalities in the lymphatics, recurrent ADL episodes are known to occur in the affected limbs due to secondary bacterial infections, thus worsening the edema leading on to elephantiasis, indistinguishable from that of filarial etiology.

MANAGEMENT

Treatment of lymphatic filariasis is described under following heads:

1. Use of drugs acting against the parasite
2. Treatment and prevention of acute ADL attacks
3. Treatment of lymphedema, elephantiasis and hydrocele
4. Control and prevention of filariasis

Drugs acting against the filarial parasite:

There are three drugs now available in this group:

- a. Diethyl carbamazine
- b. Ivermectin
- c. Albendazole

a. Diethyl carbamazine (DEC) is the drug of choice, which is effective in destroying microfilaria even in single annual doses of 6 mg/kg. It is easily available, effective, cheap and has a high safety profile. DEC is shown to kill only over 50% of the adult worms in those who harbor them. By ultrasonography it is shown that even single doses of DEC kill the adult worms when they are sensitive to the drug. If insensitive, even repeated doses do not produce any effect on the adult parasite. This drug does not act directly on the parasite and its action is mediated through the host immune system.

The earlier recommended dose of this drug was 6 mg/kg given daily for 12 days. The rationale of this dosage is under scrutiny in the light of above recent observations. The sustained microfilaricidal effect of this drug even in annual single doses makes it a good tool to prevent the transmission of this disease. The adverse effects produced by the drug in patients with microfilaremia are due to the rapid destruction of the mf and are associated with fever, headache, myalgia, sore throat or cough lasting for 24 to 48 hours. They are usually mild and self-limiting, requiring only symptomatic treatment with analgesic and antipyretic drugs. Direct adverse effects related to the drug are very rare. DEC is known to produce unpleasant side effects in microfilaremia of *O. volvulus* and *Loa loa* infections.

DEC is indicated when there is active filarial infection as evidenced by presence of microfilaria in blood or in hydrocele fluid, demonstration of adult worms by ultrasonography or positive antigen/antibody tests. Single dose of 6 mg/kg is as effective as the 12 days dose both against microfilaria and adult worms. In cases of established lymphedema and ADL, usually there are no adult worms or microfilaria. Recent studies have clearly shown that the ADL attacks respond promptly to antimicrobials and local treatment and that the role of specific antifilarial drugs is not substantiated.

DEC is also the drug of choice in the treatment of tropical eosinophilia syndrome where the drug is to be given for longer periods of 3 to 4 weeks.

b. Ivermectin: This drug acts directly on the microfilaria and in single oral doses of 200 to 400 µgm/kg keeps the blood mf counts at very low levels even at the end of one year. The adverse effects noticed in microfilaremic patients are similar to those produced by DEC but milder due to the

slower clearance of the parasitemia. Ivermectin is not effective against the adult parasite, during ADL attacks or in tropical eosinophilia. So this drug has no role in the treatment of clinical manifestations of lymphatic filariasis. Other benefits of ivermectin are clearance of lice infestation, scabies and some of the intestinal helminths.

c. Albendazole: When given in doses of 400 mg bid for two weeks, this drug is shown to destroy the adult filarial worms, inducing severe scrotal reactions which is the common site in where the adult worms are killed.

Albendazole has no direct action against the microfilaria. But when given in single dose of 400 mg in combination with DEC or ivermectin, the microfilaricidal action of the these drugs becomes more pronounced and sustained. Because of this effect and its action against many intestinal nematodes, albendazole combination with DEC or ivermectin is currently recommended for the Global Programme for the Elimination of Lymphatic Filariasis.

Use of antibiotics against Wolbachia: Studies in animals and recent trials in humans indicate that treatment targeted at Wolbachia, which are intracellular symbionts in the filarial worms may be useful to destroy the adult parasites. Treatment with tetracycline and doxycycline daily for 4 to 6 weeks results in elimination of the bacteria with profound effects on the adult worms like dysembryogenesis and death.

The utility of this form of treatment in lymphatic filariasis is still under trial.

Treatment and Prevention of Acute ADL Attacks

Systemic antibiotics, particularly ampicillin-cloxacillin combination should be instituted. Microbiological examination of the local infective sites help to select the suitable antibiotic. Attention to local site of entry of the organisms is important. Bed rest, analgesics and NSAIDs give symptom relief.

Prevention of further attacks is crucial to reduce the morbidity and economic loss from this disease. Proper foot-care has to be instructed to all patients. We have found the following regimen to be very effective, giving statistical significant results.

- i. The feet should be washed with soap and water daily and wiped dry before going to bed, with special attention to the interdigital folds, cracks and abrasions. Presence of moisture in inter digital spaces promotes fungus infections and excoriation of skin inducing ADL.
- ii. Keep the nails short, clean and promptly clipped.
- iii. Antiseptics such as povidone iodine or chlorhexidine ointment should be applied over cuts and wounds. Antifungal drugs like Whitfield's ointment or clotrimazole cream should be applied over sites predisposed to fungal infection.
- iv. Proper footwear should be worn.

- v. Edematous limb should be kept elevated during sleep.
- vi. Light exercise of the affected limb promotes lymph drainage.

Local care will not be perfect when there is gross elephantiasis with excrescences, warty growths and so on. Such cases may benefit from short or long term systemic antimicrobial therapy.

Treatment of Lymphedema, Elephantiasis and Hydrocele

Use elasto-crepe bandage or tailor made stockings while ambulant. The patient should be instructed to apply the bandage effectively. ADL should be prevented by proper foot hygiene measures.

There are various surgical options like lymph node-venous shunts, omentoplasty and excisional surgery available for established cases of elephantiasis. In elephantoid scrotum and breasts, the thickened skin and subcutaneous tissue can be surgically excised and reconstructed.

Surgery for hydrocele: Surgery is the treatment of choice for patients with persistent hydrocele due to filariasis.

CONTROL AND PREVENTION OF FILARIASIS

Once the clinical disease is established lymphatic filariasis cannot be cured. This is due to the irreversible damage to the lymph vessels caused by the adult worms. So prevention assumes great importance. **The Global Programme for the Elimination of Lymphatic Filariasis**, which has been started in countries with endemic filariasis, from 2000 AD consist of two arms.

- i. Mass chemotherapy using combinations of either DEC or ivermectin with albendazole in single annual doses for 4-6 years or regular use of DEC medicated cooking salt and
- ii. Alleviation of disability in those who have the disease.

Annual mass treatment with the above drug regimens for prolonged periods reduces the microfilaria counts to very low levels, thereby reducing the transmission rate. Mosquito control measures have to be instituted on a long-term basis. Personal protection against mosquito bites can be achieved by the use of bed nets and insect repellents.

Important points

1. Adult worms are responsible for the basic pathology. Microfilaria do not cause any symptoms.
2. Acute ADL attacks are caused by secondary bacterial infection and not by the adult worms.
3. Acute filarial lymphangitis due to adult worm death is very rare.
4. In chronic disease neither the adult worms nor microfilaria are usually present.
5. Once established the pathology cannot be reversed by treatment with antifilarial drugs.
6. Mass drug administration is a feasible way to control transmission of lymphatic filariasis.

Loiasis

Loa loa is prevalent in West and Central Africa and this is commonly known as the African eye worm. The adult worms migrate in the subcutaneous tissues of several parts of the body including the eyes. Adult female measures 70 mm in length whereas the male measures only 30 mm. The thickness ranges from 0.3-0.4 mm. They live for 10-15 years. Sheathed microfilaria are produced and these appear in the blood during day time. This infection is transmitted by *Chrysops* (*C. silacea* and *C. dimidiata*), which act as vectors. In many endemic areas monkeys form the reservoir.

The disease manifests as Calabar swellings, which are recurrent localized allergic inflammatory swellings. The swellings may overlie the adult worms at times. They commonly appear over the limbs or trunk. When the eyes are affected, intense lacrimation and pain may result. The adult worm may be seen in the eye during its subconjunctival migration. Endomyocardial fibrosis is more prevalent in areas endemic for loiasis. Rarely the microfilaria invading the nervous system may result in encephalitis, myelitis or focal seizures. The examination of CSF may show the larvae. Diagnosis usually clinical, is confirmed by demonstrating the characteristic microfilaria in the blood during daytime. Eosinophilia is invariably present.

Treatment consists of the administration of diethyl carbamazine, which kills both adults and microfilaria. The dose is 6 mg/kg given for 14 days. Treatment with this drug may produce severe reactions, including encephalitis, in people with heavy microfilariaemia. So ivermectin or albendazole are suggested for initial treatment of patients with high microfilaria counts.

Onchocerciasis

Syn: African river blindness

This is a cutaneous form of filariasis caused by *Onchocerca volvulus* prevalent throughout tropical Africa, Mexico, Guatemala, Eastern Venezuela and Northern Brazil. This disease has not been identified in India.

The female worm measures 35 - 70 cm and the male 2-3 cm in length. The adult worms lie tangled together in the subcutaneous nodules and they live for 7-15 years. The microfilaria, which are unsheathed, are widely distributed in the adjacent skin. The vectors are female black flies belonging to the genus *simulium*.

Pathology

The lesions are caused by the microfilaria. Inflammatory and allergic processes play their roles in pathogenesis. The adults form local granulomas, which appear as subcutaneous nodules. The microfilaria are distributed around these nodules. Their extent and density vary. Dead

or dying microfilaria are responsible for the pathological changes occurring in both anterior and posterior chambers of the eye leading to permanent blindness. The role of *Wolbachia*, obligate intracellular bacteria of filarial parasites, in the causation of ocular pathology is under investigation.

Clinical Features

The adult worms give rise to subcutaneous nodules, which are 0.5-5 cm in diameter. These are firm, non-tender, freely movable and are most commonly seen around the head and shoulders or the pelvic girdle. The skin manifestations are intensely itchy lesions, which in the early stages are seen as papulo-erythematous rashes. Later, the skin becomes thickened, hyperkeratotic (crocodile skin) and depigmented. The penis and scrotum may show elephantoid changes.

Ocular lesions develop especially if the adult worms are numerous over the head and neck. These are punctate keratitis, iridocyclitis and rarely choroidoretinitis, all of which ultimately lead to blindness.

Diagnosis

Demonstration of microfilaria in the skin shavings or skin snips taken from the affected area or the adults in biopsy of the nodules, establishes the diagnosis. Antifilarial antibodies may be detected in 95 percent of cases.

Treatment

The microfilaria are rapidly destroyed by diethyl carbamazine but the drug is ineffective on adult worms. The drug is started in a low dose and gradually worked up to 100 mg given thrice daily for 7-10 days. Severe allergic reactions may complicate the initial phase of therapy. Diethyl carbamazine is no more used in the treatment of onchocerciasis due to the severe systemic and ocular reactions induced by rapid destruction of microfilaria.

Presently **ivermectin** is the drug of choice for the treatment of onchocerciasis. Ivermectin given in a single dose of 150- 200 µg/kg body weight orally is very effective in destroying microfilaria and clearing the systemic and ocular lesions. Thereafter the drug dose is repeated every 6 months or yearly intervals. In the vast majority lesions clear up within six months. This drug is safe and side effects due to destruction of microfilaria are mild and do not adversely affect the eyes.

The drug suramin, a complex urea derivative, is effective against the adult worms. It is given intravenously in doses of 1 g weekly for five to six weeks. Due to complexities of dosage and toxic effects like renal damage this drug is not routinely used.

Recent animal and human studies have indicated that tetracycline or doxycycline given for 6 weeks has macrofilaricidal effect. This is due to the action of these drugs in clearing *Wolbachia* bacteria, endosymbionts of *O. volvulus*.

Ocular lesions have to be treated with mydriatics and topical steroid applications. The adult worms are removed by excision of nodules wherever they are accessible.

Control of infection in endemic areas is achieved by antivector measures, personal prophylaxis and recently, mass therapy for endemic population. Regular administration of ivermectin 150- 200 µg/kg repeated every 6 months or yearly intervals helps to reduce microfilaria rates and transmission from person to person.

Other Filarial Infections

MANSONELLA PERSTANS

This parasite is prevalent in central Africa, South America and the Caribbean. Adults are seen in the subserosal layer of viscera. The pleura, pericardium and peritoneum are involved. In many cases the mesentery is a frequent site. The microfilaria are unsheathed, non periodic and are demonstrable in blood. The vectors are the blood sucking midges-*Culicoides*. Though in the majority of cases infection is asymptomatic, some cases may develop fever, pruritus, skin rashes and abdominal pain. Demonstration of the microfilaria in peripheral blood confirms the diagnosis.

Treatment

Diethyl carbamazine is generally ineffective. Repeated doses of ivermectin effectively reduce the blood microfilaria levels. Success has been reported with mebendazole given in a dose 100 mg twice daily for 30 days and albendazole 400 mg twice daily for 10 days.

MANSONELLA STREPTOCERCA

It is prevalent in parts of Africa. It is transmitted by *Culicoides*. Adult worms are seen in the dermis and subcutaneous tissues. The microfilaria are nonperiodic and they are seen surrounding the adult worms and are demonstrable in skin snips taken from the lesions. Clinical features consist of pruritic papular rashes, edema and hypopigmentation. This worm responds to diethyl carbamazine in the usual doses. Ivermectin 150 µg/kg single dose causes sustained suppression of microfilaremia.

MANSONELLA OZZARDI

This infection has been reported from the tropical regions of South America. Adult worms are found in the visceral

adipose tissue. Microfilaria are nonperiodic and are seen in peripheral blood. Vectors include *Simulium* and *Culicoides*. In the majority of cases this infection is nonpathogenic, though fever, lymphadenopathy and erythematous skin rashes may occur at times. Treatment with diethyl carbamazine is generally ineffective. Single dose of ivermectin is shown to be effective in the treatment of this infection.

Dracontiasis

Syn: Guinea worm, Serpent worm, Dragon worm

Infection by *Dracunculus medinensis* used to be seen in several endemic pockets in India, Pakistan, Iran, Middle East, West Indies, South America and East, West and Central Africa. In India the disease was common in Punjab, Madhya Pradesh, Gujarat, Maharashtra, Andhra Pradesh and Tamil Nadu. At present India has been declared disease-free by the WHO. Endemic pockets are present in some African countries.

Morphology and Habitat

Adult male is 2.5 cm long and is short lived. The female worm is 60-100 cm long and 1.5-1.7 mm in diameter, cylindrical, white and is viviparous. The posterior end is tapering and hook-shaped. Opening of the uterus is at the anterior end. Adult females may live up to one year. Larvae are discharged in batches when the anterior end of the worm comes in contact with water.

Life Cycle

The larvae are taken up by fresh water cyclops, belonging to the family *crustacea* and these form the intermediate hosts. The larvae become infective to man in 10 days. Man gets infected by ingesting the cyclops in water. The larvae are liberated in the intestine and these migrate to the subcutaneous connective tissues to grow into adults in 9-18 months. After fertilization, the females come to lie subcutaneously under those parts of the body, which come in contact with water. A blister develops in the skin where the anterior end of the worm lies, which breaks down to form an ulcer. When the part comes in contact with water the worm protrudes its anterior end through the ulcer and discharges a milky fluid containing a large number of larvae. Over a period of 3 weeks the worm is extruded and the ulcer heals. Infection is generally acquired when the drinking water source is infested with cyclops and people with open lesions contaminate it.

Clinical Features

Initial symptoms include urticaria, eosinophilia, wheezing, nausea, vomiting and diarrhea. Formation of the blister is accompanied by local pain, itching and inflammation. The tissue around the blister may become red, tender, and edematous. Secondary infection of the ulcer is common. Periarthritis and pyoarthrosis may occur if the worms are in the neighborhood of joints. The ulcer may even act as a portal of entry for *Clostridium tetani*. Sometimes the female worm may be palpable in the subcutaneous tissue. Worms that fail to reach the surface die and get calcified. Aseptic abscesses may develop around the worms.

Diagnosis

It is easy to diagnose if the worm is seen in the center of the ulcer, which is characteristic. The worm can be induced to discharge the larvae by applying water over its anterior end. Under the microscope the motile larvae are demonstrable in the discharge from the ulcer. X-ray may demonstrate calcified worms. Blood shows eosinophilia.

Treatment

Local dressing and administration of antibiotics serve to minimize local infection. Removal of the worm is achieved mechanically. The worm is induced to discharge its larvae in water for a few days by which process it protrudes more and more. As the anterior end comes out progressively it is tied with a fine silk thread and rolled up over a matchstick till it is extracted fully over a course of 15-20 days. Live worms are easier to extract. If the worm breaks and its anterior end retracts, the track is likely to be infected. Surgical measures are indicated when conservative treatment fails.

Drug Therapy

Thiabendazole given in a dose 25 mg/kg for 3 days or metronidazole 400 mg daily for 10-20 days offer relief of symptoms, but do not kill the adult worms.

Prevention

The transmission of *D. medinensis* can be interrupted by public education; avoidance of contamination of drinking water source by persons with infective lesions; vector control by chemical treatment of water source and boiling or proper filtration of drinking water. India launched the National guinea worm eradication programme in 1984 with technical assistance from WHO. Since 1996 no fresh case has been reported.

Chapter Summary

Multiceps Multiceps	421
Intestinal Capillariasis	421
Anisakiasis	421
Angiostrongyliasis	421
Gnathostoma Spinigerum	421
Sparganosis	422

Sporadic cases of exotic helminthic infections are reported from time to time, man being accidentally infected by helminths parasitizing animals. These include *multiceps*, *intestinal capillariasis*, *anisakiasis*, *angiostrongyliasis*, *gnathostomiasis* and *sparganosis*.

Multiceps Multiceps

This is a tapeworm, the adults of which live in the intestines of dog. The larvae (bladder worm) are seen in the brain of sheep and other herbivores-*Coenurus cerebralis*. Accidentally man may be infected when the brain or eye harbor the larvae.

Intestinal Capillariasis

This has been described from Thailand and Philippines. The adults (*Capillaria philippinensis*) parasitize birds. Fish and crustaceans are the possible intermediate hosts. Infection is acquired by eating raw or partially cooked intermediate hosts. The larvae mature and live in the crypts of the small intestines. They multiply in large numbers and lead to malabsorption state or protein losing enteropathy. Eggs are passed in feces and their identification helps to establish the diagnosis. Prolonged treatment using mebendazole and albendazole is effective.

Anisakiasis

This is caused by *Anisakis* species, which are intestinal nematodes of marine animals. Several species of fish act as intermediate hosts and infection occurs by eating raw or partially cooked fish. Cases have been reported more often from Japan, Netherlands and Scandinavia. The larvae penetrate the stomach wall or intestinal wall, giving rise to pain and symptoms, sometimes simulating acute abdomen. No drug is effective against this parasite. Albendazole is reported to be useful.

Angiostrongyliasis

Man may become infected by *Angiostrongylus costaricensis* or *Angiostrongylus cantonensis*. Adults parasitize several species of rats. *A.costaricensis* is described from central and South America. Man acquires the infection by eating mollusks, which act as the intermediate hosts. Symptoms include abdominal pain, which may even resemble acute abdomen.

A. cantonensis is described from Far East and also from India. Man gets infected by eating molluscs, prawns or crabs, which harbor the larvae. The larvae migrate in tissues. Some reach the brain to give rise to meningitic symptoms. Spinal fluid may show lymphocytes and eosinophils. In the vast majority the disease is self-limiting.

There is no specific treatment available. Angiostrongyliasis can be prevented by proper cooking of crabs, prawns and molluscs before consumption.

Gnathostoma spinigerum

This is an intestinal nematode affecting dogs and cats. The intermediate hosts are fish, which when consumed uncooked leads to human infection. Infection is reported

Diseases Caused by Infections

from Far East, especially Thailand. The larvae do not develop into adults in man, but migrate and lead to the development of eosinophilic granulomas, mostly seen in subcutaneous tissue and brain. Eosinophilia may develop. CNS involvement leads to neurological features. Biopsy of subcutaneous nodules may help to give a histological diagnosis. Serological diagnosis can be made by ELISA testing. Treatment with Ivermectin 200 µg/kg for two days and albendazole 400 mg twice a day for 21 days is effective.

Sparganosis

Sparganum is the second larval stage of tapeworms of the genera *spirometra* and *Diphyllbothria* that are common

in various canines and felines. The ova are ingested by cyclops and the first stage larvae (*proceroids*) develop in them. The *sparganum*, which is the second stage larva, develops in frogs, crustacea and fishes that ingest cyclops. Man may acquire sparganosis by ingesting infected cyclops or by the application of infected frogs or fish as poultices over wounds or inflamed eyes. The condition is seen in Far East. The larva (*Sparganum mansonii*) grows and forms a cyst, which appears as nodular lesion. Treatment is to remove the nodules surgically.

Chapter Summary

- General Considerations 424
- Disorders of Sodium and Water Balance 425
- Disorders of Potassium Homeostasis 427
- Disorders of Calcium 431
- Disorders of Magnesium Homeostasis 433

General Considerations

Water constitutes approximately 60% of body weight. As fat contains less water, obese persons have proportionately less body water compared to lean individuals. Thus, the proportion may vary from 80% in the newborn to 60% in lean and young males and 40% in obese and elderly women. The water in the body is distributed in 2 major compartments, intracellular fluid (ICF) 66% and extracellular fluid (ECF) 34%. The ECF compartment is further subdivided into interstitial fluid (65%), intravascular fluid (25%) and transcellular fluid (10%). In the intravascular compartment, only 10% is in the arterial system. Majority of the fluid is distributed in the capillary system (55%) and venous system (35%). About 10% of extracellular fluid is distributed as CSF, gastrointestinal fluid, serosal fluid, fluids in the eye and others. This is the 'transcellular' fluid. The intracellular fluid constitutes the remaining part of the body water. The composition of the fluid in the intra and extracellular compartment are markedly different.

The total number of anions and cations are equal in all these compartments. Sodium (Na⁺) is the predominant extracellular cation and potassium is the most abundant intracellular cation. The intracellular concentration of magnesium (cation) is also high. Chloride and bicarbonate are the major anions in the extracellular compartment. Phosphates, sulphates and protein contributes to the anions of the intracellular fluid compartment (Table 72.1).

Water Homeostasis

Under normal circumstances, water intake and water elimination are equal and the osmolality of the body fluids

TABLE 72.1

Composition of intra and extracellular fluid compartments		
Substance	ICF	ECF
1. Sodium Na ⁺	10 mmol/L	140 mmol/L
2. Potassium K ⁺	150 mmol/L	4 mmol/L
3. Chloride Cl ⁻	2 mmol/L	104 mmol/L
4. Bicarbonate HCO ₃	6 mmol/L	24 mmol/L
5. Calcium Ca ⁺⁺	50-100 nanomoles/L	2.25-2.65 mmol/L
6. Magnesium Mg ⁺⁺	0.5 mmol/L	0.75-1 mmol/L
7. Phosphates,	1.4 mmol/L	0.8-1.5 mmol/L

Note: For univalent ions the mEq and mmol are the same

is maintained. Water balance is regulated by formation of concentrated or dilute urine. The diluting mechanisms permit the excretion of up to 12-15 litres of urine daily whereas the urinary concentrating ability can achieve full elimination of the daily metabolic waste in as little as 500 mL urine. In health, the urine osmolality could vary from 50 and 1200 mosm/kg. The water intake is mainly regulated by the thirst mechanism. When the plasma osmolality increases by 3-5 mosm/kg, the osmoreceptors in the medulla oblongata are stimulated resulting in thirst. Hypovolemia, hypotension and angiotensin II are also stimuli for thirst. The antidiuretic hormone (ADH or vasopressin) regulates the concentration of urine. In the presence of ADH the collecting tubule becomes more permeable to water and more of water is reabsorbed leading to higher concentration of urine. When the fluid in the collecting tubule traverses the renal medulla, water is reabsorbed into the hypertonic medullary area through these permeable tubules. The increased permeability is achieved by the insertion of water channels called aquaporin channels into the cell membrane of the tubule cells. In addition to the renal losses which can be regulated to some extent, water loss occurs through the skin, lungs and gastrointestinal tract. The loss through the skin and lungs depends upon the climate, exercise and body temperature. Under normal circumstances, the gastrointestinal loss is approximately 120-160 mL per day. If

the daily water loss in a person remaining indoors with outside temperature of 32°C is 200 mL, the loss during heavy exertion outside at temperature over 40°C may be even 5–6 litres.

When there is excess water in the body, the volume expansion results in stretching of the atria, release of atrial natriuretic peptide and promotion of natriuresis and diuresis. The ADH secretion decreases. The collecting tubules become less permeable to water (the aquaporin channels are delinked from the cell membrane) and the dilute tubular fluid is passed out as urine. Thus, the excess water in the body is eliminated.

Sodium Homeostasis

In a healthy adult, the total body sodium is approximately 5,000 mEq. About 90% is in the extracellular compartment. The main function is to maintain the ECF volume, osmolality and blood pressure. Under normal circumstances, the salt intake and excretion are equal. The salt intake of individuals or communities is highly variable. The daily salt requirement is about 6 g or 100 mEq (one level teaspoon = 6 g). In addition to the diet, sodium intake could occur through parenteral fluids or sodium containing drugs. Sodium concentration in the sweat is low. Significant sodium loss could occur in those with excessive sweating and in diarrhea. In health, the kidney is the main route for elimination of ingested sodium. In diseases, sodium loss could occur through other sources also.

Sodium is freely filtered by the glomerulus. The concentration of sodium in the glomerular filtrate is the same as in blood. As the filtrate traverses the proximal tubule, 60–65% of sodium and water are reabsorbed. Thus, the glomerular filtrate remains iso-osmotic at the end of proximal tubule. The next segment contributing to sodium reabsorption is the thick ascending limb of the loop of Henle where the negatively charged chloride (Cl^-) is actively reabsorbed. The sodium-potassium-2 chloride co-transport pump is active in this segment. Sodium (Na^+) which is positively charged accompanies the chloride so as to maintain the electro-neutrality. About 25–30% of sodium is reabsorbed here. As this segment of the tubule is impermeable to water, the fluid leaving the loop of Henle is hypo-osmolar (osmolality < 100). The remaining 10% of the sodium reabsorption occurs in the distal tubule and collecting duct. The reabsorption here is mediated through sodium and chloride co-transporter and $\text{Na}^+ \text{K}^+ \text{ATPase}$. This reabsorption is regulated by aldosterone which causes reabsorption of sodium in exchange for potassium. The fine tuning of the sodium excretion occurs in these segments. Thus, the urine may contain only < 1% of the filtered sodium. In those with high salt intake and normal renal sodium regulation, the urinary sodium excretion will be high.

The controlling mechanism for renal sodium excretion is mediated through afferent and efferent limb. The afferent impulses are from the receptors in atria and pulmonary vascular bed. Activation of these receptors by distension, stretching or pulmonary congestion cause decrease in sympathetic outflow, decreased renal sympathetic tone and natriuresis. Conversely, low central venous pressure leads to sympathetic stimulation and sodium reabsorption. The efferent limb consists of the sympathetic system, hormones and the forces acting on the starling equilibrium. The ‘Starling forces’—the capillary hydrostatic pressure, tissue oncotic pressure, capillary oncotic pressure and tissue hydrostatic pressure play a significant role in the reabsorption of Na^+ in the proximal tubule. The sympathetic stimulation causes increased cardiac output, blood pressure, activation of renin angiotensin system and these enhance sodium reabsorption. The hormonal factors include angiotensin II, atrial natriuretic peptide, prostaglandins and arginine vasopressin.

Disorders of Sodium and Water Balance

The ECF fluid volume and osmolality are maintained in a narrow range despite wide variations in the intake of salt and water. Disorders in water balance result from abnormalities of concentrating or diluting capacity of the kidney. The major causes include renal disease, abnormalities in vasopressin release or action and defective thirst mechanism. Urinary concentrating ability is diminished both in central and nephrogenic diabetes insipidus (DI). Both present with polyuria and dilute urine. The other disorders of urinary concentration include renal insufficiency, solute diuresis, water diuresis, use of osmotic diuretics, loop diuretics, and severe protein malnutrition.

Urinary diluting capacity is diminished in conditions like renal failure, cirrhosis liver, nephrotic syndrome capillary leak syndrome, congestive cardiac failure and conditions associated with decreased arterial blood volume. Severe chronic hypokalemia, hypothyroidism and syndrome of inappropriate ADH secretion are other important causes.

Syndrome of inappropriate ADH (SIADH) release is a common cause of hyponatremia in hospitalised patients. Disorders of urinary dilution often manifest as hyponatremia.

Hyponatremia

Hyponatremia is a common problem in hospitalised patients and is defined as plasma sodium of less than 135 mmol/L. Before confirming the diagnosis of hyponat-

TABLE 72.2

Classification of hyponatremia based on ECF volume status

1. Hyponatremia with decreased ECF volume and low total body sodium (hypovolemic hyponatremia)
 - a. Due to renal losses
 - i. Diuretic use
 - ii. Salt losing nephropathy
 - iii. Osmotic diuresis
 - iv. Cerebral salt wasting
 - b. Due to extra renal losses
 - i. Vomiting
 - ii. Diarrhea
 - iii. Burns
 - iv. Pancreatitis—third space loss
 - v. Trauma
2. Hyponatremia with increased ECF and high total body sodium (hypervolemic hyponatremia)
 - i. Cirrhosis liver
 - ii. Congestive cardiac failure
 - iii. Nephrotic syndrome
 - iv. Advanced chronic renal failure
3. Hyponatremia with normal ECF and normal total body sodium (euvolemic hyponatremia)
 - i. Glucocorticoid deficiency
 - ii. Hypothyroidism
 - iii. Severe potassium depletion
 - iv. Postoperative administration of salt free fluids
 - v. Drugs such as antipsychotics, nicotine, tolbutamide, chlorpropamide, chlorpromazine, carbamazepine and others
 - vi. Syndrome of inappropriate antidiuretic hormone secretion (SIADH)

remia based on low plasma sodium level, **pseudohyponatremia** and **translocational hyponatremia** must be excluded. **Pseudohyponatremia** is a condition characterised by low serum sodium readings when plasma is tested in patients with hyperlipidemia and hyperproteinemia. This occurs because the ‘solid phase’ of plasma is increased and the sodium is low when the plasma is assayed. The osmolality is often normal. This fallacy can be overcome by using potentiometry which measures the true liquid based sodium. Substances like glucose, mannitol or glycine increase serum osmolality while decreasing serum sodium. For every 100 mg increase in blood glucose level, the serum sodium decreases by 1.6 mmols and is due to movement of water from the intra to extracellular fluid compartment due to high sugar. This is an example of **translocational hyponatremia**. Although there may be no symptoms till the level of sodium falls < 120, proper identification and appropriate treatment are necessary.

Hyponatremia could occur acutely (within 48 hours) or may be chronic (over 48 hours). It is classified depending on the ECF status (Table 72.2).

Hyponatremia with decreased ECF volume and decreased total body sodium occurs due to selective loss of intravascular fluid and extracellular fluid.

Hyponatremia with increased ECF volume and increased total body sodium occurs in conditions associated with fluid retention and edema. In these conditions, there may be sodium retention and increase in total body sodium and the disproportionately high water retention causes the hyponatremia. This is predominantly a ‘dilutional’ hyponatremia.

Hyponatremia associated with normal ECF volume and normal total body sodium is a common disorder. Although the ECF volume may be slightly higher, there is no edema and the water is distributed throughout intra and extracellular fluid compartments.

SYMPTOMS AND SIGNS

Most patients are asymptomatic and the diagnosis is based on low sodium levels detected by biochemical tests. The signs and symptoms depend on the rate of onset of hyponatremia and its severity. Mild and moderate cases are generally asymptomatic. Symptoms of acute symptomatic hyponatremia are due to cerebral edema. Cellular edema occurs because the intracellular compartment is hypertonic compared to ECF. Therefore water moves into the cells causing edema. When symptoms occur, they may be nonspecific and vague. Anorexia, lethargy, nausea and headache followed by muscle cramps, drowsiness coma and convulsions may occur.

The early clinical signs of hypovolemic hyponatremia include postural tachycardia and postural hypotension, dryness of the mouth, lack of sweating in axilla and poor skin turgor. The urine volume may be reduced and there may be elevation of urea and uric acid. Urinary sodium is more than 20 mmol/L in renal causes and less than 20 mmol/L in extrarenal causes of hypovolemic hyponatremia. Clinical edema occurs when more than 5 L of fluid accumulates in the interstitial fluid compartment.

Management of Hyponatremia

In acute symptomatic hyponatremia developing in < 48 hours aggressive correction is warranted in view of the possible complications due to cerebral edema. Correction should be done with normal saline or hypertonic (3%) saline. Total correction to ‘normal blood level’ of around 140 mmol/L is not necessary. Initially, hyponatremia may be corrected to achieve blood level of 120 mmol/L. The rate of correction should not be over 1.5-2 mmol/L/hour and the correction is given till symptoms improve or a correction of 10 mmol/L in 24 hours is achieved. It is not safe to correct hyponatremia by more than 10 mmol/L in 24 hours. The amount of sodium required can be calculated from the formula ($120 - \text{present serum Na}^+ \text{ level}$) $\times 0.6 \times \text{body weight in kg}$. 1 litre of 3% sodium chloride provides 512 mmol Na^+ and 1 litre of 0.9% sodium chloride (normal saline) provides 154 mmol of Na^+ . If a person weighing 54 kg has serum sodium 110 mmol/L and is symptomatic, the aim is to correct at 1.5 mmol/L/hr initially up to a maximum of 10 mmol/L per day. The

total volume of 3% sodium chloride to be administered is calculated as follows. Level of Na^+ to be achieved (120) minus present level of Na^+ , i.e.) $110 \text{ mmol} \times 0.6 \times 54 \text{ body weight (54)} = 324 \text{ mmols}$. This is contained in 630 mL of 3% saline. This amount of fluid should be infused within 16-24 hours.

In chronic asymptomatic hyponatremia, aggressive correction is not required. Aggressive correction of chronic hyponatremia may lead to osmotic difference between intra and extracellular compartments resulting in movement of water from intracellular to extracellular space. The changes of cellular dehydration manifest mainly in the CNS and present as osmotic demyelination syndrome (central pontine myelinolysis). Chronic symptomatic hyponatremia evolves in more than 48 hours. Correction must not be aggressive. Initial correction of 10% (approximately 10 mmol/L) is achieved over 24-48 hours. This is followed by correction at the rate of 1-1.5 mmols/L/per day. Hypertonic saline should be avoided. Fluid restriction is the mainstay in chronic asymptomatic hyponatremia. The underlying problems like hypothyroidism, adrenal insufficiency, SIADH or intake of drugs like lithium should be looked for and corrected.

Hypertatremia

Hypertatremia is a disorder of sodium and water homeostasis associated with serum sodium level of more than 145 mmol/L. It may be symptomatic or asymptomatic. Hypertatremia may occur when there is more water loss than sodium loss or more sodium gain than gain of water in the body. As in hyponatremia, hypertatremia can be associated with ECF volume contraction, ECF volume expansion or normal ECF volume (Table 72.3).

TABLE 72.3

Causes of hypertatremia

- A. Hypertatremia associated with low ECF volume (more water loss compared to sodium loss)
 - i. Hyperosmolar nonketotic diabetic coma
 - ii. Use of osmotic diuretic – mannitol
 - iii. Tube feeding with high osmolar fluid
 - iv. Hot humid weather, febrile convulsion, excessive sweating
 - v. Post-obstructive diuresis and recovering acute tubular necrosis (ATN)
 - vi. Gastroenteritis
 - vii. Peritoneal dialysis with high concentration dextrose solutions
- B. Hypertatremia with hypervolemia (higher salt intake compared to water)
 - i. Excessive intake of NaHCO_3
 - ii. Excessive infusion of normal/hypertonic saline
 - iii. Salt water drinking/drowning
- C. Hypertatremia with normal ECF volume (mainly due to loss of free water and defective thirst mechanism)
 - i. Central diabetes insipidus (DI)
 - ii. Nephrogenic DI
 - iii. Psychogenic/polydipsia

CLINICAL MANIFESTATIONS

Infants, elderly patients, those with underlying polyuria, hypertonic fluid infusions, osmotic diuretics, those on mechanical ventilation, or uncontrolled diabetes are at increased risk for hypertatremia. Since hypertatremia represents a hyperosmolar state, the signs and symptoms are related mainly to the CNS.

Since hypertatremia often occurs in hospitalised sick patients and in predictable clinical settings, careful monitoring and prevention is very important. The mortality in children due to acute hypertatremia varies ($50 \pm 20\%$). Many of the survivors may have long-term neurological sequelae. The mortality in chronic hypertatremia is about 10%.

Management of Hypertatremia

The primary aim of therapy is to restore the serum tonicity. If hypovolemic hypertatremia is associated with hypotension or orthostatic hypotension, initially these patients are given IV normal saline till the systemic hemodynamics and hypotension are corrected. Subsequently, administration of half normal saline (0.45% NaCl infusion) or 5% dextrose can be used to replace more water than sodium.

In hypervolemic hypertatremia, the aim is to eliminate the excess sodium but at the same time administering water. Use of diuretics combined with 5% dextrose IV can achieve this. Those with renal impairment may need dialysis because the response to treatment may not be prompt. In euvolemic hypertatremia, the water loss from the body is in excess of salt loss. These patients can be managed by 5% dextrose infusion or encouraging oral intake of plain water. the dietary sodium and protein are restricted. Thiazide diuretics cause more natriuresis than water diuresis. The correction of hypertatremia should be gradual and not at a rate greater than 1.5 mEq/L/hr and the total correction can be achieved over 48-72 hours.

Disorders of Potassium Homeostasis

Potassium (K^+) is the major intracellular cation. The body contains approximately 3,500 mmol of K^+ (roughly 50 mmol/ kg) and is distributed as 90% intracellular, 8% in bone and 2% is in the ECF and serum. The presence of K^+ in the ECF is critical for cellular depolarisation and the serum potassium is maintained between 3.5 and 5.5 mmol/L. The level of serum K^+ does not reflect the total body potassium. The average normal intake of potassium is 60-80 mmol/day. This is eliminated mainly through urine (80%), gastrointestinal tract (15%) and sweat (5%). Fruits, fruit juices, dry fruits, tender coconut water, beans, chocolates and vegetables are rich in potassium. Dietary potassium is absorbed and it is driven into the cells by insulin. The sodium potassium ATPase pump in the cell wall constantly shifts the potassium to the inside and sodium out of the cell. In the kidneys, the potassium is

completely filtered by the glomerulus. The potassium in glomerular filtrate is conserved or eliminated depending on the needs of the body. About 65-70% of potassium is reabsorbed in the proximal tubule. About 25% reabsorption that occurs is in the thick ascending limb of the loop of Henle and is mediated by the $\text{Na}^+ \text{K}^+ \text{Cl}^-$ co-transport system on the luminal side of the tubular cells. The fine control of renal potassium elimination occurs in the collecting duct. There are two types of cells in cortical collecting ducts—*The principal cells and the intercalated cells*. Principal cells are concerned with K^+ secretion. This is enhanced by increased luminal flow rate, sodium concentration, aldosterone and pH. In the intercalated cells, potassium reabsorption occurs in exchange for H^+ ions through the $\text{K}^+ - \text{H}^+$ ATPase. Thus, the normal kidney regulates the serum K^+ level. In hypokalemia, urinary loss of > 30 mmol/day reflects renal potassium wasting and in hyperkalemia urinary loss of < 30 mmol/day suggests primary renal disease.

Trans-tubular potassium gradient (TTKG) provides an indirect measurement of the net K^+ secretion in the distal nephron. It is calculated as follows:

$$\text{TTKG} = \frac{\text{Urinary potassium}}{\text{Serum potassium}} \times \frac{\text{Serum osmolality}}{\text{Urinary osmolality}}$$

Normal TTKG is 5 to 10.

In hypokalemia, if the kidney is functioning normally, the TTKG will be less than 5. If the TTKG is > 10 it suggests inability of kidney to reabsorb potassium and hypokalemia is due to primary renal disease, e.g. renal tubular acidosis (types I and II) and Bartter's syndrome.

In hyperkalemia if the kidneys are normal, TTKG will be more than 10. In hyperkalemia due to aldosterone deficiency or resistance to aldosterone, and in renal failure, TTKG will be less than 5 indicating inability of the kidneys to excrete K^+ ions.

HYPOKALEMIA

In hypokalemia, the serum potassium (SK^+) level is less than 3.5 mmol/L. In early stages, it is asymptomatic and is incidentally detected by investigations. Many conditions are associated with development of hypokalemia.

Common causes includes:

1. **Diuretic therapy:** Most diuretics except the K^+ sparing diuretics can lead to hypokalemia.
2. Pyloric stenosis and continuous gastric drainage will lead to HCl loss, alkalosis and volume contraction. Renin angiotensin—aldosterone axis is activated due to hypovolemia. Aldosterone causes sodium reabsorption and potassium excretion and leads to hypokalemia.
3. **Alcoholism:** The hypokalemia that occurs in alcoholism is due to poor intake, gastric loss due to vomiting and urinary loss.

4. **Renal tubular acidosis:** Both distal (Type I) and proximal (type II) are associated with urinary K^+ loss and hypokalemia.
5. **Antibiotic induced hypokalemia:** Antibiotics like penicillin, carbencillin and gentamicin cause hypokalemia due to excessive secretion of K^+ by renal tubules.
6. Amphotericin B produces type I (distal) RTA and hypokalemia.
7. **Hyperaldosteronism:** Any condition causing primary and secondary hyperaldosteronism causes hypokalemia.
8. **Bartter's syndrome,** a syndrome characterised by hyperreninemia, hyperaldosteronism, metabolic alkalosis and hypokalemia is associated with hyperplasia of juxtaglomerular apparatus. It is associated with failure to thrive, polyuria and muscle cramps.

Other conditions causing hypokalemia are acute leukemia, magnesium deficiency, chronic diuretic or laxative use, salt losing nephropathies, familial hypokalemic periodic paralysis, Cushing's syndrome, steroid therapy, ectopic ACTH secretion, insulin administration, use of Beta 2 adrenergic agonists (salbutamol) and metabolic alkalosis.

CLINICAL MANIFESTATIONS

Even though the laboratory report may show low levels of K^+ , most patients are asymptomatic till Serum K^+ levels are below 3 mmol/L. In hypokalemia, major manifestations are due to functional cellular abnormalities in skeletal muscle, smooth muscle, cardiac muscle and renal cells. Initially, the motor power is diminished particularly in the lower limbs. This is followed by weakness or paralysis. The deep tendon reflexes may remain normal initially. The severe myopathy may progress to rhabdomyolysis, myoglobinuria and acute renal failure. Paralysis of respiratory muscles may also occur. The manifestations relating to cardiac muscle involvement is more in digitalised patients or those with ischemic heart disease. The electrocardiographic changes are non-specific ST-T changes and more specific U wave changes (Fig. 72.1). In the kidney there is vacuolation of renal tubular cells, leading to polyuria, polydipsia, metabolic alkalosis, increased ammonia synthesis and increased acid excretion in urine. The presence of acid urine in the setting of metabolic alkalosis is called **paradoxical aciduria** and it is a common feature in hypokalemic states. The other renal manifestations include reversible renal failure due to the changes in the renal tubule, phosphaturia, hypophosphatemia, hypocalcemia and water retention. In hypokalemic states, the release of insulin from pancreas is blunted resulting in hyperglycemia. In the gastrointestinal system, severe hypokalemia, often associated with hypomagnesemia below 1 mg/dL, results in paralytic ileus.

Fig. 72.1: Hypokalemia—ECG.

Note: (1) Flat/inverted T waves, (2) Prominent U waves (3) Prolonged QT interval

MANAGEMENT OF HYPOKALEMIA

While attempting to correct hypokalemia, certain important guidelines are followed. The normal intake of about 60 mmol/day of potassium often prevents the development of hypokalemia. However, cardiac patients on long-term diuretics, digitalis therapy, those on large doses of steroids, ischemic heart disease, and postoperative patients may need higher potassium intake. Since potassium is an intracellular ion, serum potassium level does not truly reflect the total body potassium. One mmol/L fall in serum potassium level represents approximately a total body deficit of 200-400 mmol. If the serum potassium is <2 mmol/L the deficit may be > 600 mmol of potassium. Administration of potassium should be carefully monitored in those receiving potassium sparing diuretics, angiotensin converting inhibitors or angiotensin 2 receptor blockers, and patients with renal failure or oliguria and anuria since this can precipitate hyperkalemia. Oral route is sufficient in most situations. In severe hypokalemia, with paralysis, potassium is given as IV infusion.

Potassium should never be given as a bolus injection or rapid IV infusion since it may cause cardiac arrest and instantaneous death. Intravenous potassium infusions are given only in intensive care units where monitoring facilities are available. The rate of infusion should not exceed 10 mmol/hour and the administration and response should be continuously monitored.

If intravenous potassium administration is needed for severe hypokalemia and in those with symptoms or signs like cardiac arrhythmia, paralytic ileus, respiratory muscle paralysis, severe myopathy or familial periodic paralysis, 100 mEq potassium chloride in 1,000 mL normal saline is given over 10-12 hours. The subsequent dose is decided based on response and blood level. Appropriate supportive measures including ventilatory/respiratory assistance should be available. The correction must be steady and gradual. If the response is not adequate in 48 hours,

concomitant hypomagnesemia must be looked for and corrected with oral or IV magnesium. The 2 important causes for non-responsive nature of hypokalemia are ongoing K^+ loss and associated hypomagnesemia. Potassium supplements are continued as a long-term treatment for those with constant urinary potassium loss.

Once the acute stage is corrected and the renal functions are normal potassium-sparing drugs can be used as adjuvant therapy. Often, it is not necessary to give potassium supplements along with K^+ sparing diuretics like spironolactone, amiloride and triamterene.

If the serum K^+ is between 3 and 4 mmol/L and the patient is asymptomatic, no aggressive treatment is necessary. However, if the patient is receiving diuretic, or laxative or has chronic diarrhea, appropriate potassium supplements in the form of fruits and vegetables or oral potassium chloride supplements may be given. In patients with ischemic heart disease or on digitalis, K^+ level should not be allowed to drop below 3.5 mmol/L as it may induce life-threatening arrhythmias. Serum K^+ level of < 3 mmol/L requires treatment. Oral K^+ replacement is adequate in most patients. Potassium chloride is used for correction of hypokalemia associated with alkalosis. Potassium chloride dissociates into K^+ and Cl^- and is absorbed in the gut instead of Na^+ and HCO_3^- respectively. Thus, the alkalosis and hypokalemia are corrected. The dose is 20 to 40 mmol orally, 2-4 times a day. In those with hypokalemia and acidosis (renal tubular acidosis types I and II) potassium bicarbonate or potassium citrate-based replacement solution may be used. The recommended oral dose is 20-40 mmol of KCl four times a day. During therapy, serum and urinary potassium levels are monitored daily.

Spironolactone, in doses of 25-50 mg, 3-4 times a day is given till the potassium level reaches 4 mmol/L. Thereafter, the dose may be reduced and smaller doses of 25 mg daily are given as maintenance dose. Triamterene and amiloride are other potassium sparing diuretics used.

Since hypomagnesemia, hypophosphatemia, hypokalemia and alcoholism are associated with chronic hypokalemia, correction of the primary conditions is necessary on long-term management. In rare situations of acidosis with hypokalemia, potassium supplements are administered initially to correct hypokalemia before attempting to correct acidosis with IV bicarbonate. For diluting potassium chloride, normal saline is preferred to 5% dextrose. Ringer lactate contains potassium. Most oral rehydration fluids also contain potassium.

HYPERKALEMIA

In hyperkalemia, serum potassium is greater than 5 mmol/L. It is considered moderate if K^+ level is between 5.5 and 6.5 mmol/L and severe if > 6.5 mmol/L. Severe hyperkalemia causes cardiac arrest. A functioning kidney is able to eliminate the potassium from the body efficiently and so most cases of hyperkalemia are due to renal failure. Pseudo-hyperkalemia may be due to errors in blood collection, hemolysis of the sample, leukocytosis or thrombocytosis. In such cases, plasma potassium is re-checked using a properly collected specimen. Though potassium is excreted mainly by the kidney, when the kidney function deteriorates gradually as in chronic renal failure, the gastrointestinal excretion increases and potassium homeostasis is maintained. The risk of hyperkalemia increases when such patients develop oliguria, infection, sepsis, or they consume potassium rich diets or use potassium retaining drugs. Stored blood, fruit juice, angiotensin converting enzyme inhibitors, spironolactone or potassium containing drugs may precipitate hyperkalemia in patients with milder degrees of renal failure.

- Hyperkalemia in these situations may be due to following mechanisms:
 - Kidney diseases:** Failure of excretion of potassium could occur either due to decreased glomerular filtration or due to defective tubular secretion of potassium. Both acute and chronic renal failure cause hyperkalemia. Defective potassium secretion is due to either deficiency or cellular unresponsiveness to aldosterone. Since the kidney cannot eliminate the K^+ rapidly, any rapid increase in exogenous potassium intake invariably causes hyperkalemia.
 - Rapid release of potassium from the intracellular compartment may occur with rhabdomyolysis, tumour lysis syndrome, intravascular hemolysis, trauma causing crush injury, infection and transfusion of stored blood. In most patients with normal renal function and normal urine output, the excess K^+ is eliminated gradually.
- Redistribution of K^+ from intracellular to extracellular compartment as in diabetic ketoacidosis, use of drugs like beta adrenergic blockers, and digitalis overdose can cause hyperkalemia.

- Hypoaldosteronism may be primary or secondary as in diabetes with tubulointerstitial disease. In these patients, the hypoplasia of the juxtaglomerular apparatus leads to hyporeninemia, hypoaldosteronism and hyperkalemia. When the tubular cell is unresponsive to aldosterone as in sickle cell anemia, SLE, amyloidosis or following renal transplantation, hyperkalemia occurs.

Clinical Manifestations and Diagnosis

Hyperkalemia is very often asymptomatic and the diagnosis is made by investigation. Muscular weakness and paresthesias may be the only initial symptoms. Rarely hyperkalemic periodic paralysis may occur. Mild to severe chest discomfort resembling cardiac pain may be the only symptom when the patient presents with ventricular fibrillation or cardiac arrest.

The diagnosis is confirmed by demonstrating serum $K^+ > 5.5$ mmol/L. Electrocardiographic changes characteristic of hyperkalemia evolve through the following stages as the serum potassium level increases from 5.5 to > 9 mmol/L. The relationship between the ECG changes and blood levels is quite variable. The ECG changes are:

- Tall peaked T waves (Serum K^+ 6-7 mmol/L)
 - Prolongation of PR and absent p wave (Serum K^+ 7-8 mmol/L)
 - Widening of QRS (Serum K^+ 7-8 mmol/L)
 - Sine wave, ventricular tachycardia, ventricular fibrillation (Serum K^+ 8-9 mmol/L)
 - Cardiac arrest (Serum $K^+ > 9$ mmol/L) (Fig. 72.2).
- In patients with recurrent chronic hyperkalemia, the following points should be particularly looked for:
- History of intake of potassium in diet, or as potassium supplements.
 - Drugs causing hyperkalemia such as potassium sparing diuretic, beta blockers, Ace inhibitor, H_2 receptor blockers, NSAIDs.
 - The combination of hyperkalemia with hyponatremia should suggest Addison's disease.

Management of Hyperkalemia

In mild and moderate hyperkalemia, attention to potassium intake, avoidance of drugs causing hyperkalemia and correction of acidosis are often sufficient. Cation exchange resins such as sodium or calcium polystyrene sulfonate given orally or as retention enema exchanges sodium/calcium for potassium and helps to eliminate K^+ from the body. 2 g of resin exchanges 2 mmol Na or 1 mmol of calcium for 2 mmol potassium. For oral administration, the resin is given in 20% sorbitol. For retention enema—10% dextrose is used as the vehicle.

Severe hyperkalemia is a medical emergency and is managed as follows:

Step 1-A: 20 mL of 10% calcium gluconate is given as a steady slow intravenous injection over 5-10 minutes and

Fig. 72.2: Hyperkalemia—ECG
Note: Read with description in test

repeated once if necessary. The solution should not be injected rapidly as a bolus. Calcium stabilizes the myocardial membrane against the arrhythmias caused by K^+ but the effect is very transient.

Step 1-B: If the patient is acidotic, 100 mL of 7.5% sodium bicarbonate is given IV. 10 mL normal saline should be given after bicarbonate injection before starting IV calcium. Calcium salts and sodium bicarbonate are physically incompatible and they form calcium carbonate when they come into contact with each other. Sodium bicarbonate causes temporary reversal of acidosis and reduces serum K^+ level by causing movement of potassium into the intracellular compartment. This is used only if the patient is clinically acidotic.

Step 2: 100 mL of 25% glucose along with 5 units of regular (crystalline) insulin is infused in 2 hours. Insulin also promotes entry of K^+ into the cells and controls hyperkalemia. Thus, it helps to gain time for initiation of dialysis.

Step 3: High doses of adrenergic agonists such as albuterol or salbutamol (5 mg/mL) when given as nebulisation in doses of 10-20 mg over approximately 10 minutes also shifts the K^+ to the intracellular compartment, thereby reducing serum K^+ level.

Step 4: Both hemodialysis (HD) and peritoneal dialysis (PD) help to remove K^+ rapidly from the body. HD does it faster and more efficiently. The potassium concentration of the HD concentrate or PD fluid can be altered depending on the clinical circumstances.

Step 5: If dialysis facility is not available, removal of K^+ from the body can be achieved by the regular use of

sodium/calcium polystyrene sulfonate. The recommended dose is 15 g 6 hourly orally and it is continued till the serum potassium falls below 5.5 mmol/L. Thereafter smaller doses are given to prevent rise in potassium levels. In all patients with renal failure, low potassium diet and avoidance of offending drugs are necessary.

Hyperkalemia suggests mainly impaired potassium elimination by the kidney and is an asymptomatic “silent killer”. So, early diagnosis and prompt treatment are life saving.

Disorders of Calcium and Phosphate Homeostasis

CALCIUM

Calcium plays a crucial role in cellular functions and is an important ingredient of the bone. Calcium exists in 2 forms, bound and free forms. The bound calcium which constitutes more than 99% of the body's calcium is in bones. The free calcium may be in the ionised or non-ionised forms. It is present in the intra and extracellular fluid compartments. The plasma concentration of total calcium is 9-11 mg/dL. About 50% of this is in the ionised form and is important for cellular functions. The non-ionised fraction of calcium in serum is bound to Albumin. So, a change in serum albumin level alters the proportion of bound and free forms of calcium in blood. The serum calcium level should be corrected for any reduction in serum albumin < 4 g/dL. Corrected serum calcium = Actual serum Ca + 0.8 (4-serum albumin/dL), e.g. if the serum calcium is 10.7 and the serum albumin is 3 g/dL, the corrected calcium will be : $10.7 + 0.8 (4-3) = 10.7 +$

0.8 = 11.5 mg/dL. The plasma concentration of ionised calcium is tightly regulated by parathormone, calcitriol $1,25(\text{OH})_2\text{D}_3$ and calcitonin. The ionic calcium is influenced by the acid-base status, estrogens and prolactin. Alkalosis causes fall in ionised calcium. The dietary calcium, approximately 800-1100 mg/day, is absorbed from the intestine and transported to the ECF compartment. In the extracellular space, it is deposited in the bone or eliminated via the kidney. The entry and exit between the skeletal and non-skeletal compartments are equal under steady-state conditions. The kidneys, intestine and skeleton are important in the short, mid and long-term homeostasis respectively.

HYPERCALCEMIA

Hypercalcemia is defined as total serum calcium more than 11 mg/dL. Hypercalcemia results from an increased intestinal calcium absorption, stimulation of bone resorption or decrease in urinary calcium excretion (See section 11 Chapter: 99).

The clinical manifestations of hypercalcemia depend on the degree and rate of its development. Symptoms like fatigue, muscle weakness, nausea, vomiting, constipation, polyuria, headache, amnesia stupor and coma may occur. Soft tissue calcification, nephrocalcinosis and nephrolithiasis occur with longstanding hypercalcemia. The electrocardiogram shows shortening of QT interval, reduction or absence of ST segment, slight increase in QRS duration and prolongation of PR interval (Fig. 72.3). It also amplifies digitalis toxicity. Presence of hypercalcemia can be confirmed by estimating serum calcium level. The underlying causes like primary or secondary hyperparathyroidism, neoplastic disorders and granulomatous diseases should be investigated for.

Severe symptomatic hypercalcemia requires aggressive management with rehydration using saline, use of loop diuretics, correction of acid base imbalance, and use of bisphosphonates.

The use of calcitonin and mitomycin are reserved for malignant hypercalcemia with serum calcium above

15 mg/dL. Steroids may be used in hypervitaminosis D, sarcoidosis and hematopoietic tumours such as myeloma, lymphoma and solid tumours like breast cancer. A new class of calcium receptor (CaR) agonists or calcimimetics are used in primary and secondary hyperparathyroidism.

HYPOCALCEMIA

Hypocalcemia is defined as serum calcium below 8.5 mg/dL. Acute hypocalcemia may occur following acute hyperventilation and respiratory alkalosis. Chronic hypocalcemia is caused by hypoparathyroidism, pseudohypoparathyroidism, vitamin D deficiency states, chronic renal failure and magnesium deficiency (See section 11 Chapter 99).

The diagnosis is confirmed by corrected serum calcium level of < 8.5 mg/dL. If hypocalcemia is associated with high plasma phosphorus, conditions like hypoparathyroidism, pseudohypoparathyroidism and advanced renal failure are the possibilities. In steatorrhea, vitamin D deficiency, acute pancreatitis and recovering acute renal failure, combination of hypocalcemia and hypophosphatemia is seen.

The ECG signs of hypocalcemia include prolongation of the QT interval, flat or inverted T waves in severe hypocalcemia, slight decrease in QRS duration and ST segment lengthening (Fig. 72.4).

PHOSPHORUS

Phosphorus is present in the intra and extracellular fluids. It participates in most metabolic processes including the release of energy from ATP. Apart from being an abundant component of skeleton along with calcium, it is also present in various tissues and cell structures. The plasma phosphorus level is controlled by hormones like PTH and calcitriol. Long-term maintenance of phosphate homeostasis is regulated by renal tubular reabsorption. About 60% of the dietary phosphate is absorbed by the intestine. There is a constant turnover daily between blood and bone phosphorus. The daily renal phosphate excretion equals the intestinal absorption.

Fig. 72.3: Hypercalcemia—ECG. Note: (1) ST segment short or absent, (2) short QT interval, (3) slight increase in QRS duration, (4) PR interval may be prolonged

Fig. 72.4: Hypocalcemia—ECG. Note: (1) prolongation of the QT interval, (2) flat or inverted T waves in severe hypocalcemia, (3) slight decrease in QRS duration, (4) ST segment lengthening

Hyperphosphatemia

Hyperphosphatemia is defined as serum phosphorus > 5 mg/dL. The most common cause is reduced renal excretion as seen in renal failure. Normally, 85-90% of filtered phosphorus is reabsorbed. When the GFR is declining, even though the remaining nephrons eliminate 90% of phosphorus, the serum phosphorus increases because of decrease in the number of functioning nephrons. Other causes of hyperphosphatemia include, hypoparathyroidism, chronic hypocalcemia, acromegaly, hypercatabolic states (tumour lysis and crush injury) and vitamin D intoxication.

Severe hyperphosphatemia decreases serum calcium level which in turn stimulates PTH. This causes increased phosphate excretion and normalisation of hyperphosphatemia. The occurrence of severe hypocalcemia with tetany and ectopic calcification is the most severe manifestation of hyperphosphatemia.

Treatment of the underlying cause of hyperphosphatemia is most important. Low phosphate diet, low protein diet, oral phosphate binders like calcium acetate and magnesium salts may be used. Aluminium containing phosphate binders should be used cautiously in CRF because of toxicity due to aluminium accumulation. A new non-absorbable aluminium and calcium free phosphate binding resin—*sevelamer* is now available and can be used in doses of 800 mg in 3 divided doses.

Hypophosphatemia

It is defined as plasma phosphate level of less than 2.5 mg/dL. It may be caused by genetic diseases or acquired conditions. Inherited hypophosphatemia include Fanconi's syndrome, X-linked hypophosphatemic rickets and distal renal tubular acidosis.

Acquired conditions include malnutrition, alcoholism, diabetic ketoacidosis, acute respiratory alkalosis, oncogenic osteomalacia and total parenteral nutrition. The clinical manifestations depend on the severity of hypophosphatemia. Metabolic encephalopathy, muscle weakness, rhabdomyolysis, hemolysis, thrombocytopenia and leukocyte dysfunction may occur. The cause of hypophosphatemia is identified and treated appropriately. Oral phosphate supplementation is achieved by increasing intake of milk products. Joule's solution containing disodium hydrogen phosphate buffered in phosphoric acid may be used orally for long-term treatment. In severe symptomatic deficiency parenteral potassium phosphate infusions may be given.

Disorders of Magnesium Homeostasis

Magnesium is predominantly an intracellular cation. It is involved in metabolic processes like protein synthesis, regulation of mitochondrial function, and immune and inflammatory processes. It is also involved in the maintenance of vasomotor tone, neuronal activity, cardiac

excitability and neuromuscular transmission. The dietary magnesium averages about 12 mmols/day. Only about 50% is absorbed. The plasma magnesium concentration is maintained between 0.75 to 1.0 mmols/L (1.8-2.4 mg/dL). The absorbed magnesium reaches the intracellular fluid and is either deposited in the bone or soft tissue. The renal elimination approximately equals the intestinal absorption and the magnesium homeostasis is maintained.

Hypermagnesemia

It is defined as serum magnesium level more than 1.9 mg/dL (or 1 mmol/L). The common cause are renal failure and use of magnesium containing drugs. The signs and symptoms are due to the effect of magnesium on the CNS and CVS. Mild cases are asymptomatic. When the serum level increases to 7 to 9 mg/dL (3 mmols/L), deep tendon reflexes are lost. When the level is > 12 mg/dL (5 mmols/L), respiratory paralysis, hypotension, cardiac conduction abnormalities and loss of consciousness occur. The initial step in the emergency management of symptomatic hypermagnesemia is administration of IV calcium.

Hypomagnesemia

It is defined as decrease in total body magnesium content. Malabsorption syndrome and massive resection of small intestine, excessive use of laxatives, chronic alcoholism and uncontrolled diabetes mellitus are the causes of hypomagnesemia. Use of drugs like gentamicin, cisplatin, cyclosporin and overuse of diuretics may also lead to hypomagnesemia. Moderate to severe magnesium depletion may result in general weakness, neuromuscular hyperexcitability with hyper-reflexia, carpopedal spasm, tremor and rarely, tetany. The ECG changes include widening of QRS, prolongation of QT interval, ST depression, low or inverted T wave and occasional U waves (Fig. 72.5). Treatment is by using oral magnesium salts. In emergency, parenteral magnesium sulphate may be used. 1.5 to 3.0 g of magnesium sulphate is given by deep intramuscular route. It provides 150-300 mg of elemental magnesium.

Fig. 72.5: ECG changes in hypomagnesemia (1) Peaked T waves, T wave amplitude falling progressively in severe deficiency, (2) QRS widened, QT widened, (3) P-R interval prolonged, (4) 'U' waves may develop, (5) ST segment depressed.

Hypermagnesemia: It is uncertain whether hypermagnesemia *per se* leads to any pathognomonic ECG changes

Abnormalities of
Acid-base Balance

R. Kasi Visweswaran

Chapter Summary

- General Considerations 434
- Anion Gap 435
- Metabolic Acidosis 436
- Metabolic Alkalosis 436
- Respiratory Acidosis 437
- Respiratory Alkalosis 438
- Mixed Acid-base Disturbances 439

General Considerations

The pH of the blood and extracellular fluid must be maintained constantly between 7.35 and 7.45 for the viability, normal metabolism and enzyme functions of the cells in the body. The diet contributes to the normal intake of acids and alkali. Metabolism of amino acids like lysine, arginine, methionine, cysteine or organophosphates yield acid. Some amino acids like glutamate and aspartate or substances like acetate and citrate yield alkali on metabolism. Generally, non-vegetarian diet gives rise to more acid production. In addition, the body produces small quantities of organic acids like acetic acid, lactic acid and pyruvic acid. The endogenous acid production is approximately 1 mEq per kg per day. The acids are added to the body as volatile acids and non-volatile acids. They are immediately buffered and transported to the lungs and kidneys for elimination. Carbonic acid (H_2CO_3) is a volatile acid since it dissociates into carbon dioxide and water ($H_2CO_3 \rightleftharpoons H_2O + CO_2$). The lungs help to eliminate approximately 15,000 millimoles of CO_2 daily and regulate the CO_2 concentration. The kidneys excrete the non-volatile acids as titrable acids and ammonium. For each milliequivalent of acid excreted by the kidney, the body gains one milliequivalent of bicarbonate. Thus, the kidneys regulate the bicarbonate concentration.

The buffer systems in the body are very important in preventing the shift of pH of the extracellular fluid. The bicarbonate-carbonic acid buffer system is the most important buffer system in the ECF. The other buffer

systems include hemoglobin, plasma proteins, phosphate ions and the bone. Since the dissolution of the bones provides alkaline calcium salts and adds bicarbonate to the ECF, the bone buffers are utilized in chronic metabolic acidosis.

When the pH of blood falls < 7.35 , the condition is called acidemia and when it rises > 7.45 , it is called alkalemia. The term acidosis and alkalosis are used to denote the pathophysiological process causing the shift in the pH. Hypercarbia is carbon dioxide retention (high $PaCO_2$) and hypocarbia is carbon dioxide washout (low $PaCO_2$). Hypoxemia is low PaO_2 levels in blood.

From the above, we can visualize four primary disturbances in the acid-base equilibrium.

- a. Fall in bicarbonate $\rightarrow$ metabolic acidosis
- b. Rise in bicarbonate $\rightarrow$ metabolic alkalosis
- c. Rise in $PCO_2 \rightarrow$ respiratory acidosis
- d. Fall in $PCO_2 \rightarrow$ respiratory alkalosis

If there is a fall in bicarbonate, the body tries to compensate by achieving a fall in PCO_2 so that the degree of shift in pH is minimized. If hyperventilation is the primary event causing a fall in PCO_2 , the body tries to compensate with lowering of HCO_3 by increasing bicarbonate excretion in urine.

In order to recognize and interpret the acid-base disorder, four parameters are used.

- 1. $PaCO_2$ —from arterial blood gas analysis (ABG) by ABG machine using “anaerobically” collected heparinised arterial blood.
- 2. pH—from ABG or pH meter
- 3. HCO_3 —Measured or calculated from pH and PCO_2
- 4. Anion gap (AG)— $Na^+ - (HCO_3 + Cl)$.

The normal values for above parameters (at sea level) are

pH	—	7.4 ± 0.05
$PaCO_2$	—	40 ± 4 mm Hg
HCO_3	—	24 ± 2 mmol/L
Na^+	—	140 ± 5 mmol/L
Cl^-	—	99 ± 3 mmol/L
AG	—	$8 - 12$ mmol/L

Approaches and interpretations of acid-base disorders is done by correlating the four parameters. A simplified approach is given below.

1. First, look at the pH and decide whether there is acidemia or alkalemia. (pH less than 7.36 is acidemia and pH more than 7.44 is alkalemia).
2. Look at HCO_3^- and decide whether the deviation in HCO_3^- will explain the deviation in pH. If the pH and HCO_3^- both are lowered or increased, the condition is of metabolic origin.
3. Look at PCO_2 and decide whether the deviation in PCO_2 will explain the deviation in pH. If the pH is high and PCO_2 is low, it suggest respiratory alkalosis. If the pH is low and PCO_2 is high, it suggests respiratory acidosis.

Example 1

PH = 7.32, $\text{HCO}_3^- = 18$, $\text{PaCO}_2 = 38$

- Step 1 $\rightarrow$ (pH < 7.35) $\rightarrow \therefore$ Acidemia
 Step 2 $\rightarrow$ HCO_3^- low $\rightarrow \therefore$ metabolic
 Step 3 $\rightarrow$ PCO_2 'normal' $\rightarrow \therefore$ not primary respiratory disorder
 $\therefore$ Metabolic acidosis

Example 2

PH = 7.48, $\text{HCO}_3^- = 24$, $\text{PaCO}_2 = 22$

- Step I $\rightarrow$ (pH > 7.45) $\rightarrow \therefore$ Alkalemia
 Step 2 $\rightarrow$ HCO_3^- normal $\rightarrow \therefore$ Not metabolic
 Step 3 $\rightarrow$ $\text{PCO}_2 = 22$ $\rightarrow \therefore$ Markedly low
 $\therefore$ Respiratory alkalosis

The body 'compensation' follows the "same direction rule" in relation to the numerator and denominator of the

pH equation $\text{pH} \propto \frac{\text{HCO}_3^-}{\text{PCO}_2}$. Thus, the compensatory

response for the four primary disorders are.

a. Metabolic acidosis	Respiratory alkalosis
b. Metabolic alkalosis	Respiratory acidosis
c. Respiratory acidosis	Metabolic alkalosis
d. Respiratory alkalosis	Metabolic acidosis

Anion Gap

The number of cations and anions in the body fluids are equal and neutralize each other. Sodium, potassium, calcium and magnesium are the cations. Bicarbonate, chloride, sulphate, phosphate, organic acid and albumin are the anions. Only sodium, bicarbonate and chloride are taken into consideration for the calculation of anion gap. Anion gap = $\text{Na}^+ - [\text{HCO}_3^- + \text{Cl}^-]$. The gap consists of the anions that are usually not measured or included in the calculation. The normal value for anion gap is approximately 12 ± 2 mmol/L. For the purpose of calculation of anion gap, unmeasured anions (UA) as well as unmeasured cations (UC) and potassium are discarded (Fig. 73.1).

Since albumin is negatively charged, it contributes to the anion gap significantly. The normal anion gap is

Fig. 73.1: Showing anions, cations, anion gap and types of metabolic acidosis

approximately three times the serum albumin level. Therefore, if the patient has hypoalbuminemia the interpretation of anion gap has to be modified as anion gap is decreased.

If acidosis (low bicarbonate), is associated with high chloride, the anion gap is unaltered. This is hyperchloremic or normal anion gap metabolic acidosis. In such cases the accompanying H^+ ions will be chloride. If the anion accompanying the H^+ ion is not chloride, the low bicarbonate will be compensated to an equal extent by accumulation of an anion other than chloride, e.g. ketoacid, lactic acid, etc. This causes a rise in the anion gap.

A clear understanding of the acid-base equilibrium, the primary disturbances, the 'compensatory' mechanisms, interpretation of ABG results, and identification of mixed acid-base disorders are all absolutely necessary to give the appropriate treatment in emergency situations.

Metabolic Acidosis

Metabolic acidosis occurs when acid is added to the body or when alkali is lost from the body. The metabolic acidosis is broadly classified as high anion gap metabolic acidosis and normal anion gap 'hyperchloremic' metabolic acidosis. Both may occur due to renal or extrarenal causes.

Classification

A. *Metabolic acidosis with high anion gap*

- i. Renal causes – Uremic acidosis due to accumulation of uremic anions occurs when the GFR is < 20 mL/min.
- ii. Extra-renal causes
 - a. Accumulation of lactic acid - (due to incomplete carbohydrate oxidation) lactic acidosis, e.g. shock, sepsis, cirrhosis, malignancies, phenformin and very rarely metformin.
 - b. Accumulation of ketoacids due to incomplete oxidation of fat, e.g. diabetic ketoacidosis, starvation ketoacidosis, alcoholic ketoacidosis.
 - c. Poisoning, e.g. ethylene glycol, methanol, ethanol, isopropyl alcohol, salicylate.
 - d. Gain of exogenous acid, e.g. hydrochloric acid, ammonium chloride, methionine and intravenous hyperalimentation.

B. *Metabolic acidosis with normal anion gap*

- i. Renal causes:
 - Proximal renal tubular acidosis (Type II RTA)
 - Distal renal tubular acidosis (Type I RTA)
 - Hyperkalemic distal RTA (Type IV RTA)
 - Chronic kidney disease with mild renal insufficiency.
- ii. Extrarenal causes:
 - Diarrhea (loss of bicarbonate)
 - Pancreatic/biliary fistula (loss of bicarbonate)

Uretero sigmoidostomy leading to reabsorption of H^+ ions and ammonia in exchange for bicarbonate in the gut.

Use of cholestyramine.

Clinical Features and Diagnosis

The clinical features of metabolic acidosis are similar irrespective of the etiology. In mild degrees of acidosis, increase in respiratory rate and in severe acidosis, deep sighing respiration (Kussmaul's breathing) occurs. A careful history of recurrent stone disease, diabetes, alcoholism, drug therapy, poisoning or overdose should be elicited.

The confirmation of diagnosis is by analysis of ABG along with anion gap.

Management

Management depends on the correction of the underlying disorder. Correction with IV sodium bicarbonate is indicated if acidosis is symptomatic and severe ($pH < 7.2$ and $HCO_3^- < 12$). The dose of bicarbonate is calculated by the formula. Bicarbonate required = $0.3 \times \text{bodyweight in Kg} \times \text{deficit}$. The deficit is calculated by noting the difference between required HCO_3^- (usually 12 to 16) and observed bicarbonate (available lab value). The correction is achieved within 2 to 4 hours and ABG is repeated. In high anion gap metabolic acidosis due to intoxications, removal of the toxins by appropriate measures may be undertaken.

Metabolic Alkalosis

Metabolic alkalosis may be initiated by loss of acids from the body or gain of alkali. Normally, such events are effectively handled by the kidney by removing the excess bicarbonate from blood. Therefore, certain additional factors are required for maintaining metabolic alkalosis. *If metabolic alkalosis is associated with low extracellular fluid (ECF) volume* as in vomiting or diuretic use, there is prompt correction of alkalosis with administration of chloride. This is called chloride responsive metabolic alkalosis. *Metabolic alkalosis is associated with normal or increased ECF* in hyperaldosteronism and Cushing's syndrome respectively. In these conditions alkalosis will be sustained only if renal functions are markedly reduced or alkali loading is very high. Such alkalosis persists despite chloride administration and it is called "*chloride resistant alkalosis*". The urinary chloride helps to distinguish between these two types of metabolic alkalosis. In chloride responsive type, the urinary chloride is less than 10 mmol/L and in chloride resistant alkalosis, the urinary chloride is more than 10 mmol/L. The body

tries to minimize the degree of metabolic alkalosis by reducing ventilation and increasing PaCO_2 .

Classification

The metabolic alkalosis is classified as chloride responsive, chloride resistant, and miscellaneous.

A. Chloride responsive metabolic alkalosis

- a. Gastric acid loss
 - i. Vomiting
 - ii. Gastric drainage
 - iii. Pyloric stenosis
- b. Urinary loss—Diuretic therapy (thiazides, metolazone, frusemide, torsemide, bumetanide and ethacrynic acid)
- c. Fecal loss—Congenital chloride diarrhea, villous adenoma of colon
- d. Recovery from chronic hypercapnia

B. Chloride resistant metabolic alkalosis

- a. Hyperaldosteronism
 - i. Conn's syndrome
 - ii. Cushing's syndrome
 - iii. Bartter's syndrome
 - iv. Liddle's syndrome
 - v. Liquorice ingestion

C. Miscellaneous

- a. Alkali administration
 - i. Milk - alkali syndrome
 - ii. Massive blood transfusion, due to excess of citrate
 - iii. Alkali supplements
- b. Hypercalcemia
- c. Poorly absorbable anion administration (e.g. antibiotic like carbencillin).

Clinical Features

Metabolic alkalosis is generally, well tolerated and patients are not symptomatic. The symptoms are generally related to hypoxemia, hypokalemia, hypocalcemia and alkalemia. Symptoms like lethargy, confusion or stupor are often related to hypoxia and hypoventilation, and are particularly worse in those with chronic obstructive airway disease. The clinical manifestations related to hypokalemia are weakness, ECG changes or even flaccid paralysis. Tetany may occur due to fall in ionic calcium level.

Diagnosis

The finding of serum bicarbonate of > 30 mmol/L associated with hypokalemia is pathognomonic of metabolic alkalosis. Although HCO_3 may be high in chronic respiratory acidosis, it is not associated with hypokalemia. Since metabolic alkalosis may co-exist with other acid-base disturbances, mixed acid-base disorders should be looked for. A single measurement of urinary

chloride in a spot sample of urine is sufficient to classify if it is chloride responsive or chloride resistant metabolic alkalosis.

Management

The primary disorder is identified and treated accordingly. In chloride responsive metabolic alkalosis, the aim is to replace the chloride deficit and normalize the sodium and potassium concentrations. Thus, the mainstay of treatment is sodium chloride infusion with additional potassium orally or intravenously. The amount of sodium chloride required depends on volume contraction and is guided by CVP monitoring. Usually, with the correction of chloride, the kidneys effectively eliminate the excess bicarbonate. In patients with cirrhosis liver, digoxin therapy or respiratory failure, the alkalosis may have to be corrected by exogenous administration of acids or acid precursors. Treatment includes administration of dilute intravenous 0.1 normal hydrochloric acid, ammonium chloride or arginine hydrochloride. Dialysis with low bicarbonate dialysate is the treatment modality of choice in severe cases associated with renal failure.

Respiratory Acidosis

Respiratory acidosis is characterized by a primary rise in PCO_2 and is invariably due to alveolar hypoventilation. CO_2 retention is invariably associated with hypoxemia and may even cause death before PCO_2 levels reach over 80 mmHg. In acute respiratory acidosis, for every 10 mmHg increase in PCO_2 , the bicarbonate will increase by 1 mmol/L. In chronic respiratory acidosis, the renal mechanisms play a role and cause elevation of HCO_3 by 4 mEq/L for every 10 mmHg rise in PCO_2 .

Causes of Respiratory Acidosis

1. Neurologic causes:

- a. Inhibition of respiratory center (central)
 - General anesthesia
 - Sedative overdose
 - Head injury/cerebrovascular accident/tumours
 - Encephalitis/brainstem lesions
- b. Neuromuscular causes:
 - Spinal cord injury
 - Poliomyelitis
 - Multiple sclerosis
 - Muscular dystrophy
 - Guillain-Barré syndrome
 - Status epilepticus
 - Amyotrophic lateral sclerosis

2. Respiratory muscle paralysis:

- Tetanus, botulism
- Myasthenic crisis
- Periodic paralysis

Diaphragmatic paralysis
Myopathies
Succinyl choline administration
Organophosphorus poisoning

3. Upper and lower airway obstruction

Obesity
Sleep apnea
Aspiration
Laryngeal edema / vocal cord palsy
Bronchoconstriction
Emphysema
Chronic interstitial lung disease
Pleural thickening/lung stiffening
Thymoma/aortic aneurysm

Clinical Features

Hypercarbia (CO_2 retention) and hypoxemia (low PaO_2) often coexist. The usual symptoms include severe breathlessness, disorientation, confusion, tremor, myoclonus, headache, asterixis, incoherence and drowsiness. Blurring of optic disc, papilledema and symptoms of increased intracranial pressure are due to vasodilatory effects of CO_2 . Sometimes, injudicious administration of high flow O_2 may precipitate coma. The vascular manifestations are due to vasodilatation. Congestive cardiac failure and cardiac arrhythmias may occur. These patients may also develop salt and fluid retention.

Treatment

Hypoxemia is mainly responsible for the mortality. Therefore, careful O_2 administration is the mainstay in the treatment. Injudicious O_2 administration may lead to worsening of hypoxemia due to suppression of respiratory drive particularly in patients with chronic obstructive airway disease. In acute respiratory acidosis, the treatment principles include maintenance of airway, administration of oxygen and judicious use of antibiotics, bronchodilators and corticosteroids. Noninvasive ventilation or intubation and mechanical ventilation may be used for more severe cases with $\text{pH} < 7.0$ and $\text{PCO}_2 > 80$. Bicarbonate administration may be necessary to bring the pH to 7.2.

Respiratory Alkalosis

Respiratory alkalosis is characterised by a primary fall in PCO_2 . The rate of production of CO_2 in the body is relatively constant. Therefore, any fall in PCO_2 can only be due to alveolar hyperventilation. It is a common acid-base disorder and occurs in normal pregnancy and at high altitude. It also occurs in critically ill patients as a simple disorder or as a part of mixed disorder. The primary fall in PCO_2 does not increase pH to levels above 7.55 and severe alkalemia is unlikely.

Causes of Respiratory Alkalosis

A. CNS stimulation and hyperventilation

Voluntary/psychogenic/ anxiety/pain
Pregnancy
Brainstem lesions
Encephalitis
Salicylate intoxication
Sepsis
Cirrhosis of liver.

B. Stimulation of intrathoracic receptors

Pneumothorax, hemothorax, flail chest, pneumonia, asthma, pulmonary edema, pulmonary embolism, pulmonary fibrosis, acute respiratory distress syndrome.

C. Stimulation of peripheral chemoreceptor

High altitude hypoxemia
Hypotension, severe anemia
Drowning, aspiration, pneumonia

D. Drugs

Respiratory stimulants (doxapram, nikethamide)
Salicylates
Nicotine
Epinephrine/nor-epinephrine.

Clinical Features

The clinical features are variable and depends on the primary disorder, rate of onset and severity of the respiratory alkalosis. The usual initial symptoms include tingling sensation in the extremities, and circumoral region, lightheadedness and confusion. Later, muscle cramps, carpopedal spasm and brisk deep tendon reflexes may be noted. Cardiac arrhythmias and seizures may also occur in severe cases. The occurrence of symptomatic respiratory alkalosis or $\text{PCO}_2 < 20\text{--}25$ mmHg in critically ill patients suggests a grave prognosis.

Diagnosis and Treatment

The diagnosis can be established by the history, physical examination and laboratory data including ABG. The treatment is directed towards the underlying cause. Often, no treatment is required for mild respiratory alkalosis if it is not associated with symptoms. In psychogenic hyperventilation, rebreathing into a closed bag can be tried. Acute mountain sickness can be prevented by slow ascent, pretreatment with acetazolamide and oxygen therapy. In the case of salicylate intoxication, the first step is to remove unabsorbed salicylate from the gut. This is achieved by inducing emesis or gastric lavage, absorption may be prevented by administration of activated charcoal, with sorbitol. The absorbed salicylates can be removed from blood by alkaline diuresis or hemodialysis. In patients on assisted ventilation with respiratory alkalosis, appropriate adjustments in the mode of ventilation

may have to be undertaken. In hypoxemia, oxygen therapy is useful.

If the pH is more than 7.55 and patient has hemodynamic instability, or altered mental status, more aggressive measures are warranted. Attempts must be made to bring the pH to less than 7.5. This can be achieved by either reducing HCO_3^- or increasing PCO_2 . The bicarbonate can be reduced by the use of acetazolamide, ultrafiltration or hemodialysis using low bicarbonate dialysate or by isotonic saline replacement.

The PCO_2 can be increased by rebreathing into a closed system or by giving controlled hypoventilation using a ventilator.

Mixed Acid-base Disturbances

When two or more acid-base disorders occur simultaneously, the condition is called mixed acid-base disorder. This can be two or three disorders combined. The usual compensation of the body to a primary acid base disorder is not considered as a mixed disorder. Mixed acid-base disorders are commonly observed in hospitalised patients particularly in the intensive care units. The clinical settings in which they occur include cardiorespiratory arrest, sepsis, drug intoxication, complications of diabetes mellitus, renal, hepatic, pulmonary or cardiac failure and those on artificial life support. A few examples are enumerated and explained below.

- a. Respiratory acidosis and metabolic acidosis
For example: Chronic obstructive airway disease with sepsis or cardiopulmonary arrest.
- b. Respiratory alkalosis and metabolic acidosis
For example: Salicylate intoxication, gram-negative sepsis, pulmonary edema, hypoxemia and mechanical hyperventilation.
In salicylate intoxication, the stimulation of central respiratory center by salicylate, stimulates hyperventilation and respiratory alkalosis. Accumulation of pyruvic acid and lactic acid or salicylic acid itself leads to metabolic acidosis.
In gram-negative septicemia, sepsis induces hyperventilation and respiratory alkalosis, and shock causes lactic acidosis.
- c. Metabolic acidosis and metabolic alkalosis
For example: Diabetic ketoacidosis with vomiting, Renal tubular acidosis with vomiting, Protracted vomiting/nasogastric suction with uremia, or alkali therapy for cardiopulmonary resuscitation.

Prolonged vomiting and nasogastric suction can cause metabolic alkalosis and when this occurs in a patient who has metabolic acidosis due to any cause, this mixed acid-base disorder can occur.

- d. Metabolic alkalosis with respiratory acidosis
For example: Chronic obstructive pulmonary disease and diuretics.
Combination of conditions with chronic obstructive pulmonary disease (respiratory acidosis) with conditions causing acid loss (vomiting) or alkali gain (diuretic therapy, exogenous bicarbonate administration) can lead to this mixed disorder.
- e. Metabolic alkalosis with respiratory alkalosis
For example: Hyperemesis gravidarum, congestive heart failure and diuretic use.
In hyperemesis gravidarum, the respiratory alkalosis occurs as a part of normal pregnancy. It is complicated by metabolic alkalosis, when loss of gastric acid occurs due to hyperemesis.
In congestive cardiac failure, the respiratory alkalosis may occur due to tachypnea and metabolic alkalosis due to diuretics.
- f. Mixed metabolic acidosis
Metabolic acidosis may be high anion gap or 'normal' anion gap (hyperchloremic). They are caused by different pathogenic mechanisms and they occur under different circumstances. Therefore, they can be combined and may coexist with other disturbances as well.
For example:
 - i. Combination of two types of high anion gap metabolic acidosis-uremia and diabetic ketoacidosis.
 - ii. Combined high anion gap metabolic acidosis due to diabetic ketoacidosis and sepsis (lactic acidosis).
 - iii. Normal anion gap (hyperchloremic) metabolic acidosis as in renal tubular acidosis may be combined with sepsis and lactic acidosis.
 - iv. Diarrhea in a patient with renal tubular acidosis may lead to normal anion gap metabolic acidosis due to two independent mechanisms.
- g. Mixed metabolic alkalosis
Different pathogenetic mechanisms causing metabolic alkalosis may be occur together in a patient at the same point of time.
For example: Vomiting and diuretic therapy
Potassium deficiency + mineralocorticoid excess.

Disturbances of Osmotic Equilibrium

K.V. Krishna Das, R. Kasi Visweswaran

Chapter Summary

Introduction 440

Disturbances of Osmolar State 440

7

Introduction

The water combined with various solutes and electrolytes contributes to the tonicity of the body fluids which is maintained within a narrow physiological range. Osmolality represents the number of osmotically active solutes in the one kilogram of water. The osmolality of plasma varies from 285-290 milliosmoles/kg. In health, plasma osmolality is closely related to sodium level. Substances like mannitol, methanol, ethanol, high levels of glucose, ethylene glycol and conventional radiocontrast agents increase the osmolality. Osmolality of plasma can be measured using an osmometer, which measures the osmolality from the freezing point. A solution with osmolality 1 (1000 milliosmoles) freezes at the temperature of 1.86°C. Plasma osmolality can also be calculated from the concentration of electrolytes, glucose and urea using the formula:

Osmolality = $2 \times Na \text{ (mmol/L)} + \frac{B. \text{ urea (mg\%)}}{6} + \frac{Blood \text{ sugar (mg\%)}}{18}$

Disturbances of Osmolar State

Osmolar disturbances also accompany disturbances of fluid and electrolytes. Serum sodium is the chief determinant of plasma osmolality. In intracellular fluid potassium does the same function. Conditions which lead to hyponatremia or absolute water retention produce hypo-osmolar states. The dilutional hyponatremia of congestive heart failure, edema in cirrhosis liver and fluid retention due to psychogenic polydipsia give rise to hypo-osmolar states whereas water depletion and hypernatremia give rise to hyperosmolar states. Diabetes insipidus is associated with hyperosmolality. Abnormally high levels of glucose

TABLE 74.1

The quantitative and molar composition of different solutions used for infusion

Solution	Chemical composition
1. 2,5,10,40% dextrose	Corresponding number of g% of dextrose
2. 0.85% NaCl (normal saline)	145 mmol/L of Na and Cl
0.45% NaCl	77 mmol/L of Na and Cl
3.0% NaCl	513 mmol/L of Na and Cl
3. 15% potassium chloride (10 mL ampoules)	2,000 mmol/L of K and Cl or 2 mmol/ml of K and Cl
4. 1.5% Na HCO ₃	178 mmol/L of Na and HCO ₃
7.5% Na HCO ₃	890 mmol/L of Na and HCO ₃
10 mL ampoules	roughly 1 mmol/mL
5. 1/6 molar lactate or (1.87% NaC ₃ H ₃ O ₃) Ringer's lactate	167 mmol/L of Na and HCO ₃
NaCl	130 mmol/L
Sodium lactate	27 mmol/L
KCl	4 mmol/L
CaCl ₂	4 mmol/L

can cause hyperosmolality as seen in nonketotic hyperosmolar coma of diabetes. Infusion of large doses of mannitol or fructose given therapeutically also lead to hyperosmolar states.

Hyperosmolar states are corrected by the administration of 0.45% saline. The underlying condition like hyperglycemia or uremia should also receive attention. Hypo-osmolar states are corrected by eliminating water by diuresis, with supplementation of salt, or by the administration of hypertonic saline (1.5 or 3% NaCl).

Osmotic pressure of body fluids plays a major role in transfer of fluid and chemical constituents across semipermeable membranes and cell walls in several tissues. Gross changes in osmotic equilibrium lead to severe abnormalities in fluid and electrolyte transfer resulting in metabolic disturbances. Estimation blood osmolality is an important investigation in critical care medicine. The composition of the commonly used IV fluids is given in Table 74.1.

TABLE 74.2

Equivalent of 1 g of solute

<i>Solute</i>	<i>mmol</i>
NaCl	17.24
KCl	13.3
CaCl	9.0
CaCO ₃	10.0
MgSO ₄	8.3
NaHCO ₃	11.9
Na ₂ HPO ₄	7.0
NaH ₂ PO ₄	8.2

Estimation of serum osmolality should be undertaken in the following conditions:

- dehydration,
- syndrome of inappropriate secretion of antidiuretic hormone (SIADH),

- hyperosmolar nonketotic coma in diabetes, and
- for the identification of low molecular weight substances in plasma.

Whenever possible, osmolality should be measured by osmometer and also calculated from the estimation of sodium, potassium, glucose and urea in the plasma (see formula above). If the measured osmolality exceeds the calculated one by 10 mosms or more the following conditions should be suspected:

- diminution of water content in the plasma as occurring in hyperlipidemia and hyperproteinemia, and
- presence of low molecular weight substances such as methanol, ethanol, ethylene glycol, etc.

Table 74.2 gives the amount of solutes expressed as millimoles in each gram of the substance.

Applied Anatomy and Physiology

ESOPHAGUS

Esophagus is a muscular tube ranging in length from 25 to 30 cm extending from the cricopharyngeal sphincter to the lower esophageal sphincter above the cardia of the stomach. Its immediate relations are the trachea, left main bronchus, the aortic arch, and the left atrium. The blood supply is derived from the small branches of the descending thoracic aorta. The inferior thyroid artery supplies the uppermost part and the left gastric artery supplies the lower end. Veins from the upper part drain into the superior vena cava, those from the middle third drain into the azygos system and the veins of the lower third drain into the portal system through the gastric veins. These veins are interconnected. The vagus nerve, fibers of which anastomose with the Auerbach's plexus, acts as the chief motor nerve. The cervical sympathetic ganglia and the fibers from the thoracic sympathetic ganglia provide sympathetic innervation. The cervical lymph nodes receive lymphatics from the upper third, mediastinal nodes from the middle-third, and the celiac and gastric lymph nodes from the lower third. The lymphatics anastomose freely. The upper one third of the esophagus contains striated muscle and the lower two-third contains smooth muscle. The esophagus has no serous coat. It is lined by stratified squamous epithelium. Under abnormal conditions when gastric acid regurgitates into the esophagus, the lining of the lower end undergoes metaplasia, to resemble columnar epithelium resembling the gastric mucosa.

Physiology

444 The cricopharyngeal sphincter remains tonically closed except during swallowing. On swallowing, a wave of

peristalsis (called primary peristalsis) sweeps down. Secondary peristalsis is set up when gastric contents regurgitate into the esophagus. On swallowing, the lower esophageal sphincter (LES) relaxes and the food bolus passes into the stomach. Reflux of gastric contents into the esophagus is prevented by the LES. This sphincter is controlled by inhibitory and excitatory neural influences. Several other factors also influence the LES tone. Prostaglandins, cholinergic agents, metaclopramide, cisapride, alkalies and high protein meal increase the tone, whereas secretin, cholecystokinin, alcohol, chocolate, smoking, and gastric acidity lower it. The esophagus acts as an active conduit for food from the pharynx to the stomach.

STOMACH

The stomach is the most distensible part of the gastrointestinal tract. Capacity of the adult stomach is 1-1.5 liters. Stomach wall is made up of mucosa, submucosa, muscle coat and serosa. Branches of the celiac axis, and to a lesser extent branches of superior mesenteric artery provide arterial blood. Veins accompany the arteries and drain into the portal circulation. Lymphatic drainage is into four main groups of lymph nodes, left gastric, pancreaticosplenic, right gastroepiploic and pyloric. From these primary nodes, further drainage occurs into the celiac group of preaortic nodes and then into cisterna chyli. The stomach receives sympathetic and parasympathetic nerves. The two vagus nerves which are parasympathetic, reach the stomach through the esophageal hiatus and anastomose with the ganglion cells in the layers of the organ. Parasympathetic stimulation leads to gastric secretion, contraction of the stomach, and relaxation of the pylorus. The sympathetic fibers derived from T6-T10 segments reach the stomach through the celiac ganglia and celiac plexus. Sympathetic stimulation constricts blood vessels, contracts the pylorus, and inhibits secretion and motor activity.

Structure

The gastric glands differ in the three regions of the stomach and are called the cardiac glands, oxyntic glands

and the pyloric glands. The oxyntic glands have four cell types—the chief cells, oxyntic or parietal cells, mucous neck cells and endocrine cells. The chief cells produce pepsinogen, the parietal cells produce hydrochloric acid and intrinsic factor, and the mucous neck cells produce mucus. The cardiac and pyloric glands have predominantly mucus-secreting cells. The pyloric glands have, in addition, endocrine cells producing gastrin.

Physiology

The proximal part of the stomach acts as a reservoir to receive ingested food and the distal portion (*antral mill*) churns the food and converts it into chyme. Gastric emptying is controlled by the antral contractions. Liquids leave the stomach faster than solids. The antrum contracts at the rate of 3/min. Gastric emptying depends on factors such as volume and composition of the meal and by the activity of the duodenum and small bowel which is mediated through neurohumoral mechanisms. Gastric emptying is slowed by *glucagon*, *gastrin*, *secretin*, *cholecystokinin*, *vasoactive intestinal polypeptide* (VIP) and *gastric inhibitory polypeptide* (GIP). Noxious stimuli like pain may also inhibit gastric emptying.

The gastric juice contains *hydrochloric acid*, *pepsinogens*, *intrinsic factor* and *mucus*. The endogenous stimulants of gastric acid secretion are gastrin, histamine and acetylcholine. Food is the most important physiologic stimulus for gastric acid secretion. Distension of the stomach enhances acid secretion through cholinergic reflexes. Amino acids and peptides in the stomach induce acid secretion through the release of gastrin. *Pepsins*, which are the proteolytic enzymes in the gastric juice, are stored as inactive precursors, the *pepsinogens*, which are converted to pepsin in the presence of acid. *Cholinergic reflexes*, *gastrin* and *histamine* stimulate secretion of pepsin. *Intrinsic factor* is produced by the parietal cells and normally the quantity of intrinsic factor far exceeds the amount required for vitamin B₁₂ absorption. *Intrinsic factor secretion* is stimulated by vagal stimulation, cholinergic agents, histamine, and gastrin.

SMALL INTESTINE

The small intestine is 6-7 meters long (range 300-850 cm). If the length is reduced below 200 cm, it leads to 'short bowel syndrome'. The widest part is the duodenum and it is fixed. The rest of the small intestine is arbitrarily divided into jejunum and ileum without any sharp demarcation. The small intestine derives its arterial supply from the celiac and superior mesenteric arteries. Its veins drain into the portal system. The vagus provides parasympathetic innervation. Sympathetic fibers originate from T9 and T10 segments. The wall of the small intestine has four layers. They are *mucosa*, *submucosa*, *muscular*

layer and *serosa*. The small intestine is the main site of digestion and absorption. The mucosa is thrown into convoluted folds, the *valvulae connentes*, which are more numerous in the jejunum. The luminal surface is covered by villi which are taller in the jejunum than in the ileum. The villi are lined by a single layer of tall columnar epithelial cells. The area between the villi is occupied by the crypts. The crypt epithelial cells are the precursors of the villous epithelial cells. In addition, the crypt contains *Paneth cells*, *goblet cells* and *endocrine cells*. The crypt epithelial cells migrate towards the villi where they mature and are finally shed off from the tip. The villus epithelium is constantly being replaced and the migration time from crypt to villus is 2-6 days. In addition to the tall columnar cells, the mucosa contains goblet cells which secrete mucus and enterochromaffin cells with endocrine function. The luminal end of the epithelial cells has the brush border, composed of tall closely packed microvilli. This region contains the enzymes for digestion of carbohydrates and proteins. The paneth cells are trapezoid cells with basophilic cytoplasm seen at the base of the crypts. They secrete growth factors, antimicrobial peptides and digestive enzymes.

The Brunner's glands are seen in the submucosa of the duodenum. They secrete alkaline mucus, epidermal growth factor and pepsinogen II.

The *lamina propria* contains blood vessels, lymphatics, nerve fibers, lymphocytes, plasma cells, eosinophils, macrophages, and mast cells. The lymphocytes and plasma cells of the lamina propria and the epithelium form part of the immune system. *Peyer's patches* are aggregations of lymphoid tissue seen in the submucosa of the ileum.

Motility of the Gastrointestinal Tract

The stomach and intestines undergo regular co-ordinated peristaltic movements. Motility and intraluminal pressures can be recorded by manometry at different levels.

Movement occurs in three phases

Phase 1— quiescent phase

Phase 2—occurs after eating in which the fasting pattern gives place to the fed pattern in the stomach and small intestine. At this stage the migratory pattern stops and bursts of contractions occur which help to mix the contents and enhance digestion and absorption.

Phase 3—this occurs during fasting. The movements are known as **migrating motor complex (MMC)**. Regular motility occurs at the rate of 3 cycles per minute in the duodenum and pass down the intestine.

The peristaltic activity is controlled by mechanical and neurohumoral factors. Chyme is mixed up by segmenting movements and propelled forwards by peristaltic movements. Movement of chyme is faster in the jejunum than in the ileum.

Two major functions of the small intestine are: (i) digestion and absorption of food and (ii) barrier function against luminal microorganisms and toxins. Intestinal failure leads to three major problems:

1. Malnutrition,
2. Sepsis,
3. Symptoms which impair the quality of life—diarrhea, vomiting and abdominal pain.

Lesions and resection of the distal parts of the small intestine produce greater abnormalities of digestion and absorption. Removal of long segments of the small intestine also leads to secondary hypersecretion in the stomach as a result of decrease in the production of the inhibitory hormones.

LARGE INTESTINE

Syn: Colon

The large intestine, which begins at the ileocecal junction and ends at the anal canal, is 90-125 cm long. The caliber of the colon diminishes progressively from cecum to the sigmoid. The portion proximal to the midtransverse colon is derived from the midgut and it derives its blood supply from the superior mesenteric artery. It is absorptive in function. The distal half is derived from the hindgut and it derives its blood supply from the inferior mesenteric artery and its main function is storage. The lower end of the rectum and anal canal is supplied by paired middle and inferior rectal arteries which arise from the internal iliac artery. The veins accompany the arteries and ultimately reach the portal system through the superior and inferior mesenteric veins. The rectum provides a site for portal-systemic anastomosis. The lymphatics of the colon and rectum accompany the superior and inferior mesenteric vessels. Lymphatics from the anus drain into the superficial inguinal nodes. Sympathetic and parasympathetic nerves supply the colon. Sympathetic fibers arise from T11 to L2 through the sympathetic ganglia and splanchnic nerves and finally reach the colon along with the blood vessels. Parasympathetic fibers arise from the vagus and the sacral outflow.

Colonic mucosa is lined by a single layer of columnar epithelial cells which are flat. The surface of the mucosa shows the *crypts of Leiberkuhn*. There are numerous goblet cells in the mucosa. The crypts show argentaffin cells also. The luminal surface of the epithelial cells shows villi. The lamina propria contains blood vessels, lymphatics, nerve fibers, lymphocytes, plasma cells, and histiocytes.

Physiology

The essential function of the large intestine is to process the intestinal wastes, to store them and to discharge them at periodic intervals. In addition, it plays an important role in the maintenance of fluid and electrolyte balance. The

colon absorbs water, sodium and chloride and nutrients, and secretes potassium and bicarbonate. The motor activity of the colon consists of segmenting and propulsive movements. The segmenting movements facilitate the absorption of water and electrolytes. Due to the absorption of water the liquid contents are transformed into solid material as the contents pass down. Distension of the rectum initiates the defecatory reflex. The goblet cells of the mucosal surface secrete mucus, which lubricates the feces and facilitates propulsion.

The amounts of water and the major electrolytes entering and leaving the colon in 24 hours are as follows.

	Entering	Leaving
Water	1500-1800 mL	100-150 mL
Sodium	180-220 mmol/L	5 mmol/L
Potassium	5 mmol/L	9-13 mmol/L
Chloride	117-157 mmol/L	2 mmol/L

Upto 400 calories can be provided through the colon by intracolonic infusion. Colonic function supplements function of the small intestine. If the colon is normally functioning, a patient can be maintained even with only 50 cm length of small intestine. At least 100 cm of small intestine is absolutely necessary to manage a patient whose colon is nonfunctional.

Digestion and Absorption

Digestive processes start in the mouth and proceed as the food passes down. The ultimate function of the gastrointestinal tract is the assimilation of ingested nutrients. The food materials which are in macromolecular form have to be broken down to smaller molecules before they can be absorbed. This process is called digestion. Absorption is the process of transfer of digested nutrient molecules across the mucosal epithelium from the intestinal lumen into the tissues. Digestion and absorption are closely interrelated. A part of the digestion occurs in the stomach. Exocrine pancreatic secretion and the bile salts aid in the process of digestion. The digestive processes of some of the nutrients continue in the brush border of the small intestinal epithelium. Small intestine is the major site of absorption of nutrients, and most of the water and electrolytes. Calcium and iron are preferentially absorbed in the duodenum. Vitamin B₁₂ and bile salts are absorbed mainly from the ileum. The rest of vitamins, minerals, and nutrients in the diet are absorbed from the jejunum. The large intestine absorbs mainly water and electrolytes.

Digestion and Absorption of Fat

The pancreatic lipase splits the triglycerides into monoglycerides and fatty acids. The bile acids help to bring these insoluble products into soluble form which is

absorbed. The products of digestion of fat are incorporated into the center of the micelles formed by bile salts to form mixed micelles. The brush border of the intestinal epithelium absorbs monoglycerides and fatty acids from the mixed micelles. The fatty acids are again converted to triglycerides in the epithelial cells and covered with a lipoprotein coat to form chylomicrons. The chylomicrons are discharged into the lacteals from where they reach the systemic circulation. Medium chain triglycerides are those composed of short chain fatty acids. They are more readily absorbed and they enter the portal vein directly instead of the lacteals.

Digestion and Absorption of Carbohydrates

Starch, sucrose, and lactose constitute the important carbohydrates in the diet. Salivary amylase initiates digestion of carbohydrates in the mouth, but dietary carbohydrates are mainly digested in the upper small intestine with the help of pancreatic amylase. Starch is broken down to *maltose*, *maltotriose* and *alpha limit dextrins*. These products and other disaccharides like sucrose and lactose are broken down further into monosaccharides by the *disaccharidase enzymes* located at the brush border of the intestinal epithelium. On further breakdown, glucose is formed from maltose, maltotriose, and alpha limit dextrins; glucose and fructose are formed from sucrose, and glucose and galactose are formed from lactose. Glucose and galactose are actively absorbed. Fructose is absorbed by facilitated diffusion.

Digestion and Absorption of Proteins

Digestion of proteins starts in the stomach where pepsin is present. However, the major site of digestion of dietary protein is the upper small intestine. This is effected by the pancreatic enzymes.

The *proteolytic enzymes* are secreted as inactive precursors, and are activated by the duodenal mucosal enzyme—*enterokinase* and by *trypsin*. The proteolytic enzymes break down the proteins to produce small peptides of 2-6 amino acids. These small peptides are further broken down by the *oligo peptidases* in the brush border of intestinal epithelium. Dipeptides and tripeptides may be actively taken up as such into the epithelial cell. They are hydrolyzed to free amino acids in the cell before they pass into the portal circulation.

Vitamins: Jejunum is the main site of absorption of all the vitamins except vitamin B₁₂, which is absorbed in the ileum.

Water and electrolytes: About nine liters of fluid (2 liters intake plus 7 liters of gastrointestinal secretions) pass through the alimentary tract daily. Only 100-200 mL is excreted in the stools. Water is transported in the

alimentary tract passively by the osmotic or hydrostatic pressure gradient generated by active solute transfer.

Sodium is absorbed mainly in the small intestine and its active transport is linked with the absorption of glucose.

ENDOCRINE FUNCTIONS OF THE GUT AND THE REGULATORY PEPTIDES

General Considerations

The term hormones (derived from the Greek word for “I arouse to activity”) is used to describe the chemical messengers acting at a distance. The other mechanism of control of bodily functions is neural. These two apparently different mechanisms of control of bodily functions act in an integrated manner. The same active principles (regulatory peptides) can be produced and released by endocrine and neural tissues and these may act as circulating hormones, local regulators, neurotransmitters or all these. The term *regulatory peptides* has been coined to describe active peptides capable of exerting their effects in one way or the other. Though these regulatory peptides were originally identified in the gut, brain or both, it is now realized that their distribution is much wider and that they are present practically in all the tissues.

Gastrointestinal Hormones

The regulatory peptide system of the gastrointestinal tract has received particular attention in recent times. Some of the regulatory peptides are secreted either by the endocrine cells interspersed among the mucosal cells or the enteric nerves, while others are present in both sites.

The peptidergic nervous system is a complex system composed of different types of peptidergic neurons. The cell bodies of the neurons lie either in the submucosal plexus or the mesenteric plexus. These neurons can cause gut movements independently and these belong to the noncholinergic, nonadrenergic class of autonomic nerves. Several peptides including *VIP*, *substance P*, *somatostatin*, *enkephalin*, and others have been identified in these nerves. Table 75.1 gives the regulatory peptides.

Gut Flora in Health and Disease

Human alimentary tract normally contains about 100 trillion microorganisms. It is sterile at birth; but soon after delivery, it gets inhabited by the microbial flora mainly from the fecal organisms of the mother and those from the surroundings. There are over 400 different species of microbes in the normal gut flora and they may reach a few hundred grams. The microbial density is less in the stomach and upper small intestine due to the presence of

TABLE 75.1

Regulatory peptides		
Peptide	Main distribution	Established actions
1. Gastrin	Stomach, duodenum	Stimulate gastric acid secretion
2. Cholecystokinin	Duodenum, jejunum and brain	Stimulate contraction of gallbladder and secretion of pancreatic enzymes
3. Secretin	Duodenum and jejunum	Stimulates secretion of pancreatic bicarbonate
4. Vasoactive intestinal peptide (VIP)	Central and peripheral nervous system and gut	Stimulates muscle relaxation, vasodilatation, secretion
5. Gastric inhibitory polypeptide (GIP)	Small intestine (duodenum and jejunum)	Stimulates secretion of insulin, inhibits secretion of gastric acid
6. Glucagon, enteroglucagon	Pancreas, gut, brain, ileum and colon	Regulates carbohydrate metabolism (pancreatic glucagon), trophic to gut (enteroglucagon)
7. Motilin	Small intestine	Stimulates gut motility
8. Pancreatic polypeptide	Pancreas	Inhibits pancreatic enzyme secretion and gall bladder contraction
9. Substance P	Central and peripheral nervous system	Sensory and vasodilatory role, stimulates muscle contraction
10. Neurotensin	Ileum, adrenal, brain	Vasodilatory, inhibits gastric acid secretion
11. Bombesin	Gut, brain, lung	Stimulates release of peptides (? antagonistic to somatostatin)
12. Somatostatin	Gut, pancreas, thyroid, brain	Inhibits release and action of many peptides
13. Enkephalins and endorphins	Gut, brain, sympathetic nervous system, carotid body, adrenal	Opiate effects
14. Thyrotrophin releasing hormone (TRH)	Brain and the gut	Endocrine action and bioactivity on the brain
15. Insulin	Pancreas, gut	Carbohydrate, lipid and other metabolic functions
16. Miscellaneous: ACTH, growth hormone, angiotensin II	mainly endocrine tissue	Probable activity on the gut and brain

gastric acid and intestinal peristalsis. Anaerobes far outnumber aerobes.

In addition, peptococcus, peptostreptococcus, klebsiella, proteus and others may also occur (Table 75.2).

Physiological Role

Gut flora are metabolically very active. They synthesize vitamin K and B-complex vitamins. They metabolize unabsorbed lipids to short chain fatty acids (SCFA) which are the main energy source for colonocytes. They ferment nondigestible dietary residues and endogenous mucus. They help absorption of calcium, magnesium and iron. In the proximal colon the pH is 5-6 (acid). The microbial growth is maximum and saccharolysis is predominant. In the rectum and distal colon the pH is neutral, bacterial growth is slow and proteolysis is predominant.

They also reduce cholesterol to coprostanol which is unabsorbable and thus they play an important role in

cholesterol balance. They are also responsible for deconjugating conjugated bile salts, converting unabsorbed protein and urea to ammonia and fermentation of dietary fibres. The gut flora stimulate and favour the spread of migrating motor complex (MMC) of the gut. Trophic functions include the control of epithelial cell proliferation and differentiation and homeostasis of the immune system. They play a role in the maintenance of normal gut endocrine function and detoxification of dietary carcinogens.

Protective function against pathogenic bacteria is achieved by preventing their growth and colonization. Adherent non pathogenic bacteria prevent the attachment and subsequent entry of pathogens into the epithelial cells.

Gut Flora in Disease

Excessive proliferation leads to malabsorption, bloated feeling due to fermentation: and nutritional deficiencies

TABLE 75.2

Bacterial contents in the normal gastrointestinal tract

Parameter	Stomach	Jejunum	Ileum	Colon
bacteria	streptococci staphylococci fungi	streptococci staphylococci lactobacilli	coliforms bacteriodes bifidobacterium clostridium	bacteriodes bifidobacterium clostridium enterococci
Bacterial density (per mL of contents)	10 ⁰⁻³	10 ⁰⁻⁴	10 ⁵⁻⁹	10 ¹⁰⁻¹²
pH	2-4	6-7	7.5	6.8-7.3

(bacterial overgrowth syndrome). It may play an important role in the pathogenesis of inflammatory bowel diseases (IBD), especially Crohn’s disease and irritable bowel syndrome (IBS). Bacterial translocation is an important factor in the pathogenesis of spontaneous bacterial peritonitis (SBP), necrotizing pancreatitis and systemic sepsis following surgery, shocked states, major injuries and burns.

Probiotics and Prebiotics

Probiotics are live microorganisms which, when administered, confer a health benefit to the host. They are approved by WHO for clinical use. *Saccharomyces boulardii* and *Lactobacillus delbrueckii* are the main probiotics in clinical use. Prebiotics are non-living nutrient elements which are not broken down by the intestinal enzymes. They nourish the probiotic flora to enhance their function.

Disorders where probiotics may be beneficial include;

- ulcerative colitis
- pouchitis
- irritable bowel syndrome
- antibiotic associated diarrhea and
- acute pancreatitis

Symptoms in Alimentary Disorders

Ptyalism: There is excessive salivation in this condition. This is a frequent complaint and it develops due to the local causes in the mouth such as dentures, dental fillings, gingivitis or other painful lesions. Excessive salivation may occur reflexly in peptic ulcer, esophagitis and other lesions of the upper GI tract. Ptyalism may be troublesome in parkinsonism. Excessive salivation in association with distaste is a common side effect of drugs like parasympathomimetic agents, antibiotics and iron salts.

Dryness of the mouth (Xerostomia): This may be a prominent accompaniment of dehydration, diabetes mellitus or drugs like atropine. Mouth breathing, chronic sialadenitis and Sjögren’s syndrome are local conditions which make the mouth dry. Mouth and conjunctiva are

dry in sicca syndrome. Dryness of the mouth predisposes to infection and interferes with speech and deglutition.

Halitosis: Bad odor of the mouth is commonly caused by poor oral hygiene, periodontal sepsis or infections in the paranasal sinuses. Deep seated lesions like lung abscess, bronchiectasis or achalasia cardia may also give rise to halitosis. The bad smell is produced by anerobic organisms multiplying in these areas.

Bleeding from the gums: Bleeding on brushing the teeth is usually caused by gingivitis and periodontal infections like pyorrhea alveolaris. Spontaneous bleeding occurs in hemorrhagic disorders and scurvy.

Bruxism: It is grinding of the teeth, especially during sleep. This is more common in children. Reflex irritation from the digestive organs may give rise to this symptom, though in many cases no cause is detectable.

Dysphagia: It is difficulty in swallowing which may be due to mechanical or neurogenic causes. *Odynophagia* is painful swallowing.

Mechanical causes are due to surgical conditions like carcinoma, stricture, diverticula and foreign bodies in the esophagus, or pressure from without as in mediastinal tumors, enlarged left atrium, retrosternal goitre or mediastinitis. The obstruction is gradual in onset and difficulty is more during the swallowing of solids than liquids.

The swallowing mechanism is deranged in paralysis of the lower cranial nerves or affection of the muscles. Neurological causes of dysphagia are paralysis of 9th, 10th or 12th cranial nerves, myasthenia gravis, motor neuron disease and cranial myopathies.

Hunger: It is an unpleasant awareness of the desire to eat when the stomach is empty. It is accompanied by irritability and a sensation of abdominal discomfort.

Appetite: It is a pleasurable desire to eat food and it may not bear any direct relationship to hunger. Many factors like emotions, social customs and training modify appetite. Satiety is the feeling of fullness after the ingestion of food.

Anorexia: It is a morbid loss of desire to eat. Unlike satiety, which occurs only on taking food, anorexia may be present even when the person is hungry. Anorexia may accompany gastrointestinal and liver diseases, infections like tuberculosis or psychological disturbances like depression.

Nausea and vomiting: Nausea is the feeling of impending desire to vomit. It is usually associated with salivation, inhibition of gastric peristalsis, and rise in tone of the duodenum and proximal jejunum. Duodenogastric reflux occurs. The spasmodic and abortive respiratory movements in the presence of a closed glottis cause retching. During retching the distal part of the stomach contracts and the proximal part relaxes. The gastric contents are forcibly ejected through the mouth. Vomiting is controlled by the two medullary centers—the vomiting center and the chemoreceptor trigger zone.

Weight loss: This is not a phenomenon specific to gastrointestinal diseases, but in many alimentary disorders considerable weight loss occurs. Diminution of food intake, malabsorption, loss of nutrients, accelerated metabolism and parasitism may contribute to the weight loss. Diseases like gastrointestinal and hepatic malignancy and liver cirrhosis may present with considerable weight loss before the local symptoms develop.

Abdominal pain: Abdominal pain may be classified into: (i) *visceral pain*, (ii) *parietal pain*, and (iii) *referred pain*. Pain arising from the abdominal organs is visceral pain.

Visceral pain: It is carried by the C fibers and, therefore, it is poorly localized. Visceral pain is evoked by stretching, rise in tension in the wall of hollow organs due to spasm and dilatation, or traction on the mesentery or the blood vessels.

Pain from solid organs is caused by stretching of the capsule, inflammation, ischemia or neoplastic infiltration of the free nerve endings. Pain from solid organs tends to be of constant dragging, lancinating or throbbing nature, aggravated by movements and respiration. Pain arising from hollow viscera such as the esophagus, intestines, biliary tract and urogenital tract tend to be intermittent, often associated with contraction of the viscus against resistance or hyperperistalsis. The nature is colicky, in which the pain starts, works up to a maximum and passes off after varying periods, with relief. These episodes tend to recur at intervals. The pain is described as gripping, twisting or squeezing. The site of pain may correspond to the dermatomal distribution of the organ, or may be over its surface marking.

Biliary colic arising from the gallbladder tends to be a steady pain despite its name. It is severe and intermittent. It starts abruptly and lasts up to five hours in uncomplicated cases. It may be felt over the right hypochondrium

and epigastrium or may radiate to the right scapula or shoulder.

Parietal pain: Pain arising from the parietal peritoneum is generally more intense and more precisely localized because it is transmitted by overlying somatic nerves.

Referred pain: Sometimes pain felt in the abdomen may be referred from other sites such as the pleura, lungs or heart or it may result from spinal root irritation (T₇-T₁₂).

Diarrhea: Diarrhea is defined as the passage of stools of fluid consistency more frequently than is usual (usually more than 3 times per day). The wet weight of the stool is increased. Diarrhea results from several factors like intestinal hypermotility, malabsorption of water and electrolytes, inflammation of the gastrointestinal tract or use of laxatives. In addition to the development of dehydration and malabsorption state, diarrhea and vomiting along with abdominal pain impair the quality of life. Acute diarrhea clears up within two weeks. Chronic diarrhea exceeds two weeks in duration. The presence of fresh blood in stools is called hematochezia.

Infections or irritants cause acute diarrhea whereas chronic diarrhea may result from many causes.

Constipation: It is the condition of infrequent evacuation with harder consistency of feces. Any reduction in frequency of normal bowel movement in an individual should be considered as constipation. There is no single definition for the term constipation. Different attributes include one or more of the following: - hard stools, infrequency (less than thrice a week) excessive straining, sense of incomplete evacuation, excessive time taken for defecation and unsuccessful defecation. Common causes are reduction of dietary bulk, dehydration, lack of exercise, recumbency, social factors like change of place and travel, drugs reducing intestinal motility, increased intracranial tension in children, myxedema, megacolon, intestinal obstruction, and psychiatric disorders. Both diarrhea and constipation should receive more attention when they are of recent onset since they may be the warning signals of serious underlying diseases such as malabsorption or cancer.

Investigations in Alimentary Disorders

Examination of Feces

Wherever possible, examination of the total quantity of feces passed at a time should be done. This helps in assessing the volume, colour, consistency, and abnormal constituents of feces. On an average Indian diet the weight of feces ranges from 250 to 500 g/day. The consistency may vary from semisolid to hard even among normal individuals. The colour is derived from products of bile pigments. Clay coloured stools are seen in obstructive

jaundice. Presence of altered blood makes the feces black and tarry (*melena*). Black colour may be due to ingestion of heavy metals or other dietary articles.

Microscopic examination: The microscopic examination of fresh feces helps in identifying protozoa such as *E. histolytica* and *G. lamblia*. Other abnormalities commonly seen are helminthic ova and larvae, cellular exudates, fat globules, and muscle fibers. Protozoal cysts and helminthic eggs are better detected by concentration techniques and staining with aqueous iodine.

Microbiological investigations: These are done for the identification of pathogenic bacteria, fungi or viruses. Fresh fecal specimens, rectal swabs, or material obtained during proctoscopic examination are used for this purpose.

Biochemical tests: Occult blood may be present in stools and is detected by the *o-toluidine blue* or *guaiac* test. As a rule, it is better to avoid iron containing drugs and consumption of meat for 3-5 days before collecting feces for occult blood test. Presence of occult blood points to a bleeding source in the gastrointestinal tract such as benign ulceration or malignancy. Absence of occult blood in feces on repeated testing is a strong point against such lesions.

Quantitative estimation of the fat content of the stool helps to establish steatorrhea. Other biochemical tests such as estimation of the electrolytes, pH value, nitrogen content, stercobilinogen, porphyrins, etc. are done at times in special situations.

Digital Examination of the Anal Canal and Rectum

This is a very valuable method which gives information on the pathology in the anal canal, rectum and even the lower parts of the sigmoid colon. Digital examination is done with the gloved index finger, properly lubricated with vaselaine, keeping the patient in the left lateral decubitus or in the knee chest position. Proper explanation to the patient is necessary to ensure his co-operation. The external parts of the anus, tone of the anal sphincter and mucosal surface of the anal canal and rectum are systematically palpated. Fissure-in-ano, hemorrhoids, carcinoma, other growths, abnormalities of the prostate and other pelvic organs can all be diagnosed with reasonable certainty. Fecal masses and foreign bodies can be identified. Examination of the material on the finger helps to diagnose bleeding from upper or lower gastrointestinal tract. Microscopy of the material and further studies help to diagnose dysentery and other ulcerative lesions.

The findings on digital examination can be further clarified by proctoscopy, ano-rectal manometry and further imaging procedures.

Gastric Acid Analysis

The time honoured method of fractional test meal has been replaced by measurement of basal and maximal acid output. Maximal acid secretion is obtained by stimulating with histamine (0.04 mg/kg), histalog (1.5 mg/kg), or pentagastrin (6 µg/kg) given parenterally. Acid output values are expressed as mmol/h.

The test: Anticholinergic drugs should be avoided at least for 48 h before the test. After fasting overnight a tube is passed through the mouth and its tip is positioned at the junction of the lower and the middle-third of the stomach under fluoroscopic control. Basal secretion is collected by continuous suction and histamine is given subcutaneously. The gastric juice is collected by continuous suction and four 15-minute samples are collected separately. Volume of each specimen and the amount of hydrochloric acid are determined. For Indians basal acid output (BAO) varies from 1-4 mmol/h and maximal acid output (MAO) from 6-30 mmol/h. By using insulin as the stimulant, the test can be employed to assess the completeness of vagotomy (*Hollander test*). With the advent of endoscopic studies, the value of gastric secretory studies in the diagnosis of gastric and duodenal ulcer and gastric carcinoma has come down. In these conditions the acid levels show considerable overlap and, therefore, may be misleading. However, very high gastric acid values are valuable clues in the diagnosis of Zollinger-Ellison syndrome and complete absence of gastric acid (achlorhydria) is suggestive of pernicious anemia.

Sampling of Intestinal Contents

Sampling of intestinal contents from various levels has been employed for chemical and microbiological studies in conditions such as malabsorption states, and hepatic and pancreatic diseases. Contents of the gastrointestinal tract can be aspirated by using special tubes, the tip of which can be accurately positioned at the particular site under fluoroscopic control. Endoscopy has revolutionized the procedure for aspiration. Conventional methods using tubes or biopsy capsule blindly have been totally replaced by aspiration or biopsy from specific areas, under vision.

Radiological Examination of the Digestive System

These time-honored studies are of considerable help in diagnosis. Diagnostic accuracy has been considerably improved by several technical refinements. Endoscopy is more reliable to visualize mucosal lesions, and to take biopsies. But to demonstrate other structural lesions, displacements, fistulae, etc. and for studying the progress of the contrast medium, radiological studies are regularly undertaken.

Plain X-ray of the abdomen: Liver, spleen, kidneys, and tumours can be identified in a plain X-ray and their size determined. Calculi in the gall bladder, bile duct, urinary tract or pancreas, calcification of organs such as the pancreas and adrenals; and radiopaque foreign bodies and fetal parts are all classically demonstrable in a plain radiograph.

A plain X-ray of the abdomen taken in the erect posture after proper bowel preparation may show the presence of gas under the diaphragm, gas in organs such as gallbladder, biliary tree and liver, that normally do not contain gas. Presence of gas under the diaphragm indicates perforation of a hollow air-containing viscus such as the stomach or intestine. Gas in the biliary tree and gallbladder should suggest fistula formation with the gallbladder, perforation or infection by gas-forming organisms. Intestinal obstruction gives rise to the presence of multiple dilated loops with fluid levels.

Contrast studies of the gastrointestinal tract: Several contrast materials have been employed to visualize different organs.

8

Barium swallow: Barium swallow is done to visualize the esophagus. After overnight fast the patient is made to swallow a thick freshly prepared paste of barium sulfate as rapidly as possible. Since most patients swallow considerable amounts of air also simultaneously, the air distended esophagus is well visualized. Barium swallow brings out lesions such as strictures, neoplasms, diverticula, esophagitis, ulcers, tears, esophageal varices, and external compression. The function of the esophagus and the lower sphincter can be assessed from the passage of the barium downwards and the pattern of peristaltic waves.

Barium meal: For barium meal studies a large quantity (250-500 mL) of freshly suspended emulsion of barium sulfate is swallowed rapidly. The rate of transit of the barium and the contours of the stomach and intestines can be assessed by fluoroscopy or television. Pictures are taken at regular intervals to delineate the different parts. Double contrast technique using air and barium helps to bring out even minute mucosal abnormalities. Barium meal studies for stomach and duodenum are indicated in suspected peptic ulcer, neoplasms of the stomach, mucosal erosions, obstructions, persistent vomiting, and vague upper abdominal symptoms.

The intestines are visualized by taking pictures in the intestinal phase of the meal. The time taken for the passage of barium, pattern of distribution in the intestinal lumen and morphological abnormalities can be assessed. Several newer techniques have helped in increasing the diagnostic efficiency and minimizing the discomfort to the patient.

Enteroclysis (Small Bowel Enema)

Barium contrast is administered directly into jejunum through a tube introduced through the nose or mouth and

positioned under fluoroscopy across the duodenum. In conventional barium study adequate quantity of barium may not enter the jejunum freely, due to the action of the pyloric sphincter. Better delineation of the small intestine can be obtained by enteroclysis.

Hypotonic duodenography: The medial wall of the duodenum, which is closely apposed to the pancreas, can be better visualized by instilling barium after using a relaxant drug such as propantheline bromide (probanthine) 30-60 mg intramuscularly or 15 mg intravenously.

Barium enema: The large intestine up to the ileocecal junction can be visualized by barium enema. Meticulous preparation of the large bowel before examination is absolutely essential to ensure accuracy. The patient should be on a low residue diet for 2 days prior to the examination. Evacuation is achieved by a purgative and, if needed, a thorough bowel wash. Barium sulfate suspension is given as an enema to fill the whole large intestine and the progress of barium is watched under the fluorescent screen. Pictures of the barium-filled colon are taken. After evacuation of the barium, air is pumped through the anal canal to fill the colon and further pictures are taken. This double contrast study helps to demonstrate mucosal lesions clearly. Barium enema is indicated in lesions of the colon and rectum such as carcinomas, ulcerative colitis, diverticulitis, polyposis, strictures, and megacolon.

Gastrointestinal Endoscopy

The advent of flexible fiberoptic endoscope has revolutionized endoscopy. Incorporation of video screens in which magnified images can be seen simultaneously has made the procedure much more efficient. Almost all parts of the stomach, many parts of the duodenum and small intestine, and almost the whole of the colon can be visualized using endoscopes which are capable of manipulation to bring to focus several areas such as the fundus of the stomach, cecum, ileocecal region and others which could not be fully visualized by the earlier endoscopes. At present the procedure is very reliable, freely available in many centers, and almost noninvasive. Endoscopy enables direct examination of the lesions, biopsy, cytology of suspicious areas, and documentation by photography. Therapeutically, endoscopes are used to remove polyps and foreign bodies, dilate strictures and cauterize ulcers and bleeding points. At present all parts of the alimentary tract are accessible to endoscopy.

Upper alimentary endoscopy: Examination of the esophagus, stomach and duodenum is done by a panendoscope. Upper alimentary endoscopy is indicated in patients with upper gastrointestinal bleeding, all types of chronic dyspepsia, and when lesions are demonstrable by X-ray but their pathological nature is not clear.

Whenever facilities are available, endoscopic examination should be undertaken to confirm the nature of mucosal lesions. Endoscopic esophageal variceal injection, variceal ligation, percutaneous feeding gastrostomy and similar procedures are commonly undertaken in gastroenterology departments at present. Endoscopic ultrasonography is a technique which gives more precise data from locations usually inaccessible to conventional ultrasound. It gives better imaging of the pancreas and even tumours less than 3 cm in diameter can be detected. Endocrine adenomata and cancer with vascular invasion arising from pancreas, and small lesions arising from other parts of the gastrointestinal tract are particularly well seen by endoscopic ultrasonography.

Special Types of Endoscopes

1. *Capsule endoscope* – A battery powered computer chip camera is assembled inside a capsule. Patient swallows it orally and the signals are recorded, which can be viewed in the monitor screen. The cost of an endoscopic capsule may come to Rs.30, 000.
2. *Zoom endoscopes* — The lesions can be zoomed to 50 to 150 times magnification.
3. *Laparoscope assisted pan-endoscopy (LAPE)*— Endoscope is introduced per orally and the small intestine is sleeved on to the endoscope with the help of the laparoscope. The entire small intestine can be visualized. It is very useful in obscure gastrointestinal bleeding.

Proctoscopy: Anal canal and rectum are visually examined with the proctoscope. Digital examination of the rectum is mandatory before introducing the proctoscope. Proctoscopy is contraindicated in severely painful lesions and strictures of the anal canal. Digital examination and proctoscopy help to diagnose the vast majority of lesions in the rectum and anal canal. These procedures should be done as part of the clinical examination in all patients presenting with symptoms pertaining to the lower alimentary tract.

Digital examination is contraindicated in the first 3-4 days following myocardial infarction, since there is the risk of triggering off serious arrhythmias.

Further refinements in the study of the anal sphincter mechanism especially in the investigation of fecal incontinence, are ultrasonography to detect tears of the external sphincter muscle, pudendal nerve latency to assess nerve conduction and anal canal manometry.

Proctosigmoidoscopy: The anal canal, rectum, and distal sigmoid colon can be visualized through a sigmoidoscope. Rigid and flexible sigmoidoscopes are available. The simplicity of the procedure and availability of the instrument in all hospitals have contributed to widespread use of this procedure. Hemorrhoids, polyps, acute and

chronic inflammatory bowel disease, neoplasms, ulcerating lesions, and sources of bleeding can be diagnosed by sigmoidoscopy and biopsy.

Colonoscopy: Flexible fiberoptic colonoscopes are available and the whole of the large intestine can be examined with them. Proper bowel preparation using an osmotically active cathartic is mandatory to clear the colon of fecal matter and enable full visualization.

Indications for colonoscopy are:

1. In lower gastrointestinal bleeding not accessible to the sigmoidoscope.
2. In inflammatory bowel disease, to assess the extent.
3. In the evaluation of radiologically demonstrable abnormalities in the large bowel situated beyond the reach of the sigmoidoscope.
4. Therapeutically, these instruments are used to remove polyps and foreign bodies and to arrest bleeding points.

Peritoneoscopy (Laparoscopy): Examination of the peritoneal cavity is safely carried out using a peritoneoscope (laparoscope). Under aseptic precautions, air is introduced into the peritoneum and the laparoscope is introduced through a small incision on the anterior abdominal wall. Liver, spleen, gallbladder, omentum, loops of intestines, pelvic organs and peritoneum can be seen directly. Localized lesions can be biopsied under vision through the peritoneoscope. Laparoscopy is indicated for detecting the cause of ascites, diagnosing liver diseases and in detecting metastatic carcinoma. Surgical procedures can also be undertaken through the laparoscope. Heart disease, acute infections, hemorrhagic diatheses, and peritoneal adhesions are contraindications for laparoscopy. Rarely complications such as hemorrhage, peritonitis and perforation of organs may occur.

Choledochoscopy: In this procedure an endoscope is passed into the biliary tree, usually during surgery. It helps to visualize the major biliary passages, remove stones and release obstructions.

Endoscopic retrograde cholangiopancreatography (ERCP): This is a procedure undertaken to delineate the common bile duct and pancreatic duct. After fixing the endoscope at the ampulla of Vater, the ampulla is cannulated using special catheters and several procedures can be performed. These include collection of the respective digestive juices, contrast injection and visualization of the duct pattern, removal of stones and growths, sphincterotomy and others.

Angiography: Abdominal angiography may be required for the investigation of several gastrointestinal diseases. With the help of suitable catheters, the celiac, superior and inferior mesenteric arteries and their branches can be selectively cannulated and contrast injected. Angiography

is indicated to detect the site of acute and chronic gastrointestinal bleeding, determine the cause of ischemic bowel disease, and in other vascular disorders of the gastrointestinal tract. Therapeutic indications include the administration of vasoconstrictor drugs (e.g., pitressin), clotting factors or microemboli to arrest bleeding, and local cytotoxic drugs for neoplasms.

Ultrasound Imaging

Ultrasound scanning is a safe, noninvasive, simple and relatively inexpensive examination. It is useful in imaging solid, cystic or air-containing tissues and organs. Ultrasound examination is indicated in hepatobiliary diseases like primary or secondary tumours, liver abscess, differentiation of medical from surgical jaundice, cholelithiasis, and various lesions of the pancreas. In skilled hands, ultrasound examination is a very reliable procedure. This has become a primary investigation to establish hepatobiliary disease, organomegaly, ascites, pregnancy, and others. Ultrasound-directed percutaneous biopsies from lesions, and aspiration of pus from abscess cavities are undertaken regularly at present. The average cost for ultrasonography of the abdomen is around Rs. 400.

Computed Tomography (CT) Scan

This technique is widely employed in the investigation of diseases of abdominal organs. Solid tissues like liver, pancreas, kidneys, adrenals, and tumors of lymph nodes and fluid-containing masses like cysts and abscesses produce diagnostic images. It is also useful in the investigation of biliary tract disease, and in the differentiation of medical from surgical jaundice. With the help of CT scan, percutaneous biopsy needles can be accurately positioned to get biopsies. This investigation has the advantage of being noninvasive, but its high cost and nonavailability in smaller cities and towns are disadvantages. The cost of CT scanning of the abdomen is around Rs. 3000. Several newer techniques using CT scanning have been introduced.

Virtual colonoscopy is a CT technique which generates high resolution two-dimensional axial images from which three-dimensional images of the colon resembling those seen on colonoscopy are reconstituted.

The reliability of this imaging procedure in detecting colonic lesions including cancer is being investigated.

Magnetic Resonance Imaging (MRI)

MRI scans are increasingly used in complicated abdominal conditions. MRI is more useful than CT scan

in defining soft tissue lesions and is especially useful in conditions like internal intestinal fistulae.

Isotopic Investigations

These are of great value in diagnosis. Absorption and fecal elimination of many substances such as cyanocobalamin and fats can be studied by using suitable isotopes. Functions of several organs can be assessed.

Biopsy

Histology is a valuable aid in confirming the diagnosis. The advent of flexible endoscopes have made all parts of the alimentary tract accessible for biopsy.

At present endoscopic biopsy is preferred for all the tubular organs. For solid organs such as the liver, pancreas, lymph nodes and solid tumors ultrasound directed or CT directed biopsy is done on account of its reliability and safety.

Laparoscopy: This is the procedure to visualize intra-abdominal and pelvic structures in vivo using appropriate laparoscopes. Several refinements and modifications have resulted in the manufacture of sophisticated instrument and development of techniques which make it possible to inspect almost all organs in the peritoneal cavity. Laparoscopy is safe and minimally invasive. In experienced hands the findings are quite reliable. Biopsy procedures and surgical interventions can be undertaken at the same time.

However, when the other non-invasive tests are not conclusive, and particularly so when malignancy is suspected, early laparotomy has to be undertaken. In some centers, mini laparotomy is used as a diagnostic tool in the investigation of jaundice and other hepatobiliary problems. By this procedure, after exposing the left lobe of the liver, liver biopsy, transhepatic cholangiography, portal manometry, and collection of bile for cytology can be carried out.

Investigative techniques have reached a high level of perfection. With the availability of modern facilities it is possible to arrive at a proper diagnosis in almost all cases, without resorting to surgery. These investigations also help the physician in assessing the functions of organs accurately, so as to plan the therapy more objectively. The proper selection and interpretation of the tests demands the diagnostic skills of the physician and a very meticulous clinical examination.

Diseases of the Mouth and Tongue

K.R. Vinaya Kumar, K.V. Krishna Das

Chapter Summary

Inflammation of the Salivary Glands	455
Recurrent Aphthous Ulcer	455
Oral Submucous Fibrosis	456
Orofacial Granulomatosis	456
Non-specific Inflammatory Diseases of Periodontium	456
Dental Caries	457
Vincent's Infection	458
Diseases of the Tongue	458
Oral Cancer	459

Inflammation of the Salivary Glands**Syn:** Sialadenitis**Causes of Generalized Sialadenitis**

- Bacterial infections:** *Staph. aureus*, *Ps. aeruginosa*, *Strep. viridans*, and rarely pneumococci and *E. coli*.
- Viral infections:** Mumps.
- Other conditions:** Sjögren's syndrome, leukemia, lymphoma, sarcoidosis (*Heerfordt's syndrome*), lupus erythematosus, tuberculosis, other mycobacteria, actinomycosis, obstruction of the ducts, salivary calculi, and rarely Reiter's syndrome.

Causes of Parotid Enlargement

- Reaction to drugs** such as iodides, guanethidine, chronic toxicity by copper, lead or mercury.
- Alcoholism, Laennec's cirrhosis and calcific pancreatitis.**
- Suppurative parotitis:** This may complicate prolonged fevers like typhoid. Infection reaches the gland from the mouth through the duct. Dehydration and poor oral hygiene predispose to infection. An abscess develops in the parotid gland. Once the abscess forms, pus has to be drained by incision. Suppurative parotitis is prevented by proper care of the mouth in predisposed individuals.

RECURRENT APHTHOUS ULCER**Syn:** Cancer sore, Mikulicz aphthae, Aphthous stomatitis

Aphthous ulcers are the most common lesions affecting the oral mucous membrane. The exact etiology is unknown. Recent observations suggest an autoimmune etiology. Microscopically, the lesion shows a non-specific ulcer with necrosis of subepithelial small blood vessels.

Clinical Features

Crops of painful ulcers occur periodically at intervals of weeks to months. The ulcers can be divided into minor (60-70%) and major aphthae (30-40%).

Minor Aphthous Ulcers

These occur mainly on the labial, buccal, and tongue mucosa. They are shallow, measuring 2-4 mm in diameter. The floor is covered with fibrin and the periphery is erythematous. Rarely, the ulcers may become secondarily infected, but they heal without scarring.

Major Aphthous Ulcers

These appear commonly in the soft palate and lower labial mucosa. They are larger, measuring over 1 cm in diameter, and are deep and indurated. They persist for more than 4 weeks and heal with scar formation. Other clinical features are similar to those of minor aphthae.

Diagnosis is clinical. Minor aphthae have to be differentiated from the oral manifestations of herpes simplex, agranulocytosis, infectious mononucleosis and cyclic neutropenia. Major aphthae showing induration should be differentiated from malignancy.

Treatment

There is no specific treatment. Topical application of steroids in the initial phase may abort an attack. Pellets of glucocorticoids or 0.1% triamcinolone in orabase applied locally four times daily are effective in 2-3 days. Rarely systemic corticosteroids may be required.

Other modalities of treatment include tetracycline mouth wash and 2% anesthetic ointment or jelly. Castor oil 5-10 mL administered at bed time in milk for 3-4 days helps in shortening the duration and aborting an attack (personal observation-KVK).

Oral Submucous Fibrosis

Submucous fibrosis is commonly seen among all races inhabiting South-east Asia. It is common in South India. There may be an increase in incidence in those who chew betel nut continuously for several months. Recent studies have shown a high content of copper in some of the nut preparation available commercially. The significance of this finding needs further study.

Pathology

Pathological changes include ribbon-like atrophy of subepithelial collagen and moderate infiltration by chronic inflammatory cells. There may be dysplastic changes in the epithelium and many cases develop squamous cell carcinoma on follow-up.

The disease starts insidiously and runs a chronic course. Early symptoms include burning sensation of the mouth and difficulty to tolerate spicy foods. Gradually, fibrosis sets in, and this may interfere with opening of the mouth. In advanced cases the uvula becomes fibrotic and small. The fibrotic process may rarely extend to the pharynx and esophagus in advanced cases. Later on, recurrent erosions and ulcers develop which heal slowly. Carcinoma develops from these erosive or ulcerated areas and not uncommonly it is multicentric.

Clinical diagnosis is based on the symptoms and the leathery inelastic feel of the oral mucosa. Diagnosis is confirmed by biopsy.

Management

There is no specific treatment. Smoking and chewing of tobacco and betel nut should be stopped. Repeated submucous infiltration of 25 mg of hydrocortisone hemisuccinate into the fibrous areas may help in resolving early lesions and improving the mobility of the lower jaw and tongue. All patients have to be followed up and suspicious lesions biopsied. If malignancy is detected, it is treated by irradiation.

Orofacial Granulomatosis

Oral lesions are common in patients suffering from Crohn's disease of the intestines. These include aphthae, diffuse swelling of lips and cheeks, chronic inflammatory hyperplasia with fissuring of the mucosa, mucosal tags, vertical fissuring of lips, and hyperplastic gingivitis. Sometimes similar lesions may occur even in the absence of the intestinal lesions.

Outlook for orofacial granulomatosis is variable. Some cases are self-limiting. Drugs which are found to be partially effective include danazol and clofazamine.

Non-specific Inflammatory Diseases of Periodontium

Limited surveys reveal that periodontal disease occurs in up to 90% of several communities in India. Periodontium comprises gingiva, periodontal membrane, and the alveolar bone which support the teeth. All the non-specific infections together are called as **pyorrhea**. Pyorrhea is common in persons past middle age. Dental infection is the most common focus of sepsis in any individual. The infection takes the form of gingivitis in the beginning and then it progresses to periodontitis, and finally the teeth fall off. Many local and systemic factors influence the course of the disease. Local factors that aggravate the progress of periodontal disease are traumatic occlusion, malalignment of teeth, mouth breathing, calculus, illfitting appliances and xerostomia. Systemic conditions include protein malnutrition, puberty, pregnancy, menopause, diabetes, anemia, scurvy, granulocytopenia, drugs like phenytoin, and immunodeficiency states.

The earliest change is the formation of a bacterial plaque in the cervical margin of the tooth. The plaque contains *Streptococcus viridans*, *Staph. albus*, *Staph. aureus*, lactobacilli, *Helicobacter pylori* and actinomycetes. The toxins produced by the bacteria evoke an inflammatory response in the gingival crevice. The gingiva and interdental papilla become edematous and bleed on palpation. Further bacterial proliferation and toxin formation occur and inflammation progresses.

The gum attachment migrates apically. The periodontal fibers undergo degeneration and the alveolar bone also undergoes resorption. This stage is called periodontitis. At this stage an acute periodontal abscess may form. Continued inflammation and resorption of alveolar bone leads to loosening and loss of teeth.

Clinical Features

Gingivitis may be symptomless except for halitosis and painless bleeding from gums on brushing. The gingiva are red and the normal stippling is absent. Periodontitis is characterized by dull pain. Periodontal abscess causes throbbing pain which increases when the patient is recumbent. Pus can be expressed from the gingival crevice.

Diagnosis

The diagnosis of non-specific periodontal disease is made by clinical examination. Depth of the gingival pocket can be measured by a periodontal probe.

Intraoral *bite wing X-rays* are useful in assessing the pattern and extent of bone loss. In all cases of severe periodontal disease full clinical examination and investigation should be done to exclude the underlying systemic disorders.

Management

The disease can be prevented by avoiding the formation of dental plaques. Plaques can be removed by regular brushing and flossing. The calculus formed should be removed by scaling. Analgesics and antibiotics are required to control pain and infection respectively. Acute gingival or periodontal abscess has to be drained. If there are deep pockets, gingivectomy has to be done. Loose teeth have to be extracted if they cannot be refixed by appropriate dental management.

Dental Caries

Dental caries is defined as the local destruction of susceptible hard tissues by acidic byproducts formed by bacterial fermentation of dietary carbohydrates. Caries may affect the crown or the root of the tooth.

Dental caries is one of the most widespread diseases present all over the globe, but shows wide variation in prevalence among different communities. In several parts of India the prevalence is 65-70% among the general population. It results from demineralization and dissolution of the enamel and dentine. The etiology of dental caries is complex and several factors serve to start off the process. Factors which affect the extent and progress of the disease are the composition of the enamel, food habits, content of carbohydrates in the food, oral hygiene, heredity, and fluoride intake in food and water. Food debris and bacteria accumulate on the pit and fissure surface of the teeth to form a plaque consisting of bacteria, mucus, and desquamated epithelial cells. Refined carbohydrates like sugars adhere to the plaque and help in liberating acid products by action of the mixed bacterial flora, the most important among them being *Streptococcus mutans*. The infant acquires *Streptococcus mutans* from the mother or other primary care givers. Under the plaque, the pH is lowered below 5.3 and this causes demineralization of the enamel. The calcium salts are removed, leaving the tooth surface rough and chalky white. At this stage the proteolytic organisms destroy the protein matrix of enamel rods. This process proceeds towards the dentine and a cavity is formed. In the dentine the progress is faster and the pulp is reached. The response of the pulp depends upon the age and general resistance of the individual and virulence of the organism. Either an acute pulpitis with necrosis may develop or the inflammation may become chronic. Secondary dentine may be formed from the pulp in an attempt to limit the infection. At times the pulp may undergo hyaline degeneration and calcification.

 2. Dentine
 3. Pulp
 4. Soft tissues
 5. Cementum
 6. Alveolar bone
 7. Gingiva
 8. Gingival crevice,
- (A) and (B) Site for periodontal abscess.
(C) Site of accumulation of plaque.

Finally, the bacteria and their toxins reach the periapical tissues and produce acute periapical periodontitis and progress to acute periapical abscess. If the host resistance is poor, the infection can spread to adjacent tissues, maxillary sinuses, base of the skull, and through the bloodstream. More often the inflammation becomes chronic leading to the formation of a granuloma which acts as a chronic focus of sepsis. An inflammatory cyst may be formed (Fig. 76.1).

Clinical Features

In children caries is usually seen in the pit and fissures of the occlusal surfaces whereas in elderly persons it is noticed more in the cervical margins of the teeth, though any surface may be affected. The whole process may proceed slowly over the years or can be rapid to develop within months. Widespread acute caries involving all surfaces of several teeth is referred to as *rampant caries*.

The condition remains asymptomatic till the lesion reaches the dentinoenamel junctions, since there are no nerve endings in the enamel. Early lesions appear as chalky white areas on the enamel surface which can be detected by a probe. These are translucent on X-ray examination. Later, the chalky areas become brown or black. Initial symptom is *sensitivity* to sweet, cold or hot drinks produced by stimulation of nerve endings in the dentine. Pain develops when the pulp becomes hyperemic.

Acute pulpitis causes unbearable pain, often described as toothache, on the affected side. The pain is only poorly localized and the patient may not be able to pinpoint the affected tooth. As the acute condition subsides, pain becomes dull. If the pulp undergoes necrosis, pain is abolished and the condition remains symptomless for a while. As the inflammation extends outside the tooth, pain returns. Exacerbations and remissions alternate for considerable periods of time.

Treatment

Powerful analgesics give moderate relief of pain in the acute stage. Prompt relief is obtained by injection of a local anesthetic. A broad-spectrum antibiotic like ampicillin 250 mg 6 h or ciprofloxacin 500 mg b.d is required for 3-5 days to control infection. Abscesses have to be drained surgically. Since appropriate dental care is to be instituted, the case should be immediately referred to a dental surgeon.

Caries is incurable once it is established, since the dentine is not capable of undergoing repair. Early lesions are treated by removal of the affected parts and filling up the defect with suitable materials. Technical advances in dentistry have been remarkable and even grossly affected teeth can be restored to functional stage, without recurrence of pain. If the tooth is grossly damaged beyond repair, it has to be extracted. At present the policy is to restore the tooth to normal functions and preserve it as far as possible.

Prevention

Dental caries is an easily preventable disease. Prevention should start during pregnancy, when the teeth of the fetus are getting mineralized. Adequate supplements of calcium, vitamin D and other nutrients to mothers during pregnancy and later to the child, ensure proper teeth formation. Inclusion of fresh vegetables and fruits which require proper mastication helps to keep the teeth and gums healthy. The habit of allowing the baby to sleep with the milk feeding nipple in the mouth helps to promote caries. Soft drinks which contain sugar favour the growth of organisms and promote the development of caries. Proper brushing of the teeth and massage of the gums before the child goes to bed is an effective preventive measure against caries.

Fluoridation of community water supplies at 1 ppm reduces the incidence of caries. Fluoride applied topically either directly or by using fluoridated tooth pastes or chewing gums improves local resistance of the teeth. Fluoride tablets containing 2.2 mg of sodium fluoride (equivalent to 1 mg fluorine) have been used to supplement the intake in babies. One tablet is dissolved in 1.25 L water and this water is used for making up milk formula and cooking for children below the age of three years. Above the age of three years

one tablet may be administered daily. Periodic dental check-up of preschool and school children and education of the mothers are absolutely essential to lower incidence of caries in the community. In many parts of India where the fluoride content of drinking water is high, additional supply of fluoride through toothpastes has been incriminated as a factor aggravating fluorosis. This has to be borne in mind while making recommendations for fluoride supplementation.

Vincent's Infection

Syn: Vincent's angina, Acute necrotizing ulcerative gingivitis

It occurs as a painful condition caused by a mixed bacterial flora consisting of *fusiform bacilli* and *Vincent's spirochetes*. It may be associated with extensive necrotizing ulcerative mucositis, or acute pseudomembranous lesions of the pharynx or tonsils. The condition is predisposed to by poor oral hygiene, food impaction, excessive smoking, and local trauma.

The gums are painful, swollen, hemorrhagic and foul smelling. A serious complication is noma which begins at the corners of the mouth and proceeds to rapid necrosis of the entire thickness of the cheeks. Rarely septicemia and meningitis may occur.

Treatment

The organisms respond dramatically to penicillin in the usual dosage. Metronidazole 200 mg given orally thrice daily for 7 days gives good relief and is a satisfactory alternative.

Diseases of the Tongue

Glossitis: It is inflammation of the tongue and in general denotes soreness and redness of the tongue. The tongue appears beefy red and the papillae are prominent. In some cases the papillae may be ironed out. Glossitis may result from deficiency of B complex vitamins, megaloblastic anemia, cirrhosis of liver, irritants like alcohol, excessively spicy foods, and all causes of stomatitis. Specific lesions of syphilis, gonorrhea, tuberculosis, actinomycosis and AIDS may start in the oral cavity.

Leukoplakia: This is a chronic lesion characterized by the presence of white, firm, smooth patches over the tongue present over a variable extent. Though painless at first, it may become fissured and painful later. Being a precancerous condition, persons who develop leukoplakia have to be regularly followed up.

Geographical tongue: It is the name given to chronic migrating superficial glossitis. Though it appears fierce, it is not clinically significant. The cause is not clear.

Glossodynia: It is pain arising from the tongue, which is apparently normal.

Atrophy of the tongue (bald tongue): Mucosal atrophy occurs in iron deficiency anemia, pellagra, vit B₁₂ deficiency, or syphilis. The tongue may be sore. Lesions of the hypoglossal nerves or their nuclei cause atrophy of the muscles. In this condition the tongue shows longitudinal furrows.

Pigmentation of the tongue and oral mucosa: Main causes of this condition are given below.

1. Poor oral hygiene.
2. Irritation due to dentures or extensive metal fillings.
3. Addison's disease.
4. Side effects of drugs like phenothiazines and oral contraceptives.
5. Peutz-Jeghers syndrome.
6. Accumulation of heavy metals like lead, mercury and bismuth.
7. Malignant melanoma.

Fissured tongue (scrotal tongue): The dorsal and lateral surfaces of the tongue are covered by deep fissures which are soft, painless and often asymptomatic except for the appearance. This may cause anxiety to the patient.

Hairy tongue: This abnormality develops due to elongation of the filiform papillae at the dorsum of the tongue, as a result of failure of the keratin layer to desquamate normally. Staining by food, tobacco, "pan" or chromogenic microbes gives this a black or brown color.

Oral Cancer

This is the most frequent form of cancer in Indian subjects, especially males. More than 95% cases have squamous

cell carcinoma. The sites of predilection are the lips, posterior two-third of the tongue, inner aspects of the cheek and gingival margins. The growth is single in the majority of cases but cancer arising from submucous fibrosis may be multiple.

Etiology

Excessive chewing of tobacco in the form of *pan* (betel leaf, lime, and tobacco) and retention of the cud in the mouth are closely associated with oral cancer in India. Other associations are cigar or pipe smoking, smoking with the lighted end of the cigar or *beedi* inside the mouth (as in Andhra Pradesh), and keeping snuff in the mouth.

Conditions like submucous fibrosis, alcoholism, syphilitic glossitis, chronic irritation by malaligned teeth and *Plummer-Vinson syndrome* are associated with higher risk of cancer. Leukoplakia is a common precancerous lesion.

Since the early lesions are painless, there may be considerable delay in seeking medical aid. Presence of induration of the ulcer or growth should draw attention to the possibility of cancer. All chronic ulcerating or indurated lesions in the mouth should be examined carefully by palpation and biopsied without delay to detect carcinoma and the case may be referred to the appropriate speciality services.

Treatment

Mainly local irradiation is advised. Surgical measures are employed in special circumstances.

Regular attempts to educate the public and training of volunteers to detect oral cancer in the community by the Regional Cancer Center, Trivandrum has served to bring oral cancer cases at a much earlier stage for therapy.

77

Diseases of the Esophagus

K.R. Vinaya Kumar, K.V. Krishna Das

Chapter Summary

Symptoms in Esophageal Disease 460
 Vomiting 460
 Esophagitis 461
 Achalasia Cardia 461
 Diffuse Esophageal Spasm 462
 Esophageal Hiatus Hernia and Peptic Esophagitis 460
 Carcinoma of Esophagus 464

8

Symptoms in Esophageal Disease

Diseases of the esophagus manifest as esophageal pain and/or dysphagia. The esophagus is not readily accessible to physical examination and in the ordinary case the examiner has to satisfy himself with interrogation regarding these symptoms. Investigations include contrast radiography using barium swallow, esophagoscopy, and biopsy from different regions under vision.

Esophageal Pain

It may be of three types:

1. *Heart burn*—burning sensation produced by reflux of acid gastric contents into the esophagus.
2. *Odynophagia*—pain during deglutition which is due to inflammation of the esophagus.
3. *Colicky pain*—caused by vigorous contraction or distension of the esophagus. Esophageal pain may arise either because of obstruction by food or diffuse esophageal spasm. Esophageal pain may be mistaken for angina pectoris. Presence of dysphagia suggests that the pain arises from the esophagus. Autonomic disturbances like sweating may accompany these attacks. Nitrates may relieve the pain of esophageal spasm.

Dysphagia

460 It may be oropharyngeal or esophageal.

Causes of Oropharyngeal Dysphagia

Neuromuscular disorders: Lower cranial nerve paralysis, myasthenia gravis, oropharyngeal myopathies, motor neuron disease, hydrophobia, and iron deficiency states.

Mechanical obstruction: Tumors, stricture, diverticula or webs as in iron deficiency anemia.

Esophageal dysphagia: This can be distinguished by the onset of dysphagia when the patient initiates swallowing. The passage of food is delayed. Though some degree of localization of the pain is possible, on many occasions it is referred to other regions like the suprasternal notch. Mechanical causes lead to obstruction to solids whereas neuromuscular causes lead to difficulty in swallowing solids and fluids.

Neuromuscular causes: These include achalasia cardia, diffuse esophageal spasm, vagal paralysis, progressive systemic sclerosis and Chagas' disease.

Mechanical causes: These may be intrinsic or extrinsic.

Intrinsic causes: These include: (i) carcinoma, (ii) strictures, (iii) diverticula, and (iv) esophageal rings and webs, e.g. the mucosal or muscular ring at the junction of the squamous and columnar epithelium (*Schatski ring*).

Extrinsic causes: These include compression by mediastinal masses like lymph nodes, tumors, enlarged left atrium, aortic aneurysm, mediastinitis, or infiltration by bronchogenic carcinoma.

Dysphagia should be fully investigated to find out the cause. If none is detected, the investigations should be repeated after a suitable interval. Carcinoma of the esophagus may present with bizarre symptoms for long periods of time and a high index of suspicion is necessary to make an early diagnosis.

Vomiting

Vomiting is a forceful expulsion of the gastric contents through an open mouth. This has to be distinguished from

regurgitation which is the effortless entry of the gastric or esophageal contents into a closed mouth. This may be spat out or swallowed.

Vomiting may be caused by different mechanisms. The common causes of vomiting are given below:

Gastric causes: Irritant foods, drugs or other chemicals, bleeding into the stomach, gastritis, and pyloric obstruction.

Neurological causes: Rise of intracranial tension, intracranial bleeding, inflammation of brain or meninges, vertebrobasilar ischemia and migraine.

Metabolic causes: Uremia, hepatic failure, diabetic ketoacidosis, lactic acidosis, acute intermittent porphyria, and poisoning.

Endocrine causes: Hypoadrenal crisis, hyperparathyroidism, hyperthyroidism, and pheochromocytoma.

Reflex causes: Labyrinthine stimulation occurring in motion sickness, ocular causes.

Psychogenic vomiting: Anxiety state, hysteria, depression.

Pregnancy: Hyperemesis gravidarum.

Drugs

Several drugs lead to nausea and vomiting as prominent side effects. This may be due to local irritation as in the case of anti-rheumatic drugs, antibiotics and iron salts or vomiting may be caused by stimulation of the medullary centers. Anti-cancer drugs, oral contraceptives and estrogenic steroids come under this group.

Vomiting is a very unpleasant symptom due to the associated autonomic phenomena such as sweating, salivation, palpitation and tachypnea. Severe vomiting leads to dehydration, hyponatremic hypokalemic, hypochloremic alkalosis and ketosis. Repeated vomiting may also lead to gastro-esophageal tears (Mallory-Weiss syndrome), esophageal rupture, subconjunctival hemorrhage or even intraocular and intracranial hemorrhage.

Precise diagnosis of the underlying condition and specific treatment is required in all cases. Correction of the metabolic derangement should be instituted in severe vomiting as in hyperemesis gravidarum. In severe cases infusion of intravenous normal saline should be started without delay. Further management depends upon the degree of electrolyte and acid base disturbances. Infusion of fluid should be started as soon as the patient is first seen. Even in the presence of moderately severe vomiting, frequent small sips of fluids (30 mL given every 10 min) help to retain some fluid and in many cases this is very beneficial.

Fluid can be administered rectally. Up to 1.5 L of normal saline can be given in 24 hours by this route. The fluid is given through a narrow bore urinary catheter introduced high up in the rectum and given at the rate of

75-100 mL/hour. The infusion bottle should be suspended 30-50 cm above the bed. If fluid is given at greater pressure into the rectum the fluid may be ejected. Prokinetic agents such as metoclopramide, domperidone and cisapride can restore normal gastric motility and give good symptomatic relief. Antihistamines such as pheniramine 25-50 mg oral are useful to prevent vomiting in motion sickness. Phenothiazines such as trifluoperazine hydrochloride 5-10 mg oral are effective in mild forms of vomiting due to neurological causes. In more severe forms injection of procloperazine maleate 12.5-25 mg IM may be required. Vomiting can be very disturbing in cancer chemotherapy. Selective 5-HT receptor antagonists such as ondansetron 4-8 mg given slowly IV before starting chemotherapy prevents this complication.

Esophagitis

Inflammation of the esophagus may occur in several diseases, some of which are listed below:

1. *Irritants*—corrosives, alcohol, spicy foods and drugs.
2. *Infections*—systemic infections like influenza, cytomegalo virus, HIV, measles and chickenpox, and local infections like herpes simplex and candidiasis.
3. *Peptic esophagitis*—associated with gastroesophageal reflux.
4. *Specific infections*—tuberculosis, syphilis, gonorrhea.
5. *Post-irradiation esophagitis*.

Management: When a specific cause is identified, it should be removed. Small feeds given frequently and administration of demulcents and antacids gives symptomatic relief. Omeprazole 20 mg oral bd given for 3-4 days may help. If swallowing is difficult, ranitidine injection 50 mg IM 8 h will be beneficial.

In the case of infections, specific anti-infective agent is indicated. Management of corrosive poisoning is given in Section 4.

Achalasia Cardia

Syn: Cardiospasm

In this disorder there is abnormality of lower part of the esophagus which results in failure of relaxation of the sphincter when food reaches the lower end. The esophagus progressively dilates and becomes atonic. The dysfunction is due to degeneration in the Auerbach's plexus and vagal fibers (Fig. 77.1).

Clinical Features

The presentation may be varied. There may be dysphagia, recurrent respiratory infections or vague upper abdominal symptoms. Even with dysphagia the general health is preserved. At the end of the meal the patient exerts pressure which opens the sphincter and the food material

Fig. 77.1: Achalasia cardia dilated esophagus

passes down to the stomach with a gurgle. Food collected in the dilated esophagus undergoes fermentation. Repeated aspiration of this material into the respiratory tract results in recurrent bouts of respiratory infection. Carcinoma may supervene on achalasia cardia.

In some cases of achalasia there may be vigorous contractions of the esophageal muscles causing chest pain (*vigorous achalasia*).

Diagnosis

Clinically, the condition should be diagnosed when long-standing dysphagia is accompanied by good general health. Some cases may be identified for the first time from chest radiographs. The presence of a mediastinal shadow with a horizontal fluid level produced by the dilated fluid-filled esophagus should draw attention to this condition. Barium swallow confirms the diagnosis (Fig. 77.2). In all cases, esophagoscopy and biopsy should be done to exclude stricture and carcinoma. Other conditions which produce esophageal lesions similar to achalasia are gastric carcinoma infiltrating into the lower end of the esophagus, amyloidosis and Chagas' disease.

Treatment

Conservative management consists of dietary adjustment such as frequent small feeds, anticholinergic drugs like propanthine 15-30 mg thrice a day 15 minutes before meals, and attention to general health. Calcium channel blockers such as nifedipine have been tried with limited success.

Pharmacotherapy is often unsatisfactory and unpredictable. All symptomatic patients require a definitive therapy such as balloon dilatation, injection of botulinum toxin or surgical cardiomyotomy (Heller's operation). Balloon dilatation under endoscopic or fluoroscopic control is a quick and safe procedure which gives lasting relief. It is the first choice in many centers. Endoscopic injection of botulinum toxin also gives similar results for varying

Fig. 77.2: Achalasia cardia: Barium swallow. Note the grossly dilated esophagus

periods. It has to be repeated. Surgery gives permanent relief but regurgitation is a complication.

Diffuse Esophageal Spasm

Syn: Corkscrew Esophagus

This is caused by disordered peristalsis. Multiple contractions occur simultaneously in addition to normal contractions induced by deglutition. The disorder may be primary or secondary to esophagitis and carcinoma. The lower esophageal sphincter is normal. Emotional stress and hurried eating precipitate symptoms. These patients complain of retrosternal pain induced by swallowing.

Barium swallow demonstrates the irregular peristalsis. Motility studies confirm the diagnosis. Carcinoma has to be ruled out by endoscopy.

Treatment

Nitroglycerine in a dose of 0.5 mg sublingually relieves the spasm, and it also helps in relieving the pain if given before eating. General measures to allay anxiety, education in proper eating habits, and reassurance, clears symptoms in most cases.

Esophageal Hiatus Hernia and Peptic Esophagitis

The lower esophageal sphincter may be incompetent and regurgitation of gastric contents into the esophagus may occur in a variable proportion of normal subjects, but in a few cases it causes symptoms. The sphincteric action is assisted by the intra-abdominal pressure which helps in closing of the sphincter with increase in pressure. In hiatus

Fig. 77.3: Normal gastro-esophageal junction

hernia, the esophagogastric junction slides above the diaphragm and reflux occurs into the esophagus when intra-abdominal pressure rises.

Gastric acid, pepsin, and bile lead to inflammatory changes in the esophagus. The lower end of the esophagus may show metaplasia of the epithelium and the lining may resemble gastric mucosa (*Barrett's esophagus*). Peptic ulceration and adenocarcinoma may develop in such metaplastic epithelium as late complications. Peptic esophagitis may be complicated by hemorrhage, stricture formation and perforation (Fig. 77.3).

Hiatus hernia is more common in obese females. This may be of two types. In the *sliding type hernia*, the esophagogastric junction slides through the *diaphragmatic* hiatus. In the *paraesophageal type of hernia*, a knuckle of the fundus of the stomach passes up to the thorax alongside the esophagus. These hernias as such may be symptomless but symptoms start appearing when peptic ulceration develops.

Clinical Features

The common symptoms is heart-burn felt at the lower part of the sternum, when the patient lies down flat, stoops forward as in tying the shoe lace or lifts heavy objects. The pain is relieved by adopting the erect posture. Certain foods aggravate this pain. Rarely gastric contents may regurgitate into the mouth or may be aspirated into the respiratory tract.

Diagnosis

It is confirmed by radiology and esophagoscopy. The lesion is demonstrable by barium meal taken in the Trendelenberg position.

GASTRO-ESOPHAGEAL REFLUX (GER)

This term denotes the reflux of the acidic gastric contents into the esophagus. It is not a disease. It is seen in many subjects, especially children. Normally the lower esophageal sphincter maintains a pressure 15 mm Hg

above the gastric pressure and so, there is no regurgitation of gastric contents into the esophagus.

Gastro-esophageal Reflux Disease

GER becomes a disease when it is causing symptoms such as heart burn, or when it is associated with endoscopic changes or histopathological changes in the esophageal mucosa. It is a common disease and about one third of the adult population have symptoms at some point in their life time. Obesity and smoking are weakly associated with GERD. Males suffer more.

Heart burn and regurgitation are the common symptoms of GERD. Dysphagia chest pain, dysphonia and globus are also seen in severe cases. Laryngitis, reflux bronchospasm, precipitation or aggravation of asthma and strictures and ulcerations of the lower end of esophagus are seen as complications. Severe disease may be associated with Barret's esophagus. Ambulatory PH monitoring done with a PH probe positioned 5 cms above the gastroesophageal sphincter records the GERD though out the day.

Endoscopy and PH metry are the diagnostic investigations. Endoscopy can assess the severity of the illness and can also detect complications such as strictures, Barret's lesions, ulceration and esophageal adenocarcinoma (Fig. 77.4).

Treatment

The medical treatment of GERD and esophageal hiatus hernia is similar in the early stages and hence they are described together. Mild cases require only dietary regulation, elevated position of head during sleep and antacids. Weight reduction and short courses of treatment with prokinetic drugs such as metoclopramide 10-15 mg bd or mosapride 10 mg bd help to relieve symptoms. H₂ receptor blockers such as ranitidine or famotidine are useful, but protein pump inhibitors such as omeprazole 40 mg bd or pantoprazole 40 mg bd are more effective. Severe cases require high doses of PPI for long duration

Fig. 77.4: Barrett's esophagus. Note: gastric metaplasia in the esophagus (arrow)

(several years). Cases resistant to medical therapy may be benefited with surgical interventions such as laparoscopic fundoplication. Complications such as esophageal strictures are managed with endoscopic balloon dilation.

(Further reading: Paul Magyed. L. Nicholas Talley. Gastro-intestinal reflux disease. The Lancet 2006;367:2086-2100).

Paraesophageal hernias: These may not be symptomatic in many cases since the lower esophageal sphincter is intact but sometimes large hernias may produce symptoms like cardiac arrhythmias, dyspnea, and dysphagia. Gangrene or perforation may present as surgical emergencies at times.

Carcinoma of Esophagus

This is common in India, especially in the southern states. 30-40% of all esophageal carcinomas occur at the lower end of the esophagus—95% is squamous cell carcinoma and 5% is adenocarcinoma. In many countries the proportion of adenocarcinoma is increasing. Etiological factors include smoking, alcoholism, Barret's esophagus,

obesity, poverty, burns of the esophagus and Plummer Vinson syndrome.

Due to the absence of serous coat, esophageal cancer disseminates early. The growth may be ulcerating, polypoid or annular.

Progressive dysphagia, initially to solids and later to fluids as well, is the time honoured description, but in a minority of cases symptom may be vague and atypical. Loss of weight is an early symptom. Barium swallow, esophagoscopy and biopsy confirm the diagnosis. These investigations must be undertaken in all patients with symptoms referable to the esophagus.

Treatment

Lesions in the distal third are more amenable to therapy. Surgical resection and irradiation are beneficial in early cases. In advanced cases irradiation may give symptomatic relief. A feeding gastrostomy may prolong life, but the miserable condition of the patient after the surgery is a strong point against palliative surgery. Self expandable metallic stents are available which can be introduced endoscopically. Radiation can be applied over the stent.

Diseases of the Stomach

K.R. Vinaya Kumar, K.V. Krishna Das

Chapter Summary

Gastritis	464
Peptic Ulcer	465
Duodenal Ulcer	466
Gastric Ulcer	469
Zollinger-Ellison Syndrome	470
Carcinoma of the Stomach	470
Gastric Outlet Obstruction	471
Hematemesis	471
Melena	472
Fresh Blood in Stools	472

Gastritis

Definition

“Gastritis” denotes inflammatory process of various etiological factors involving the wall of the stomach, particularly the mucosa.

Classification

There are two types of gastritis—(i) acute gastritis, and (ii) chronic gastritis. Chronic gastritis is further classified into: (a) chronic superficial gastritis, (b) atrophic gastritis, (c) granulomatous gastritis, (d) eosinophilic gastritis, and (e) hyperplastic gastritis.

Acute Gastritis

Chemicals like strong acids or alkalies, drugs such as salicylates and indomethacin, ethanol, ionizing radiations, acute mental and physical stress, shock, hypoxia and renal failure may cause acute gastritis. The pathological change leads to breakdown of gastric mucosal barrier. The hydrogen ions diffuse into the mucosa from the lumen. Vascular damage occurs. Acute hemorrhagic gastritis may be localized or diffuse. Superficial erosions may develop due to necrosis of the epithelium and extravasation of blood from the damaged vessels in the lamina propria.

Symptoms include upper abdominal pain, nausea, vomiting, hematemesis and melena. Endoscopy reveals edema of the mucosa, hyperemia, surface erosions, and hemorrhages. Proper treatment results in complete recovery within a few days.

Treatment

Removal of the cause, bland frequent diet, antacids and correction of fluid and electrolyte levels give relief. Hematemesis may develop which demands emergency management. H_2 receptor blockers such as ranitidine 150 mg oral b.d or famotidine 40 mg oral b.d help to bring early relief. Proton pump inhibitors (PPIs) such as omeprazole 40 mg bd are very effective.

Chronic Gastritis

Chronic gastritis can be subdivided into types A and B. Type A gastritis is probably an immune-mediated disorder. Some of these cases develop pernicious anemia. *Helicobacter pylori* is causally associated with type B or chronic bacterial gastritis. Many drugs such as NSAIDs and others may produce chronic chemical gastritis. Attention to these factors helps to relieve the condition in many cases.

Chronic superficial gastritis: In this form the gastric glands are normal but cellular infiltration consisting of lymphocytes and plasma cells occur in the lamina propria adjacent to the surface and the gastric pits. The body and fundus of the stomach are affected leaving the antrum free.

Chronic atrophic gastritis: This is more common as age advances. It is associated with pernicious anemia, diabetes mellitus, thyroid disorders, Addison's disease and iron deficiency anemia. Mucosa over the body and fundus is diffusely affected. Mucosal cells atrophy partially or completely resulting in variable thinning of the mucosa. Gastric epithelium may undergo metaplasia and be transformed into intestinal type of epithelium. There is also infiltration by lymphocytes and plasma cells. Acid secretion falls. Majority of cases are symptomless, but pernicious anemia or gastric bleeding may develop in some. Parietal cell antibodies are demonstrable in 60% of cases. Carcinoma of the stomach is more common in

these patients, treatment is only symptomatic. The atrophic epithelium does not generally recover.

Granulomatous gastritis: Several granulomatous disorders such as tuberculosis, Crohn's disease, sarcoidosis, syphilis and others may be associated with gastritis. The gastric mucosa shows chronic inflammation, ulceration and hypertrophy. Treatment of the underlying condition leads to regression of the gastric lesions as well.

Eosinophilic gastritis: This is part of widespread eosinophilic infiltration of the gastrointestinal tract, the cause is not evident in many cases. Peripheral blood may show increase in eosinophils. Treatment with corticosteroids and antihistamines is often successful.

At times larval forms of nematodes such as *Anisakis marina* may cause infestation of the gastric mucosa. This is associated with secondary eosinophilic infiltration.

Hypertrophic gastritis: This is characterized by large hypertrophic folds of gastric mucosa. There are two varieties:

1. This causes hypersecretion of gastric juice poor in acid and rich in protein. This is called *Menetrier's disease*. The excessive protein loss may lead to hypoproteinemia and edema. Treatment consists of high protein diet and symptomatic measures.
2. In the other variety, gastric juice is rich in acid and low in protein. This hyperacidity responds to H_2 blocker drugs or omeprazole.

Other rarer causes of gastritis include infections caused by pyogenic bacteria or anaerobes and *Candida albicans*. External irradiation leads to both acute and chronic gastritis.

PEPTIC ULCER

This term refers to nonmalignant ulceration of gastric or duodenal mucosa as a result of acid-peptic influences. These are seen in the stomach, duodenum or other sites where gastric type mucosa may be present, e.g. lower end of esophagus or Meckel's diverticulum. Peptic ulceration may be acute or chronic. **Acute peptic ulceration** may result from ingestion of corticosteroids, non-steroidal anti-inflammatory drugs, corrosive agents and unwholesome food. Severe stressful conditions such as mental stress, burns, shock and others may lead to acute mucosal ulceration and these present as hematemesis and melena complicating the primary disease.

Chronic peptic ulceration generally affects the stomach or duodenum and less commonly other ectopic sites of gastric mucosa. Normally, the ulcerogenic effect of acid and pepsin is counteracted by the mucosal resistance of the gastroduodenum. Ulceration results when this equilibrium is upset.

Duodenal Ulcer

This is 10 to 20 times more common in males than females, and it is 12 to 30 times more common than gastric ulcer. Chronic duodenal ulcers occur in the first part of the duodenum just distal to the pyloro-duodenal junction. 50% are on the anterior wall. Multiple ulcers occur in 10-15%. In 10% duodenal and gastric ulcers coexist. The pathogenesis of duodenal ulcer is not completely understood. It is more common in the rice-eating population of India.

Hereditary factors, dietary habits, heavy smoking and chronic use of drugs like aspirin, antirheumatic drugs and corticosteroids may predispose to this disorder. Psychological stress aggravates ulceration and precipitates bleeding. Duodenal ulcer is associated with HLA B₅ as reported from the west. It is also more common in blood group O nonsecretor subjects. The ulcer is sharply demarcated and the site of predilection is the first part of the duodenum. The role of *Helicobacter pylori* in the pathogenesis of ulceration has been established.

8

Helicobacter pylori

It is a Gram-negative spiral organism which is now accepted as the major causative factor in chronic duodenal ulcer, gastric ulcer and chronic gastritis. It plays a role in the pathogenesis of gastric carcinoma and mucosa associated lymphoid tissue (MALT) lymphoma of the stomach. It is demonstrable in almost all cases of duodenal ulcer and over 80% of cases of gastric ulcer. About 50% of the adult population is infected with *H. pylori* and this is possibly one of the most common bacterial organisms colonising humans. Some cases of pernicious anemia are also closely associated with the presence of *H. pylori*. *H. Pylori* infection is more prevalent in the low socioeconomic groups. Spread of infection is by the oral route, ingestion. Family contacts, especially children are affected more. Once infection occurs, spontaneous elimination of the organism is rare.

H. pylori moves under the mucus layer in the stomach by its flagella and thrives in this location. Presence of urease helps the organism to produce carbon dioxide and ammonia from urea and this mechanism protects it from gastric acid. *H. pylori* produces a vacuolating cytotoxin (VACA) which enters the epithelial cells. Its pathogenic role is not fully known. *H. pylori* causes inflammation of duodenal mucosa, hyperacidity and duodenal ulcers. Inflammation of the stomach may lead to hypochlorhydria and predispose to gastric carcinoma.

The organism is demonstrable beneath the mucus layer adjacent to the cells, mainly in the mucosa of the gastric antrum and duodenum, especially if there is gastric metaplasia of the mucosa. Only some types of *H. pylori* are pathogenic. It is also known that *H. pylori* which can

cause gastric adenocarcinoma can protect against esophageal adenocarcinoma. There are reports that *H. pylori* may even protect against reflux esophagitis. So eradication is indicated only under appropriate situations. The indications for investigation to demonstrate *H. pylori* are listed below:

1. All patients with peptic symptoms <45 years of age.
2. Patients <45 years with alarm symptoms. Endoscopy is also indicated.
3. Patients <45 years with recent onset of symptom. They also require endoscopy.

Alarm symptoms indicating need for endoscopy include the following:

1. Unintentional weight loss
2. Dysphagia
3. Odynophagia
4. Persistent vomiting
5. Hematemesis, melena
6. Recent onset iron deficiency state
7. Epigastric mass
8. Previous gastric surgery
9. NSAID use

In NSAID induced ulcers and Zollinger-Ellison syndrome, *H. pylori* has no major pathogenic role.

Helicobacter heilmannii is a native organism in animals. Rarely it may infect humans. It may cause mild gastritis. This infection is more associated with MALT lymphoma.

H. pylori is detected non-invasively by the urea breath test which is an isotopic test. Indirect evidence of infection is by demonstration of antibodies. Biopsy of the ulcers can be done for demonstrating the organism.

CLINICAL FEATURES OF PEPTIC ULCER

The classical feature is the hunger pain felt in the epigastrium, relieved by food. Pain starts within three hours of eating food and it may be described as burning, aching, pressure, fullness or as a sensation of hunger. The pain comes on every day for a few weeks and then subsides for considerable periods. Pain may be more prominent at night. The pain is usually relieved by food, antacids, or even by vomiting. A small proportion of ulcer subjects may be asymptomatic. Occurrence of complications may be the first sign of disease in them. Compared to the disabling symptoms, physical signs are only minimal. Physical examination may reveal tenderness in the epigastrium or to the right of the midline. Ulcer patients are able to localize the pain and this feature helps to distinguish them from cases of functional dyspepsia.

Differential Diagnosis

Epigastric pain is a common symptom in several alimentary disorders such as gastric carcinoma, pancreatic

carcinoma, pancreatitis, biliary tract disease, peptic ulceration of the esophagus, duodenitis and ancylostomiasis. The pain of irritable bowel syndrome may mimic peptic ulcer.

Diagnosis

The history of pain coming on with hunger and relieved by hot fluids or antacids is suggestive, but final diagnosis depends on the demonstration of the ulcer by gastro-duodenoscopy. Endoscopy confirms the presence of ulcers. Since the clinical features of benign ulcers show considerable overlap with those of malignancy, upper gastrointestinal endoscopy should be done to see the lesion and confirm it histologically in all cases, where the clinical presentation is not straightforward. Duodenal ulcer is seen as an ulcer crater in the proximal part of the duodenal bulb in the barium meal. The duodenal bulb may show marked deformity (trifoliate appearance). Indirect demonstration of the lesion is by barium meal examination.

There is a great tendency to recur after initial healing. It is seen even after surgery. The persistence of *H. pylori* infection is the most common cause for recurrence.

Course and Complications

Chronic duodenal ulcer persists with exacerbations and remissions over several years. Precipitating factors are change in diet and lifestyle, drugs and mental stress. Complications include hematemesis, melena, pyloric obstruction, and perforation, and pancreatitis due to posterior penetration.

Management

Aims of Therapy

1. Relief of pain as early as possible
2. Favour healing of ulcer
3. Prevent complications and
4. Avoid recurrence.

General Measures: The patient should be advised to take food regularly at 2.5 to 3 hour intervals to avoid pain. A cup of milk taken at bed time often helps to abolish nocturnal pain in many cases. Sometimes patients report that milk leads to worsening of acidity. Excepting highly spiced food, there is no choice between the various foods to be avoided. Till the advent of H_2 receptor blocking drugs, one of the mainstay of management was strict dietary therapy. In some cases dietary adjustment itself may give considerable relief and even help in gradual healing of the ulcer. It is important that persons who are predisposed to develop peptic ulcer should maintain this dietary discipline for life, to avoid relapse.

Tobacco smoking should be stopped forthwith, since it favours ulcerogenesis and hinders ulcer healing. Resumption of smoking is a common cause for relapse of ulcer-symptoms. Alcohol should be avoided, especially the spirits. It is advisable to restrict coffee to two cups daily or less.

Drug Therapy

Several drugs are available for treating peptic ulcers. Table 78.1 shows the available groups of drugs, their main actions and major side effects. Antiulcer drugs are among the most widely used drugs in modern medical practice.

Specific drugs should be started along with the general measures. Choice of drugs depends on the individual case. Though antacids are effective in relieving pain and are cheap, they achieve ulcer-healing only in a smaller proportion of cases. Therefore, it is better to add an H_2 receptor blocker or proton pump inhibitors concurrently. These drugs are available as tablets for oral use. They are very powerful inhibitors of gastric acid, giving pain-relief within a few days of administration. Cimetidine 300 mg and ranitidine 50 mg are also available as IM or IV injections and they are indicated when oral medication is not possible or when more urgent relief is needed as in hematemesis or melena. Both H_2 -receptor blockers and proton pump inhibitors favour ulcer-healing when given for 3-6 weeks. Their role in preventing relapse of ulcer is less definite. Still, long-term continuation of treatment may help to reduce relapse rate in those who are otherwise prone to relapse. In the vast majority these drugs can be stopped after 6-12 weeks of therapy. Newer H_2 receptor blockers are rizatidine 300 mg hs oral for 4-5 weeks and rextidine 150 mg hs for 4-6 weeks. Proton pump inhibitors in common use are omeprazole 20-40 mg oral daily lansoprazole 15-30 mg oral daily and pantoprazole 20-40 mg daily, esomeprazole 20 mg bd and rabeprazole 20 mg bd. Adverse effects of proton pump inhibitors include gastrointestinal upsets, allergy and susceptibility to food and water borne infections. Rarely inhibition of absorption of vitamin B_{12} may occur, if treatment is prolonged.

Eradication of *H. pylori*

Though *H. pylori* is very sensitive to many antibiotics *in vitro* it is difficult to eradicate it due to its location in the mucus layer of stomach where antibiotics do not reach readily. Multiple drugs are required for prolonged duration. Present day triple therapy given for 10-15 days gives an eradication rate of 95%.

A common regimen effective in the vast majority of cases is listed below:

Omeprazole	20 mg bd or 40 mg od
Amoxycillin	1g bd
Clarithromycin	500 mg bd, all given for 10 days consecutively

TABLE 78.1

Drugs used for peptic ulcer			
Drugs	Action	Dose for oral administration	Major side effects
Antacids			
Aluminium hydroxide Magnesium hydroxide Magnesium trisilicate Magnesium carbonate	Neutralizes gastric acid	15-30 mL of suspension one and three hours after each meal and at bed time, for 6 weeks	Diarrhea or constipation, inhibition of absorption of iron, calcium and phosphates, and milk-alkali syndrome
Mucosal protecting agents			
Sodium alginate	Coats the mucosa	0.5-1 g after food and at bed time	Nil
Carbenoxolone sodium		100 mg tid for 4-8 weeks	Retention of sodium and loss of potassium
Sucralfate (aluminium salt of sucrose-octa sulfate).	Coats the mucosa	1 g four times a day	Nil
Antihelicobacter agents			
Colloidal bismuth: tripotassium dicitrato-bismuthate (De-nol) Omeprazole, amoxycillin, clarithromycin preventing relapse	Eliminates <i>H. pylori</i> , thereby hastening ulcer-healing and	20 mL three or four times a day for 30 days	Unpleasant taste, staining of mouth and teeth
H₂-receptor blocking agent			
	Suppression of acid secretion and favour ulcer-healing		Drowsiness, allergy, gynecomastia, impotence and inhibition of gastric intrinsic factor
Cimetidine		200 mg 6 h and 400 mg bed time	Reduction of gastric acidity may predispose to Salmonella infection
Ranitidine		150 mg bid or 300 mg bed time	
Famotidine		20 mg bid or 40 mg bed time	
Proton-pump inhibitor			
Omeprazole lansoprazole, pantoprazole, esomoprazole and rabeprazole	Inhibits H+K+ ATPase, and suppresses acid secretion,	10-20 mg twice a day and 20 mg bed time favours ulcer-healing	Very few, Diarrhea, skin rashes headache, impotence and gynecomastia 30 mg od
Prostaglandins			
Misoprostol	Cytoprotection and reduces acid production	200 mg four times a day	Diarrhea
Note: Antacids and acid inhibiting drugs are continued for 4-8 weeks in full doses and then maintenance treatment is given depending on the individual response.			

Elimination rate is about 95%. Repeated courses and quadruple therapy including metronidazole or tinidazole to the triple drug regimen may be slightly more effective. Colloidol bismuth augments the efficacy of this regimen.

Metronidazole resistance is widespread in India. In resistant cases and in relapses, quadruple therapy including tetracycline 500 mg 6 h and tinidazole 300 mg t.i.d are effective.

It is ideal to assess the success of treatment by endoscopy which will reveal healing of the ulcer. Apart from specific treatment aimed at the local problem in the stomach, other drugs including analgesics such as dextropropoxyphene 65 mg, parasympatholytic drugs such

as propantheline bromide 10-20 mg, and anxiolytic drugs such as chlordiazipoxide 10 mg, may be required to control symptoms.

Surgical Measures

At present treatment of peptic ulcer is by and large a medical problem. More than 90% of ulcers heal with proper treatment. Surgery is indicated in a small proportion of cases which fail to heal or where there is suspicion of malignancy. The usual procedure is highly selective vagotomy in which the vagal fibers supplying the parietal cell bearing area of the stomach are interrupted, leaving the rest of the nerve intact. This operation

serves to reduce the acid secretion and thereby favour ulcer-healing.

Indications for Emergency Surgery

- 1. Bleeding of the ulcer, not responding to conservative management.
- 2. Perforation of the ulcer. This is an urgent indication.
- 3. Pyloric stenosis and gastric outlet obstruction.
- 4. Frank carcinoma or atypical features on histology of the ulcer.

Complications

If left untreated, peptic ulcers lead to complications. Acute complications include severe ulceration with intractable hematemesis, and perforation. Major chronic complication is the development of cicatricial stenosis of the pylorus resulting ‘in pyloric obstruction. Penetration of the ulcer outside the peritoneum leads to development of adhesions with the omentum and neighbouring viscera and ulceration of the structures adjacent to the posterior wall of the stomach and duodenum, especially the pancreas.

Hematemesis presents as an acute medical emergency. It is often precipitated by the use of nonsteroidal antirheumatic drugs, corticosteroids or aspirin. Perforation presents with sudden onset of severe pain, tenderness over the epigastrium, rigidity of the abdominal wall, signs of peritonitis and presence of gas under the diaphragm, demonstrable by X-ray taken in the erect posture. If this emergency is not recognized, the condition rapidly proceeds to local and general peritonitis with its associated high mortality. Ideal treatment is to close the perforation surgically at the earliest opportunity.

Pyloric obstruction develops 10-20 years after onset of duodenal ulcer. When this develops the clinical picture changes. Once pyloric obstruction is established surgical treatment becomes inevitable.

Gastric Ulcer

Gastric ulcers occur in the mucosa of the stomach, 90% being located along the lesser curvature. Gastric ulcers are seen more frequently in males, in the sixth decade of life. Chronic analgesic users are affected more. Most of the benign ulcers are single and 90% are located in the antrum immediately distal to the junction of the antrum with the acid secreting mucosa of the body of the stomach.

The exact mechanism of ulcerogenesis is not known. Unlike as in duodenal ulcer gastric ulcer patients have only normal or low acid levels. NSAIDs and *H.pylori* are the two most common causes. Corticosteroids and acute stress may cause acute ulceration manifesting frequently as hematemesis.

Clinical Features

Gastric ulcer patients present with epigastric pain of long duration. The pain is generally precipitated by intake of food but in many cases it is indistinguishable from that of duodenal ulcer. Nausea, vomiting, and significant weight loss may be present. Physical examination is unrewarding in the majority of cases.

Diagnosis is confirmed by endoscopy which should not be delayed if symptoms persist for a few weeks or more. Endoscopy and biopsy should be performed in all cases. Not infrequently gastric ulcers are malignant. It is, therefore, important to establish the exact nature of the ulcer before starting therapy. Carcinoma of the stomach may start as ulcer or very rarely malignant change may supervene on a benign ulcer. Gastric ulcer in association with achlorhydria is almost always suggestive of malignancy.

Indirect demonstration of the ulcer is by barium meal imaging, by which the ulcer crater and abnormal patterns in the gastric mucosa can be demonstrated. With the advent of gastroduodenoscopy and biopsy, barium imaging in gastric lesions has lost its prime importance. But, in the diagnosis of motility abnormalities, gastroesophageal reflux and stasis, barium studies are still extremely helpful. Size of the ulcer as revealed by X-rays is not a reliable guide to the nature of the lesion. Table 78.2 gives the radiological differences between benign and malignant ulcers.

Management

Dietary regimen is similar to that for duodenal ulcer. Antacids, ranitidine and omeprazole constitute the sheet anchor of treatment. Over 90% of ulcers generally heal in about six weeks. Drugs which encourage healing of duodenal ulcer are very effective in benign gastric ulcers as well. Repeat endoscopy is essential to confirm ulcer

TABLE 78.2	
Radiological differences between benign and malignant ulcers	
Benign	Malignant
1. Flat, broad or conical crater with smooth margins	Irregular crater with fissure-like expansions and a nodular contour of its base
2. Radiating gastric folds converge on the ulcer and they arise from the margins of the ulcer crater	Radiating folds are absent due to tumor infiltration of gastric wall
Note: Even in the presence of slightest doubt proceed to endoscopy.	

healing. If the ulcer has not healed by three months or if the ulcer size has increased at the end of four weeks, surgery may be considered. The recommended surgical procedure is antrectomy with Billroth I anastomosis. General management, indications for surgery and complications are similar to those described under duodenal ulcer. If there is evidence of *H. pylori* infection, it should be eradicated.

Zollinger-Ellison Syndrome

This syndrome consists of recurrent ulceration of the stomach, duodenum and jejunum and marked increase in gastric acid secretion caused by a gastrin secreting tumour, commonly arising from the non- β cells of the islets of Langerhans. Most common site is the duodenum (70%). Others include the pancreas (25%) and extra intestinal areas (5%).

About 60% of gastrinomas are malignant, the rest are benign. Around 90-95% of patients with gastrinomas show marked hyperacidity and ulceration of the gastrointestinal tract. Majority of the ulcers occur in the first part of duodenum or the stomach. Multiple ulcers are common. The ulcers are generally fulminant, progressive and resistant to medical therapy. Symptoms include abdominal pain, features of recurrent gastric ulceration, diarrhea and evidence of malabsorption. Due to the very high gastric acid, the intestinal pH remains low and therefore several nutrients do not undergo proper digestion and absorption.

Diagnosis

By maximal histamine test the basal acid output exceeds 10 m mols/h and this should suggest the diagnosis. Increased levels of serum gastrin can be demonstrated by radioimmunoassay. Normally, fasting serum gastrin level is below 160 pg/mL. Values above 1000 pg/mL are diagnostic of gastrinoma. Injection of secretin in normal individuals results in the fall of serum gastrin levels, but in gastrinomas, there is a paradoxical rise, which is specific. Location of the tumour can be made in some of the cases by CT scan or MRI. Endosonography, selective angiography, MR angiography and operative sonography are useful for precise localization. Selective catheterization of portal venous blood enables to identify the source of gastrin production.

Management

Medical treatment consists of large doses of antisecretory drugs. Large doses of H_2 receptor antagonist drugs or proton pump inhibitors help to give symptomatic relief and ulcer healing in some cases. Surgical treatment of choice is total gastrectomy or excision of the gastrinoma if it can be identified.

Carcinoma of the Stomach

Gastric carcinoma is common in Indians. Men are affected more than women. Atrophic gastritis and gastric polyps predispose to gastric carcinoma. It is more common in persons with blood group A. The growth may be polypoid, ulcerative, diffuse or infiltrative, and superficially spreading. Gastric carcinomas are mostly adenocarcinomas.

The antrum or body of the stomach may be equally affected. Around 10-20% involve the cardia. Extension of the tumour may occur by direct spread in the gastric wall and to the perigastric tissues. Lymphatic metastases develop in the perigastric, para-aortic, portal, and splenic nodes. Spread through the thoracic duct leads to enlargement of the left supraclavicular lymph nodes (*Virchow's sign*). Distant metastases, especially to the liver, occur through the blood stream.

Clinical Features

Upper abdominal discomfort or pain, anorexia, and weight loss are the prominent features. When antral tumours produce pyloric obstruction, they lead to vomiting of stale food. Affection of the cardia around the esophageal opening causes dysphagia. Late features include anemia and widespread metastasis.

Physical Examination
